Silicon nitride-like films (SiN_x) have high density, hardness and refractory character which make them suitable for silicon device technology (IC passivation, diffusion and oxidation barriers, interlevel isolation) as well as for wear and corrosion protection applications. Highly stoichiometric SiN_x films with a very low hydrogen content are generally deposited by HT (High-Temperature, 700-800°C) CVD techniques which, of course, cannot be utilized for processing temperature-sensitive substrates such as plastics or low-melting-point metals [1,2]. For such applications Plasma Enhanced Chemical Vapor Deposition (PECVD) is more appropriate, since it allows to obtain good deposits at lower temperatures. PECVD processes are commonly based on SiH_4 and NH_3 (or N_2) feeds and result in films which tend to be non stoichiometric and to contain appreciable amount of hydrogen (known to be detrimental to the barrier properties) usually in the form of Si-H and N-H groups [2-9]. The refractive index of the coating represents a useful control parameter for nitride deposition (2.0 is the value reported for the thermal films); for plasma deposited SiN_x it can vary from about 1.8 to 2.2 and it increases by increasing the Si/N ratio and by decreasing the H content of the coating [2,3,4,7,9].
Nowadays, other precursors for SiN_x deposition less hazardous than SiH_4, which is toxic and explosive, are under study. So far many organosilicon compounds, already largely used for plasma deposition of SiO_2-like films, have been tested as feed sources in PECVD of silicon nitride, but, from an extended survey of published results, it seems that high quality films, i.e. with low hydrogen and negligible organic carbon content, are very hardly obtained [12-21].
Hexamethyldisilazane (HMDSN), reported in many papers, results in $SiC_xN_yH_z$ films with a high content of organic carbon (i.e. CH_x and $Si(CH_3)_x$ groups, as detected by IR analysis), which is seen to decrease only with high addition of NH_3 and/or by heating the substrate at high temperature; NH_3 addition, however, leads to a higher H content, as Si-H or N-H groups, while highly inorganic SiO_xN_y can be easily achieved by adding small amounts of oxygen to the feed gas [13,15,17,19]. Also tetramethyldisilazane (TMDSN), due to the lower number of methyl groups in its structure, has been utilized for nitride deposition in H_2-N_2 remote plasmas. By increasing the N_2-to-H_2 ratio in the upstream feed gas the SiN character increases, even though a not negligible amount of $Si(CH_3)_x$, SiH and NH is detected [14].
Dimethylbis(2,2-dimethylhydrazil)silane, an organosilicon compound with a high N-to-Si ratio, has also been investigated, in mixture with H_2 and He, for nitride plasma deposition; a substrate temperature higher than 400°C was necessary to obtain inorganic silicon nitride films [12]. High electrode temperature is also reported to reduce the organic character of films deposited from 1,1,3,3,5,5hexamethylcyclotrisilazane (HMCTSN) plasmas, at high input power and NH_3 concentrations [18].
In this work, Bis(dimethylamino)dimethylsilane (figure 1) has been utilized as precursor for silicon nitride-like coatings at low substrate temperature. BisDMADMS is a low cost compound at our knowledge not tested before for this application; it is characterized by two N-atoms and one Si-atom and a fairly low boiling point (128°C). We report the results of FT-IR and XPS investigation for films obtained at low substrate temperature

in RF inductive coupled plasmas (ICP) fed with BisDMADMS-Ar mixtures, without N_2 or NH_3 addition; the effect of feed composition and input power on the chemical characteristics of the films and their stability towards ageing are presented.

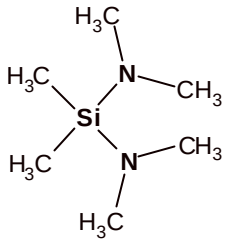

Figure1.Molecular structure of Bis(dimethylamino)dimethylsilane.

2. Experimental details

The utilized Inductive Coupled Plasma reactor consists of a RF (13.56 MHz) powered planar coil (two turns) placed on the top of a quartz plate covering a cylindrical stainless steel plasma chamber. The coil is surrounded by a high magnetic permeability ferrite which concentrates the magnetic field below the quartz plate. The feed gas is admitted through a shower ring positioned close to this plate. The gas flow rates are controlled by MKS mass flow controllers, while the BisDMADMS vapor flow rate is controlled by means of a MKS vapor source controller and all the system is pumped by a turbomolecular-rotary pumping system. The substrates, c-Silicon (100) slabs, were placed on the electrically grounded and thermally controlled bottom electrode. Electrode temperature was never found to exceed 80°C.

Glow discharges were fed with mixtures of BisDMADMS (ABCR, 97% purity) and Ar, with a total flow rate of 22 sccm, at a constant pressure of 9 mTorr. The BisDMADMS-to-Ar flow rate ratio was varied from 0.05 to 0.6, while the input power was changed in the range 150-700 W. In the same power range, a set of experiments was performed using HMDSN (ABCR, 98 % purity) instead of BisDMADMS as film precursor, for comparison. Some experiments were also carried out replacing Ar with He to study the role of the inert gas.

FT-IR Absorption analysis have been performed, within one hour after the deposition, in transmission mode using an Equinox 55 (Bruker) apparatus, by N_2 purging the analysis chamber, in the wavenumber range 500-4000 cm^{-1} (4 cm^{-1} resolution); all the spectra acquired have been normalized to film thickness.

XPS analyses have been performed by means of a PHI 5300 ESCA instrument with a non-monochromatized MgKα radiation. Wide scan, in the Binding Energy range 0-1000 eV, and high-resolution (Si2p, N1s, C1s, O1s) spectra were acquired at an electron take-off angle of 45°, within one hour after the deposition. The atomic percentages reported have been calculated, using the sensitivity factors of the instrument, from the high resolution peaks, acquired after ten minutes of surface cleaning by means of a 4 KeV Ar ion sputtering. Some FT-IR and XPS results have also been compared with those obtained with a 160 nm thick HT-CVD Si_3N_4 film (HT-SiN) on silicon substrate.

Deposition rate have been evaluated from thickness measurements carried out by means of a a-step 500 profilometer (Tencor Instruments) on samples partially masked during the deposition. Refractive index (at 632.9 nm) has been measured with a Jobin Yvon-Sofie single wavelength ellipsometer.

3. Results and Discussion

In figure 2 the FT-IR absorption spectrum of BisDMADMS in the gas phase (a) is compared with those of films deposited at 300 W with different gas feeds: 100% BisDMADMS (b), He-BisDMADMS (c), and Ar-BisDMADMS (d). The details of the bands detected (assignments and positions) are reported in Table 1 [11-20]. It can be observed that the coating obtained in pure monomer is highly organic since strong absorption of CH_x and $Si(CH_3)_x$ features are present. Furthermore, since SiH, NH, and reasonably C=N and NH_2 groups can be detected, a poorly crosslinked structure with a general stoichiometry $SiC_xN_yH_z$ is expected. He addition does not affect appreciably the FT-IR spectrum, while, if Ar is utilized as buffer gas, a more inorganic coating is obtained, since the intensity of CH_x, $Si(CH_3)_x$ and SiH absorptions are markedly reduced.

The FT-IR spectra of films deposited as a function of input power (150 - 700 W) at BisDMADMS-to-Ar ratio of 0.1 are reported in figure 3. As the input power is increased, the organic features as well as those of SiH and NH decrease and the main absorption band shifts towards lower wavenumbers. By integrating the areas of

the absorption peaks at 3380 cm^{-1}(NH), 2960 cm^{-1} (CH_x) and 2180 cm^{-1} (SiH), it can be appreciated the strongest effect of input power on CH_x and SiH absorptions, which are reduced of about 95 % when input power is increased from 150 to 700 W, while the reduction of NH absorption is 70%. Thus, at higher power values the FT-IR spectrum becomes close to that of a silicon nitride, as it can be appreciated by the comparison of the spectrum at 700 W (d), where the SiN stretching is peaked at 850 cm^{-1}, with spectrum (e) corresponding to thermal nitride film (SiN stretching peaked at 835 cm^{-1}).

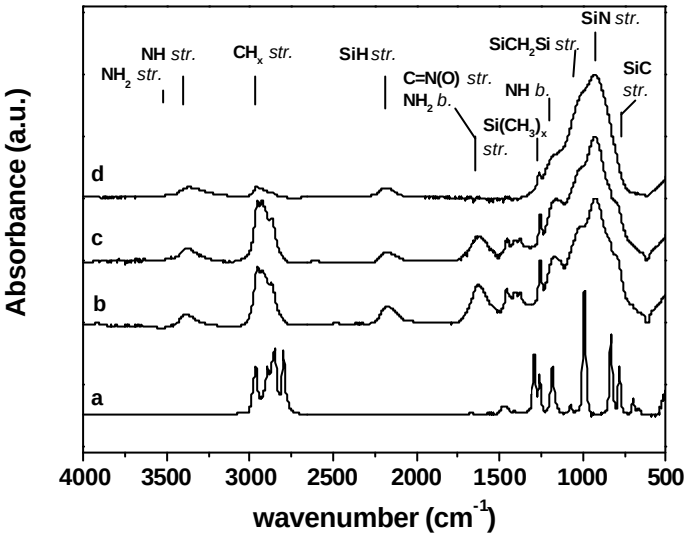

Figure 2. Normalized FT-IR absorption spectra of BisDMADMS (gas phase) (a) and of films deposited at 300W from plasmas fed with: 100% BisDMADMS (2 sccm) (b); BisDMADMS – He (2 sccm-20 sccm) (c); BisDMADMS - Ar (2 sccm - 20 sccm) (d). Band assignements are in table 1.

Table 1. Positions and assignments of the FT-IR features.

Wavenumber (cm^{-1})	Assignements
3480	NH_2 *stretch.*
3380	NH *stretch.*
2960	CH_x *stretch.*
2180	SiH *stretch.*
1630	C=N (O) *stretch.*
1550	NH_2 *bend.*
1460	CH_x *bend.*

800	$Si(CH_3)_x$, SiC *stretch.*

XPS analysis confirms the significant change of chemical composition *vs.* input power revealed by FT-IR spectra. As the input power is raised the carbon content decreases from 60 % at 150 W to 10% at 700 W, while the nitrogen and silicon percentages increase from 11 to 32% and from 18 to 43 %, respectively. A N-to-Si ratio of 0.74 is obtained at 700 W. XPS peak position, after charge correction, has been found almost constant at 398.9 eV for N1s, while for Si2p a shift from 102.0 eV (150W) to 102.8 eV (700W), consistent with a more nitrogen rich chemical surrounding, has been detected. A certain amount of oxygen (about 9 %) has been always detected and it is believed to be due to moisture or oxygen uptake during air exposition after the deposition or released from the reactor walls during the process, as it is usually reported also for other plasma processes as well as for the deposition of thermal silicon nitride films [2,6,12,17]. In fact, about 5% of oxygen has been found in the HT-SiN reference sample which is characterized by a N-to-Si ratio of 0.99 (and by a B.E. of 398.8 eV for N1s and 102.7 eV for Si2p). However, it should be pointed out that the atomic

percentages found may be affected by the sputter cleaning procedure (i.e. differential sputtering and/or ion bombardment induced surface remixing phenomenon).

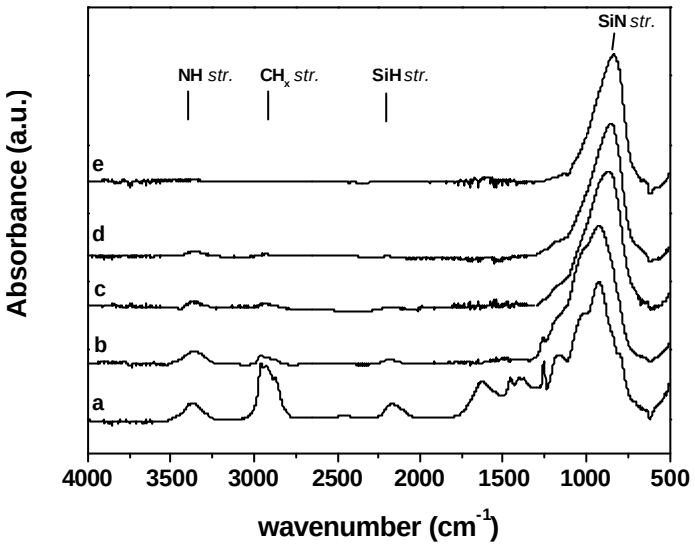

Figure 3. Normalized FT-IR absorption spectra of films deposited in plasmas fed with BisDMADMS-Ar (ratio=0.1) at 150 W (a), 300 W (b), 500 W (c), 700 W(d). The spectrum of a thermal SiN_x film (HT-SiN) is also reported for comparison (e).

Due to their similarity in terms of XPS peak position, N-to-Si ratio and IR absorption, a curve-fitting of the SiN stretching FT-IR absorption band was performed for the HT-SiN film and for the sample deposited at 700 W. The results for the plasma coating are shown in figure 4 and the details are reported in table 2. The SiN signal is typically asymmetric and even though the Si-N bond in a nitride network gives origin to four vibrational modes, in both cases six peaks have been utilized for the fitting [6,9]. In fact, in agreement with published data, in addition to the four gaussian curves due to the nitride network vibrations, two further small peaks have been introduced at 1075 and 1154 cm^{-1}, assigned to SiOSi stretching and NH bending, respectively. In the plasma coating the intensity of SiOSi stretching and NH bending are higher and the SiN features are shifted to higher wavenumbers but with the same relative intensity ratio as in HT-SiN.

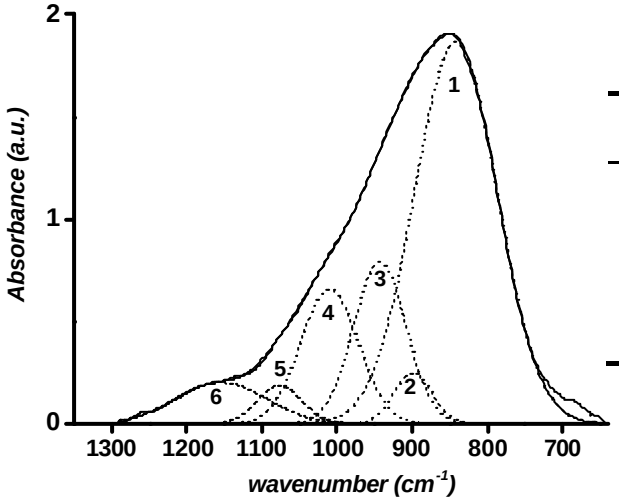

Table 2. Best-fitting of the FT-IR SiN absorption band.

curve	*Vibrational mode*	*Position (cm^{-1})*	*FWHM (cm^{-1})*
1	SiN *stretch.*	842	130
2	SiN *stretch.*	899	60
3	SiN *stretch.*	943	82
4	SiN *stretch.*	1010	90
5	SiOSi *stretch.*	1075	70
6	NH *bend.*	1154	142

Figure 4. Best fitting of the SiN stretching FT-IR absorption band for the coating deposited in a BisDMADMS-Ar fed discharge at 700 W and monomer-to-Ar ratio of 0.1. Peak assignmets, positions and FWHM's are reported in table 2.

The effect of BisDMADMS dilution in Ar has been investigated at the input power of 300 and 700 W in the monomer-to-Ar ratio range of 0.05 - 0.6. By increasing the BisDMADMS-to-Ar ratio the coating becomes more organic and less cross-linked. In particular at 700 W the SiN moves from 850 cm^{-1}, at the ratio of 0.05 (very close to SiN stretching in HT-SiN), to 895 cm^{-1} at a ratio of 0.6, indicating a higher organic character; moreover, an increase of the absorption of CH_x, SiH and NH bands has been revealed. A similar trend, but more marked, has been observed at 300 W where, for the monomer-to-Ar ratio of 0.6, a coating very close to that deposited from pure BisDMADMS (figure 2) has been obtained.
Summarizing, it can be concluded that when BisDMADMS is utilized as film precursor, high input power and low monomer-to-Ar ratio are required to produce silicon nitride-like films. Under the experimental condition utilized, at 700 W and BisDMADMS-to-Ar ratio of 0.1 the deposition rate was 20 nm/min and the refractive index of deposited films was found to be 1.87 ± 0.02.
Figure 5 shows the FT-IR spectra of films obtained at the BisDMADMS-to-Ar ratio of 0.1, at 300 and 700 W, recorded as deposited and at one month after the deposition. It is clear that while the chemical composition of the coating deposited at 300 W changes, the film obtained at 700 W does not show any ageing since the FT-IR spectrum appears unmodified. Coating (b) of figure 5, in fact, shows an evident oxygen uptake since the intensity of the OH stretching at 3100-3500 cm^{-1} and of Si-O-Si stretching at 1050 cm^{-1} increase after one month, while the intensity of SiH bands decreases suggesting that reactive SiH may undergo oxidation and hydrolysis reactions with oxygen and water molecules diffused through the film network, in agreement with the reported mechanism of ageing for highly organic and poorly crosslinked coatings (i.e. $SiC_xN_yH_z$ films) [11, 17, 18].

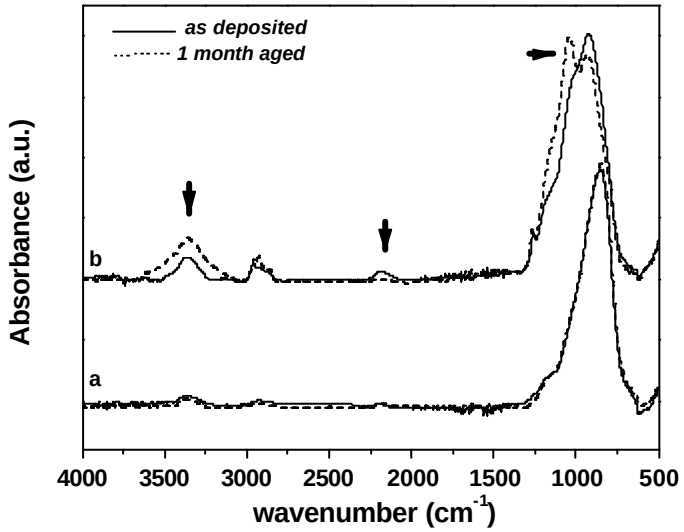

Figure 5. FT-IR spectra of coatings obtained in bisDMADMS-Ar (ratio = 0.1) fed plasmas at 700 W (a) and 300 W (b) acquired within 1 hour after the deposition and after 1 month of air exposure. The arrows indicate the variations occurred in the spectra.

The importance played by the BisDMADMS with respect to other organosilicon compounds for nitride deposition, has been defined by performing a set of experiments under the same conditions utilizing hexamethyldisilazane (HMDSN) as film precursor. XPS analysis of films obtained by HMDSN reveal a carbon content higher than 40 % and a nitrogen content not lower than 10 %; their FT-IR spectra show the main band always peaked at 800 cm^{-1}, assigned to Si-C bonds. Therefore BisDMADMS is more suitable to obtain SiN-like coatings while HMDSN produces silicon carbonitrides films. This could be a consequence of the higher bond energy of Si-C (92 Kcal/mol) with respect to C-N (73 Kcal/mol); in fact, the HMDSN molecule has six carbon atoms all strongly bonded to silicon, while in the molecule of BisDMADMS there are four C-N bonds and two Si-C bonds and therefore in the plasma phase BisDMADMS is expected to undergo a higher fragmentation with a more effective reduction of its organic fraction.

4. Conclusions

In this work FT-IR and XPS investigations of the chemical composition of silicon nitride-like thin films deposited in IC plasmas fed with BisDMADMS-Ar mixtures have been performed. The results show that this novel organosilicon compound is particularly suitable to produce silicon nitride-like film, also at low substrate temperature and without the addition of reactant gases; at high input power and low BisDMADMS-to-Ar ratio the nitrogen content is maximized and the carbon concentration in the film is low. Stable quite inorganic films with good optical properties (refractive index of 1.87) have been obtained under the best experimental conditions.

Time-Resolved Mass and Energy Spectral Measurements in an Acrylic Acid Pulsed Plasma

S.A. Voronin[1], M. Alexander[2] and J.W. Bradley[1]

1 Dept of Electronic Engineering, University of Liverpool, Liverpool, UK

Abstract
We present a technique for obtaining time-resolved mass spectra and ion energy distribution functions (IEDFs) using a commercial quadrupole mass energy analyser. The measurements were carried out in a 1.3 Pa pressure acrylic acid RF discharge, pulsed at a frequency of 1 kHz. Both the extractor and detector of the analyser were triggered independently which allowed *time-of-flight (mass) independent* measurements.

Keywords: acrylic acid, mass spectrometry, time-resolved, ion energy distribution, plasma diagnostics, pulsed RF plasma.

Introduction

Pulse-modulated processing plasmas are extensively used for a number of material processing applications such as reactive ion etching, reactive magnetron sputtering, plasma enhanced chemical vapour deposition and plasma polymerization. Modulating the applied power, typically through variation of the pulse frequency and duty ratio has advantages in terms of enhancing consumed electrical power efficiency and greater control over the plasma properties, particularly the ion energy distribution function at a work piece of substrate [1]. Making accurate time-resolved energy and mass spectra measurements at the plasma-material interface is important for obtaining better understanding of pulsed plasma particle dynamics, ion bombardment energy, sheath structure and plasma chemistry.

A number of commercially available mass spectrometers are capable of making mass- and energy-resolved measurements of positive and negative ions, neutrals, excited species and electrons extracted from a plasma discharge. Time-resolved mass spectra and IEDFs measurements were done either in inner gases plasmas and chemically active plasmas [2-4], by gating the digital ion counting pulse on the analyser detector. This common technique is reliable and simple in use. However, it has some disadvantages.

First of all, time-of-flight (TOF) of the ions through the optics is rather long (dozens-hundreds microseconds). Measurements made at one time point (connected to the spectrometer detector triggering signal) are "delayed" with respect to the TOF to the time point where the ions originally came. Hence, the transit time required for an ion to transit from the entrance orifice to the secondary electron multiplier (SEM) must be taken into account when referring the IEDFs to the modulation pulse front. Ion transit times τ_t are mass-dependent ($\tau_t \sim (M_i)^{-1/2}$) which makes it impossible to obtain a mass spectra and IEDFs for ions of different masses at one selected time point at once. Another problem, that occurs by using this method – is an increase in IEDFs uncertainty when two energy groups of ions exist in a discharge. Typically this can happen when ions with higher energies from "on" time and ions with lower energies from "off" time exist simultaneously. This may cause deviations of the IEDFs (obtained in afterglow) from the expected single low-energy peak, namely, a simultaneous contribution from the second high-energy peak [2].

Moreover, ion transit time to the detector must be smaller than the period of modulation of pulsed plasma. Otherwise ions from an earlier pulse periods will corrupt the data measured in the subsequent pulse period.

Karkari et al [5] used a simple technique of electrostatic gating the ions at the entrance of the spectrometer for ion spectral measurements in a high-frequency pulsed Ar discharge. A high positive retarding potential was applied to the grid mounted in front of the extraction orifice. The potential of this grid was rapidly lowered to zero for a chosen duration, which provided a window for the ions to enter the spectrometer. At other times, a large repulsive bias is applied, electrostatically shuttering the ions. We base our system on this method, to examine the fundamental characteristics of an RF discharge in an acrylic acid plasma, which is an important monomer compound used for plasma film polymerisation [6].

Several significant steps have been made to improve this technique for complex measurements in a multicomponent chemically reactive pulsed RF plasma. (i) An extractor was located inside of the barrel of the mass spectrometer (behind an orifice) and directly triggered from the external circuit. This prevented possible film deposition on it and no "parasitic" discharge could happen between an extractor and orifice due to the high vacuum inside the barrel (~10^{-1}-10^{-2} Pa near the orifice). (ii) Within the gating time the potential of the extractor was rapidly lowered to an adjusted value between -20 V and +20 V instead of zero what gave more control of the ion extraction. (iii) SEM was also triggered with a prescribed delay with respect to extractor gating window. This allowed us to increase the counts response (compare to situation if the SEM was constantly enabled) and at the same time to detect ions of different masses at one investigated time point for one scan.

Experimental setup

The plasma used in this study was maintained inside a glass cruciform by the application of RF excitation (13.56 MHz) from a four-turn coil copper strip, wound around one axis of the vessel. The system, pumped by a rotary pump and its electrical part are described elsewhere [7]. A needle valve was used to control acrylic acid flow and pressure, while a Baratron gauge was used to monitor the pressure. Schematic diagram of the discharge geometry and electrical arrangement is shown in figure 1a.

The RF power and data acquisition signals are synchronized by a pulse-width generator (figure 1a,b). The exciting RF voltage U_{rf} (applied to the driving coil) is generated by an Advanced Energy RFG-150 power supply triggered from pulse U_{pulse}. It is coupled to the coil electrode via a separate matching unit. Power input is measured using the built-in meter and the reflected power never exceeded 3%.

The positive ion energy distribution functions with respect to the earth potential were measured by a Hiden EQP 300 energy-resolved mass spectrometer. Its input orifice (diameter of 100 μm) was located close to the centre of the vessel (figure 1a). The ions from the plasma enter the spectrometer through the orifice of the end cap. In a new electrode configuration by Hiden Analytical the extractor was mounted in the vacuum inside the barrel behind the orifice (figure 2c). This excluded the possibility of unwanted discharge between an extractor (at high voltage) and other electrodes which could occur if the extractor was immersed into the gas medium as in [5].

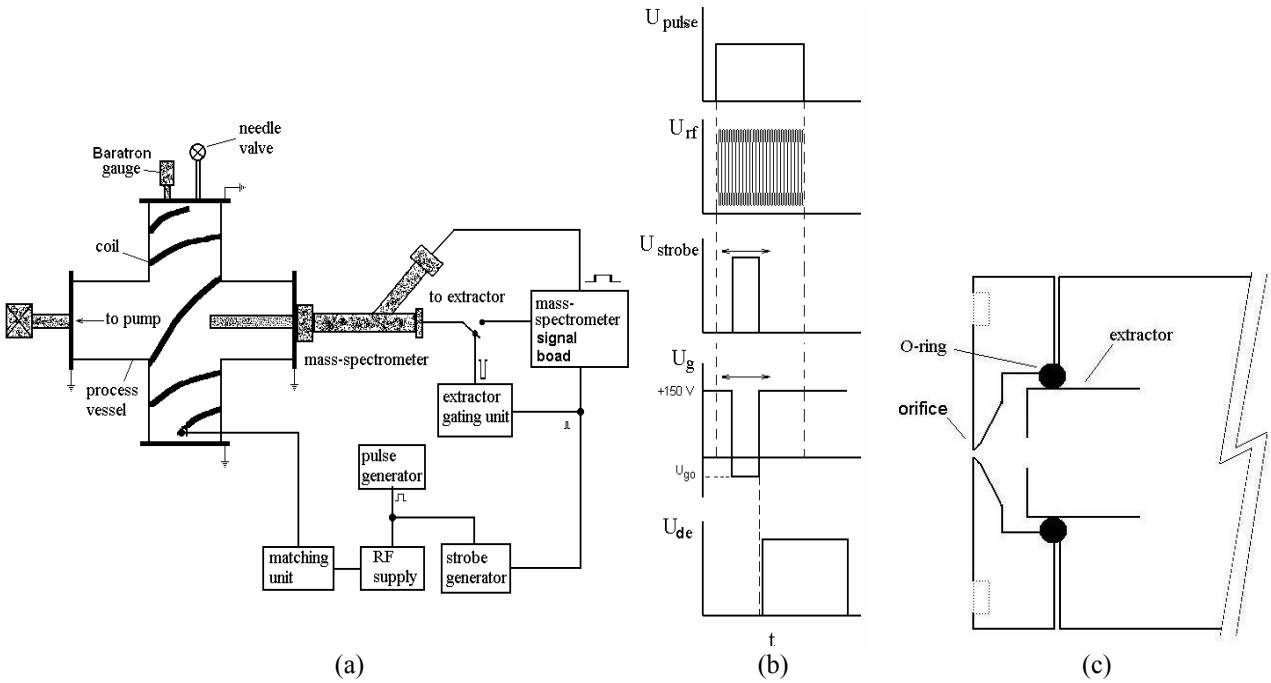

Figure 1. (a) Schematic diagram of experimental set-up and (b) signal diagram. (c) Extractor location inside the barrel

Both an extractor gating unit and mass spectrometer circuit board were connected to the extractor through the electric switch (figure 1a) to get an opportunity to supply the extractor externally (from pulsing generator) or internally from EQP 300 signal board.

In the periods of the pulse when ions were not to be selected for measurement, the extractor was held at a constant positive voltage U_g = +150 V to repel all positive ions from the plasma (figure 1b). A 10 μs pulse U_{strobe} was launched from the generator with a prescribed delay with reference to the leading edge of the pulse U_{pulse}. At the measured time point with respect to the strobe signal U_{strobe} the potential of extractor U_g was rapidly reduced to the adjusted potential level U_{go} (between -20 V and +20 V) allowing the ions to achieve the spectrometer optics and SEM. In that way the ion energy distribution functions and mass spectra could be obtained at the same instant of time. By using a gating switch based on a MOSFET transistor the fall and rise times of the extractor bias were as short as 0.02 μs and 0.1 μs respectively. These times were much shorter than the gating window width (10 μs), thus a number of "false" ions (accelerated or decelerated ions in the gaps orifice-extractor-focusing lens within these transient time periods) was relatively insignificant. Hence, possible distortion of IEDFs causing those "transient" ions was minimized. Within a short time (~2 μs) after an extractor gating pulse was over, a detector enabling pulse U_{de} of 250 μs duration was generated by an EQP internal signal board allowing the digital ion counting pulses to be counted (figure 1b). To proceed from transit time for Ar^+ (m/z=40) is 80 μs, time-off-flight of ions with masses between 2 amu and 300 amu will assuredly lie in the limit of 250 μs. To assure adequate signal-to-noise ratio counts were accumulated over a period of 30 ms.

Results and discussion

The experimental data are presented for a fixed acrylic acid pressure of 1.3 Pa and RF power 10W. The modulation frequency is 1 kHz and 50% duty cycle (500 μs "on" time and 500 μs "off" time). The analyser was originally tuned for ion mass m/z = 73.

The time-averaged IEDFs for m/z = 19 (H_2OH^+), m/z = 55 (CH_2CHCO^+) and m/z = 73 ($[M+H]^+$) are shown in figure 3. Two energy peaks are observed of those three described by Charles and Boswell [8].

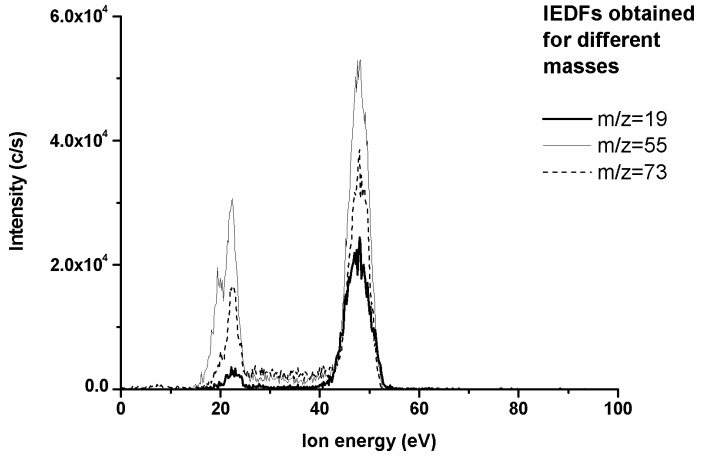

Figure 3. Time-averaged IEDFs of different ion masses obtained with the spectrometer for a pulsed RF acrylic acid plasma.

The low-energy peaks (~20 eV) correspond to ions extracted to the earthed analyser in the post-discharge. The dominant higher-energy peaks (~48 eV) are associated with the IEDFs for continuous wave when the plasma is on. In [9] it was experimentally found, for the same discharge conditions, that transient periods between "off" and "on" times (when the plasma potential jumps up) were about 20 μs. This time is much shorter than the modulation pulse period (1 ms). Hence the high-energy ions contribution to the IEDFs are negligible. This explains why the high-energy peaks above 50 eV are not recognisable in the figure.

Figure 4 shows the time-resolved IEFDs obtained for different ion masses using the shuttering method. Each of the IEDFs shown represents a measurement with a particular time delay from the leading edge of the pulse in steps of 10 μs. For closer examination the IEDFs obtained during "on" and "off" periods are shown in different energy scales (plots 4a,c,e and 4b,d,f respectively). Figure 5 represents the time-resolved positive ion mass spectrums, obtained at the same time points with the IEDFs.

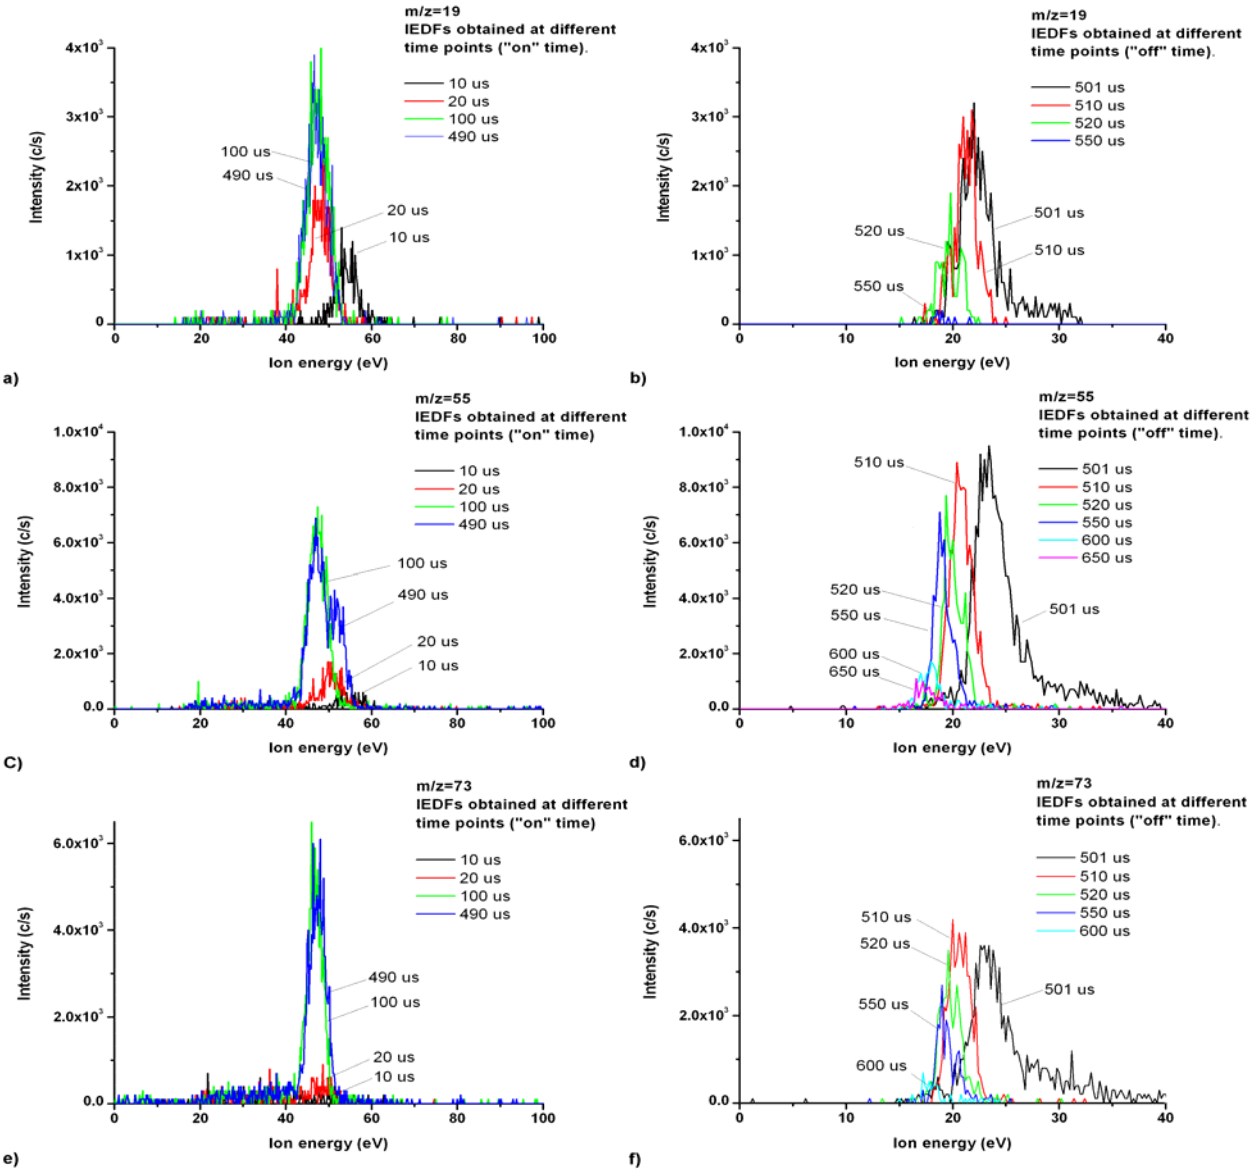

Figure 4. Time-resolved IEDFs of the different ion groups obtained at the different time points.

At the beginning of a pulse the plasma potential rises sharply to peak values greater than those for the case of a continuous wave [9]. This causes an initial spike of the ion energies (t = 10 μs and 20 μs in figure 4). The peak intensities are small due to the low plasma density at the beginning of the "on" period. It must be admitted that the peak intensities for m/z = 19 in this transient time period (figure 4a) are relatively much bigger than those for heavier ions of masses 55 and 73 (figures 4c and 4e). The same tendency is observed on the mass scans (figures 5a and 5b). Due to their high energies and as a result of high velocities the ions must cross the plasma sheath and arrive at the analyser much earlier than for 20 μs. Slower time response of the heavier masses shows that their ionization happens in a deep bulk, not near the sheath, and once created, they drift toward the EQP.

After a period of 20 μs the discharge approaches its steady state and the IEDFs obtained at t = 100 μs and t = 490 μs have a single peak with a mean ion energy of 48 eV which is similar to high-energy area of the time-averaged IEDFs (figure 3). The corresponding mass spectra are shown in figures 5c and 5d. At the end of "on" time the mean ion energies drop sharply to about 23 eV and then slowly decrease together with the peak intensities (figures 4b,d,f). Here is an opposite situation to that at the beginning of the pulse. The heavier ions stay longer in the chamber while lighter ones reach the chamber walls and recombine earlier due to their higher mobility. As a result their peak intensities decay quickly (figure 4b and figures 5e – 5i).

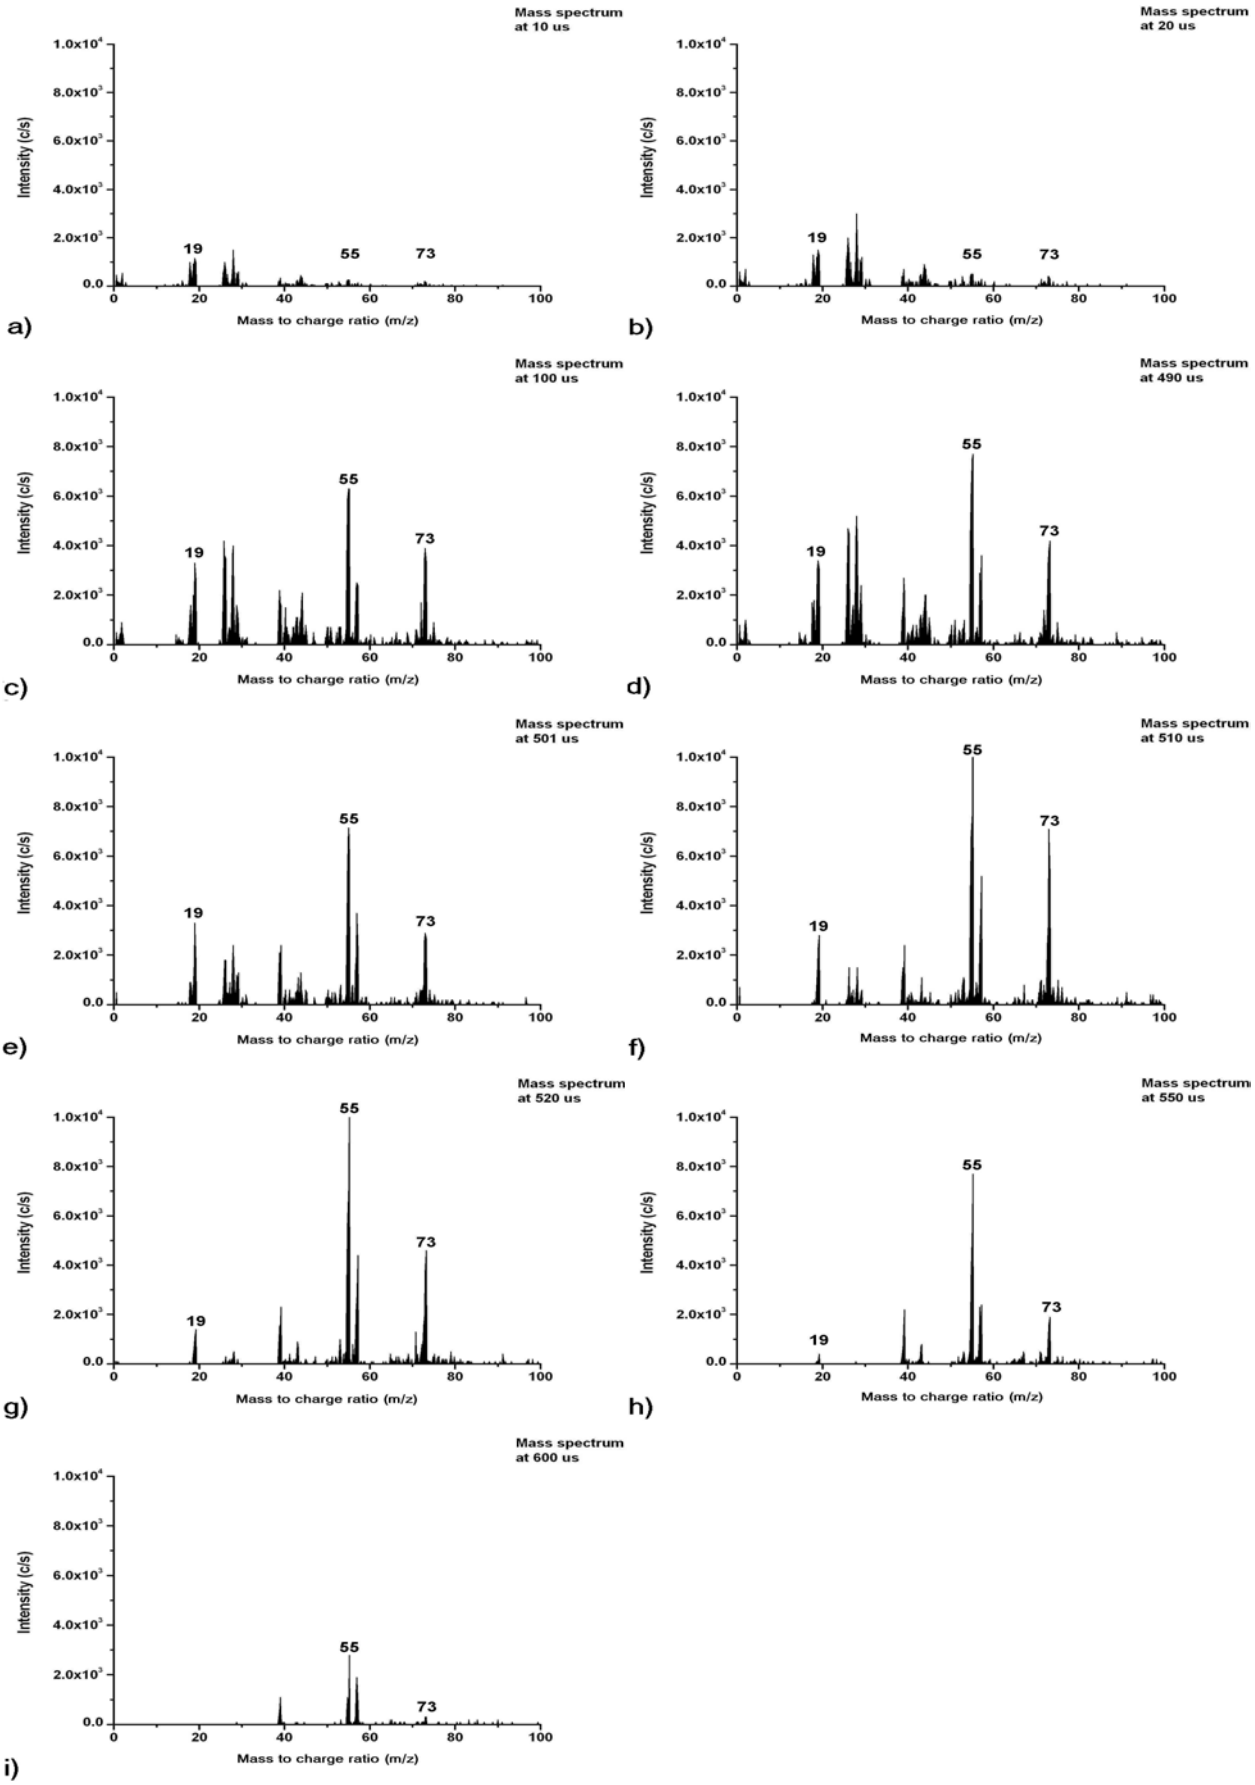

Figure 5. Time-resolved mass spectrums obtained at the different time points. (a) – (d) "on" period, (e) - (i) "off" period.

This impacts the time-averaged ion energy distributions (figure 3). The low-energy peak intensity to higher-energy peak intensity ratios for the case of large ion masses are greater than those for the ion m/z = 19. Furthermore, the low-energy peaks of masses 55 and 73 are slightly shifted to the left with respect to the lighter ion peak. Higher intensities at the beginning of afterglow than those for the "on" time (figures 4c and 4d) might be explained by a higher fragmentation of heavier components when the plasma is "on".

One should note that the mass scans were done with respect to the peak energies of m/z = 73. As it is seen from figure 4 the energy peaks for different ion masses at the same measurement points are slightly different. This means that unlike IEDFs, the mass spectra, obtained this way are not completely accurate. However, they do show the short-term and long-term variations of the mass to change.

Conclusions

Using a technique of electrostatic gating the ions the time-resolved IEDFs and mass spectra were obtained independently of the ion time-of-flight in an acrylic acid RF pulse discharge. Time dependences of the mean ion energy values of different ion masses were determined. Analysis of the obtained IEDFs and mass spectra showed that ionization took place in the bulk plasma. At the beginning of an RF pulse the lighter ions could almost immediately reach a potential target, but heavier ones incurred a delay. In the afterglow heavier ions stayed longer, while lighter fractions were evanescent. This effects on the time-averaged IEDFs: low-energy peak of the heavier ion is bigger than and shifted to the left with respect to that for the lighter ion.

Abstract

In this work, we have more particularly investigated the particle formation in a CH_4/N_2 discharge in order to understand the effect of the nitrogen addition on the particle structure and behaviour. Optical emission spectroscopy has been used to characterize the plasma bulk in order to evidence the formation of various excited species. Nitrogen incorporation leads to a better decomposition of CH_4 and enhances the formation of CH and CN radicals contained in the plasma. Changes in the particle growth appear for nitrogen content up to 50 %. Moreover, infrared analyses evidence, both in the particles and in the coatings, the emergence of nitrogen related bond absorption bands [C-N, C=N, C≡N and N-H] whereas the CH ones seem to vanish for a nitrogen ratio up to 50%. A good correlation has been established between OES results and IR analyses.

Keywords : Carbon nitride particles, dusty plasmas, optical emission spectroscopy, CH and CN radicals.

Introduction

Amorphous hydrogenated carbon thin films (a-C:H) have been widely studied. Indeed, carbonated thin films are of big interest because of their physical and chemical properties [1] : great hardness, good thermal conductivity, great electric resistivity… Their mechanical and electronic applications are numerous. These coatings are used to impart particular properties to unspecified surfaces. One way to depose a-C:H thin films is to use Plasma Enhanced Chemical Vapour Deposition (PECVD).

Some works have evidenced the appearance of particles in the plasma bulk, in addition to coating formation on the electrodes. Langmuir et al. [2] first observed the formation of dusty particles in reactive plasmas. Most recently and for over a decade, some works have been made in silane plasmas [3,4,5] and only a few papers deal with the particle formation in pure methane plasmas [6,7,8].

Particle formation in a plasma takes a particular interest because they fundamentally alter plasma properties such as the dielectric response of the background plasmas or the distributions of plasma potential and density [9]. Thus, the presence of dusts leads to inhomogeneities in the coatings and are responsible of surface contamination. They can alter the quality of deposited thin films and etching works in microelectronics devices (etching, sputtering or deposition processes). Moreover, particles that appear in methane plasmas are of interest in astrophysics to study nebulae or comet tails.

In order to understand the particle formation and growth within the plasma, the effect of nitrogen addition in methane is studied. Nitrogen is preferentially chosen because different effects can be produced on diamond-like carbon, such as the formation of the hypothetical super hard compound β-C_3N_4 or the creation of fullerene-like bonding structures [10]. In this paper, investigation is focused on the effect of nitrogen addition on the particle and thin films structure, and on the emission line intensity of excited species in the plasma.

Experimental set-up

The experiments are performed in a classical capacitively coupled parallel plate radio-frequency stainless steel reactor. The dimensions of rf and grounded electrodes are respectively 13.5 cm and 20 cm in diameter with a space of 2.5 cm. A gas pumping, achieved by two separate pumping systems permits to reach a residual pressure lower than 10^{-3} Pa in the reactor. Gas flow rates were typically 5.6 sccm (9.45 10^{-3} $Pa.m^3.s^{-1}$) for all the CH_4/N_2 mixtures and pumping using a primary pump system is used in order to maintain a constant pressure of 120 Pa within the reactor's enclosure. A 13.56 MHz radio frequency power is delivered by a rf generator (Hüttinger PRG 300) and an output power of 80W is applied. The generator is capacitively coupled with the powered electrode inducing a negative dc self bias voltage (V_{dc}) on the cathode. Experimental time is 30 min.

In order to study the effect of nitrogen partial pressure on the plasma composition, and on the thin film and the particle formation, different gas mixtures are used with a nitrogen ratio in the range 0-90%. For each experiment, particles are collected and a stainless steel substrate is put onto the grounded electrode in order to analyse the amorphous hydrogenated nitride carbonated film. Particle generation and growth are observed and evidenced using an Argon ion laser light scattering (λ=514.5nm). Particles and films are analysed by Scanning Electron Microscopy (SEM) and Fourier Transformed Infra-Red spectroscopy (FTIR) using a Nicolet Spectrometer. Optical Emission Spectroscopy (OES) is used to obtain a qualitative study of excited species contained in a CH_4/N_2 rf plasma at the boundary between the cathodic sheath and the plasma bulk. Previous works [11] evidenced that the values of the emission line intensities are maximum at the cathodic sheath boundary. OES analyses are made using a lens focusing the light onto an optical fiber connected to a spectrometer (Chromex 500i) and coupled with a multichannel analyzer (CCD Pl 330×1100, Princeton Instruments).

Results and Discussion

1. Optical emission spectroscopy analyses.

The optical emission spectrum of a CH_4/N_2 plasma shows the typical species of a pure methane plasma (CH, H_α, H_β, H_2, C_2…) associated to the excited species corresponding to a nitrogen gas (CN, NH, N_2, N_2^+…). In order to understand the various contributions of radicals on the chemical growth of particles and coatings created in the reactor, we are especially interested in the following species :

- CH ($A^2\Delta$; v'=0 → $X^2\Pi$; v''=0) system at 431 nm,
- CN ($B^2\Sigma$; v'=0 → $X^2\Sigma$; v''=0) system at 388.1 nm,
- NH ($A^3\Pi_i$; v'=0 → $X^3\Sigma^-$; v''=0) system at 336 nm,

The figure 1 respectively presents the temporal evolutions of CH (fig. 1-a) and CN (fig. 1-b) radicals for different nitrogen percentages in the gas mixture. We can observe for CN radicals an increase of the emission line intensity during the first minutes after the discharge is on. This increase is improved with the nitrogen ratio in the plasma. In the same time, at the beginning of the experiment, the CH emission line intensity decreases for poor-nitrogen plasmas whereas the nitrogen addition leads to a slope inversion. The CH intensity presents the same temporal evolution than the CN ones for rich-nitrogen plasmas. Then, we can observe a stabilisation of the emission lines for these radicals after about 8-10 minutes of experiment in accordance with the different experimental conditions. The analysis of the dc self bias voltage Vdc permits to understand these temporal evolutions as can be seen in the figure 2. According to previous works in a pure methane plasma [11], the decrease of the absolute value of the Vdc is correlated with the particle formation within the gas discharge. The particle growth leads to a diminution of the |Vdc| which tends to a minimum value about 3-5 minutes of experiment corresponding to a maximum of particle generation, and recover it initial value at the end of the particle perturbation correlated with the stabilisation of the CH and CN

emission lines. Thanks to the CH and CN emission line evolution during the first ten minutes, we can assume a chemical perturbation of the excited species containing in the plasma due to the particle formation.

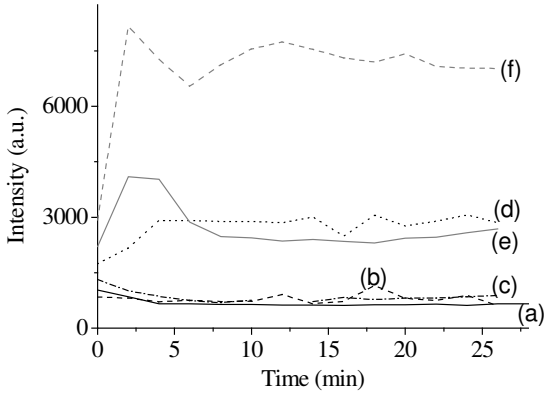

Fig. 1-a

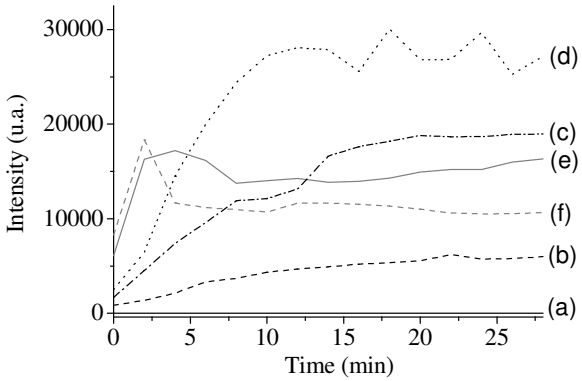

Fig. 1-b

Figure 1 : Temporal evolution of the CH radical emission line at 431 nm (fig. 1-a) and of the CN radical emission line at 388.1 nm (fig. 1-b) .

(a) 100% CH_4, (b) 90% CH_4 / 10% N_2, (c) 75% CH_4 / 25% N_2, (d) 50% CH_4 / 50% N_2, (e) 25% CH_4 / 75% N_2, (f) 10% CH_4 / 90% N_2.

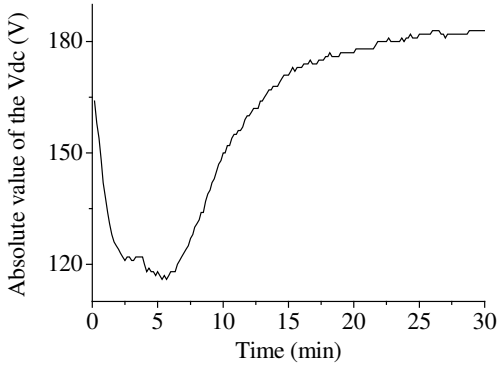

Figure 2 : Temporal evolution of the absolute value of self bias voltage for a 75% CH_4 / 25% N_2.

The influence of the nitrogen ratio in the plasma on the CH and CN radicals is quite different. For a nitrogen-poor gas mixture (from 0 to 25% of N_2), whereas the CN emission regularly increases, the CH one stays almost constant. For nitrogen ratio varying from 25% to 50%, both the CH and CN emission increases. Nevertheless, whereas the CN emission begins to decrease for nitrogen ratio up to 50%, the CH one keeps constant values until 75% and then strongly increases for nitrogen-rich gas mixture (10% CH_4 / 90%N_2).

According to T. Vandevelde et al. [12], in a high pressure micro-wave reactor, the nitrogen ratio increase furthers the CH_4 precursors dissociation. We can suppose, in our process, that the nitrogen addition in the methane gas discharge leads to a better decomposition of CH_4 precursors and enhances the formation of CH and CN radicals contained in the plasma. Indeed, until a nitrogen percentage equal to 50%, the CH and CN emissions increase. But, up to 50% of N_2, the CN emission line decrease probably results from a diminution of the CH_4 precursors in the reactor and a CN radical consumption for the particle and coating growth. In the same time, in the range [50%-75% N_2], the CH emission stagnation is due to a compensation between the higher CH_4 dissociation, the CH participation in the particle and deposition formation and the lack of methane ratio in the gas mixture. The huge increase of the CH radical emission for nitrogen-rich plasmas (10% CH_4 / 90% N_2) seems to confirm the CN radical participation in the thin film and the dust growth instead of the CH ones.

Concerning the NH radicals, the temporal evolution of the NH emission line is more difficult to study. Indeed, the N_2C emission line at 337.1 nm is close of the NH ones at 336 nm. NH emission line is almost completely obscured by the N_2C ones. Figure 3 presents the shape of the N_2C emission line for different nitrogen ratio. Whereas none NH emission line appears for nitrogen ratios less than 50%, we can notice for rich-nitrogen plasmas, the appearance of a small peak attributed to the NH radicals. Intensity measurement seems to indicate an increase of the NH emission line following the N_2C ones for nitrogen ratio up to 50%.

The NH formation comes from the recombination phenomena between the nitrogen species and the hydrogen ones both released during the particle and coating formation and exit of the methane precursor dissociation. It's quite difficult to predict a possible correlation between the NH radicals and the thin film and the particle growth.

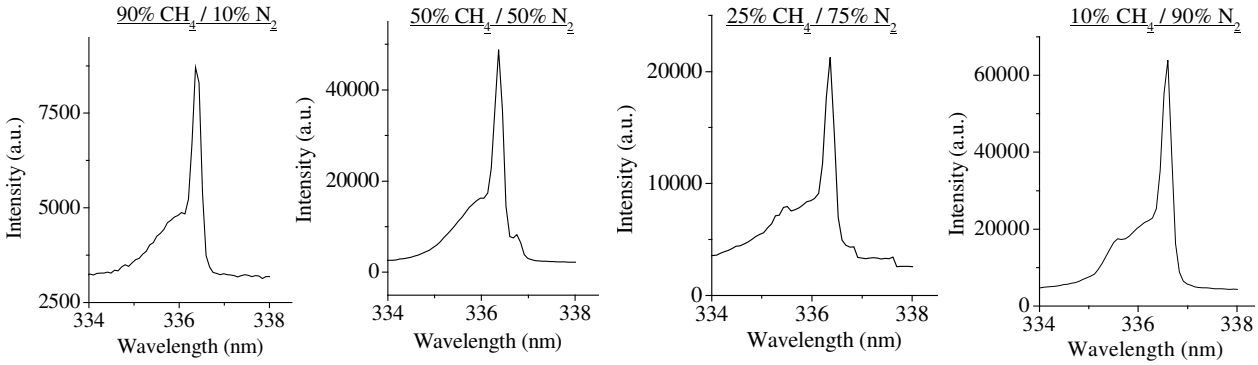

Figure 3 : Analysis of NH and N_2C emission line for different CH_4/N_2 ratios.

In order to support the optical emission spectroscopic results and to confirm the role played by the CH, CN and NH radicals containing in the plasma, particles and coatings are analysed using infrared spectroscopy.

2. Infrared analysis.

The infrared absorption spectra of the amorphous hydrogenated carbon nitride particles and coatings, obtained for different CH_4/N_2 gas mixtures, are performed and reported in figure 4. Even if structural differences seem to exist between the thin films and the analysed dusts, the two spectra show the presence of four typical absorption bands for the a-CN_x:H compounds, as observed by Mutsukura in amorphous carbon nitride deposited films [13].

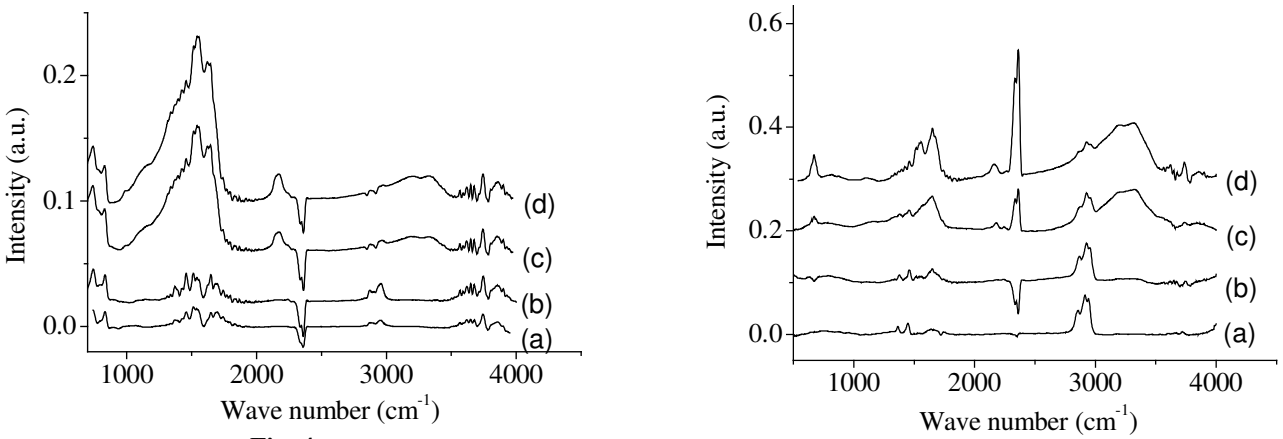

Fig. 4-a **Fig. 4-b**

Figure 4 : Infrared absorption spectrum of a-CN_x:H particles (fig. 4-a) and thin films (fig. 4-b) obtained in CH_4/N_2 plasmas.

(a) 100% CH_4, (b) 90% CH_4 / 10% N_2, (c) 50% CH_4 / 50% N_2, (d) 10% CH_4 / 90% N_2.

1- The absorption region in the range 3200-3500 cm^{-1} is consistent with modes involving N-H and/or OH stretching vibrations [14]. The increase of this band by addition of nitrogen content in the reactor suggests for the particles as for the coatings an incorporation of NH bonds. The NH absorption band appears for nitrogen ratios up to 50%.

2- The 2800-3100 cm^{-1} absorption region is related to CH stretching vibrations [sp^3 CH_3 in symmetric (2875 cm^{-1}) and asymmetric (2960 cm^{-1}) vibrational modes, sp^3 CH_2 and sp^3 CH (2920 cm^{-1})] [15]. Whereas CH related band regularly decreases in the coating with addition of nitrogen in the gas mixture, CH incorporation in the particles seems to increase until 50% of N_2 ratio, then vanishes for nitrogen-rich plasmas.

3- The third band in the range 2000-2300 cm^{-1} is related to the triple-bonded –C≡N nitrile (2109-2178 cm^{-1}) and C≡N- isonitrile (2225-2275 cm^{-1}) structures [16]. The emergence of nitrile and isonitrile structures appears for nitrogen ratio up to 50% and the shape of this band suggests an important conjugation with various structures (aromatic rings, aliphatic chains….).

4- The 1000-1800 cm^{-1} broad absorption band decomposition is more difficult. This band is often associated to various bond vibrations such as C-N (1100-1300 cm^{-1}), and C=N (1617 cm^{-1}) stretching modes or NH bending modes (1620 cm^{-1}) [17]. But peaks attribution is not clear because of the activation of the Raman active G (graphite-like sp^2 carbon at 1570 cm^{-1}) and D (disordered sp^2 carbon network at 1370 cm^{-1}) peaks due to nitrogen inclusion in the carbon matrix. Moreover, for Ferrari et al. [18], the absorption band in this range is mainly due to skeletal C=C vibrations. Nitrogen effect in amorphous carbon can be assimilated to doping or photo-excitation in conjugated polymers. Nitrogen doping leads to a breakdown of the electrical symmetry (removal or injection of charges). The band around 1300-1800 cm^{-1} should be only due to the C=C sp^2 phase.

Even if the meaning of this band is quite obscured, we can deduce that the increase of this broad band with the nitrogen addition is due to nitrogen incorporation in the carbon matrix and C-N, C=N and NH incorporation seems evident for the particles as for the coating.

Conclusion :

IR results confirms the optical emission spectroscopy. The N_2 rise in the reactor leads both in the particles and in the coating to an increase of nitrogen related bands (that is to say an increase of C-N, C=N, C≡N and NH bonds). Whereas the CH links regularly decrease in the coating resulting from an incorporation of the CN and NH species containing in the plasma, the increase of the methane dissociation thanks to the nitrogen flow is confirmed in the particles by an increase of CH bonds in the particles for nitrogen percentage less than 50%. But for nitrogen rate up to 50%, the CH bonds in the particles decrease and vanish for nitrogen-rich plasmas.

The CN and NH radicals seem to be incorporated either in the coating or in the particles in order to produce N-H, C-N, C=N and C≡N bonds substituting for C-H bonds present in a-C:H coatings and particles. These results confirm the OES assumptions. Indeed, the nitrogen increase leads to a decrease of the CN radicals in the reactor which are incorporated both in the particles and in the coatings, leading to an increase of nitrogen related peaks. On the other hand, the CH related band vanishes for nitrogen rich plasmas leading to a rise in the reactor of the CH radicals which do not take part in the formation of coating and particles.

Abstract
In this paper an application of a recently developed laser plasma source of extreme ultraviolet (EUV) for optical measurements is presented. The source is based on a double-stream gas puff target. The xenon-helium target was irradiated with laser pulses from a Nd:YAG laser system (E = 0.55 J, t = 3.9 ns, f = 10 Hz, M^2 = 2.5). A laser-plasma created this way is an efficient and debris free source of EUV radiation and is useful for EUV lithography technologies as a processing and metrology tool in the semiconductor industry.

1. Introduction

Probably laser produced plasmas (LPPs) will be able to meet the technical and operational requirements of sources for EUV lithography (EUVL) [1]. There are no transparent optics below 100 nm of wavelength, therefore collective and imaging optics for the future lithographic tools are based on multi-layer mirrors (MLMs) [2]. The spectral window of Mo/Si mirrors is a common consensus for all considered materials of EUVL: Sn, Xe and Li [1]. A development of proper EUV sources dedicated to metrology of EUV optics should follow the progress during multi-layer fabrication. This paper directly addresses this problem. One can produce a stack of Mo/Si layers that satisfy demands of a 2 % bandwidth (BW) with a peak reflection of about 70 % at 13.5 nm, measured near to normal. A double stream Xe/He gas puff laser-plasma EUV source was proposed [3,4] and recently applied successfully to the optical measurements of the Mo/Si multi-layer mirrors. The source has been developed in the frame of the EUV sources development project under the European MEDEA+ programme, dedicated for EUV lithography technologies (metrology of EUV optics such as mirrors or masks, EUV resists and EUV processes). The sources for EUV metrology do not have the same specifications as sources for EUV lithography exposure tools (Conversion efficiencies (CEs) of 3 % within 2 % BW per 2π steradians, high repetition rate, pulse to pulse repeatability). The characterization research of the source, including CE, spectral, spatial and temporal measurements of EUV emission have been carried out. The diagnostic tools such as grazing incidence spectrograph, a pinhole camera and absolutely calibrated semiconductor detecting systems in order to characterize properties of the source were utylized. The optimization of the source has enabled the optimum parameters to be identified. A gas puff target approach EUV source made it possible to measure the reflectivity of the Mo/Si mirrors at a selected grazing angle and after one laser shot.

2. Experimental arrangement

A Schematic diagram of the experimental set-up is presented in Fig.1. An electromagnetic valve to control gas puff target was located in the center of the source chamber. A Nd:YAG Laser (E = 0.558 J, t_{FWHM} = 3.9 ns, M^2 = 2.5, f_{max} = 10 Hz) was located inside a cylindrical pipe that was tightly connected to the source chamber. Between the chamber and the laser a lens of focal length 50 mm was positioned. This solution simplifies the set-up and prevents users from laser exposures. Since it was found in previous experiments that EUV emission is very sensitive on changes of laser focus position in a region of the gas puff target, a micromanipulator to move the valve perpendicularly to the laser beam axis was employed. Experiments have been performed using a specially prepared chamber that coupled to the source chamber, and which were motorized stages inside for alignment of the mirrors. In this chamber a Mo/Si multi-layer mirror (Fraunhofer Insitute, Jena, Germany) was located and enabled the selection of radiation from the plasma. The mirror was set at 45º thus allowing a 33 % reflectivity for 13.5 ± 0.5 nm. Moreover Mo/Si mirrors fabricated by Reflex s.r.o., Prague, Czech Republic were installed inside the chamber on motorized translation and rotation stages in order to measure angular distribution of reflectivity. Three mirrors were used, two of which were

previously etched with a stream of argon for 6 and 12 minutes respectively. In addition this chamber enabled the connection of various diagnostics such as spectrograph, pinhole camera and silicon photodiodes and is shown schematically in Fig.1. A flat field grazing incidence spectrograph with the varied grooves period grating (Hitachi, average 1200 grooves/mm) equipped with a CCD back illuminated camera (Roper) was used. Spectra with one laser shot were recorded. A spectral resolution of this spectrograph was of the order of 0.1 Å. For spatial imaging of the plasma emitting at 13.5 nm (radiation from plasma reflected from selective Mo/Si mirror was investigated) a platinum pinhole of 20 μm in diameter was applied. A pinhole was located at 54 cm from the plasma and covered with a Zr filter of 200 nm thickness, deposited on Si_3N_4 filter of the same thickness giving a transmission of 15.4 % at 13.5 nm. Because of low contrast a magnification of about 0.4 was employed. Spatial images were recorded during 60 laser shots. Absolute measurements of energy at 13.5 nm with a detection system of a silicon photodiode AXUV 100 Si/Zr (IRD) were performed. This detector equipped with a diaphragm of 8 mm in diameter and to two different flanges marked '1' or '2' in Fig. 1 dependently on measurements was coupled. Then in order to measure the time duration of EUV pulses fast HS1 photodiode (IRD) with mentioned above a stack of Zr/Si_3N_4 filters connected to '1' flange was applied. Both photodiodes recorded radiation reflected from the Mo/Si mirror (Jena).

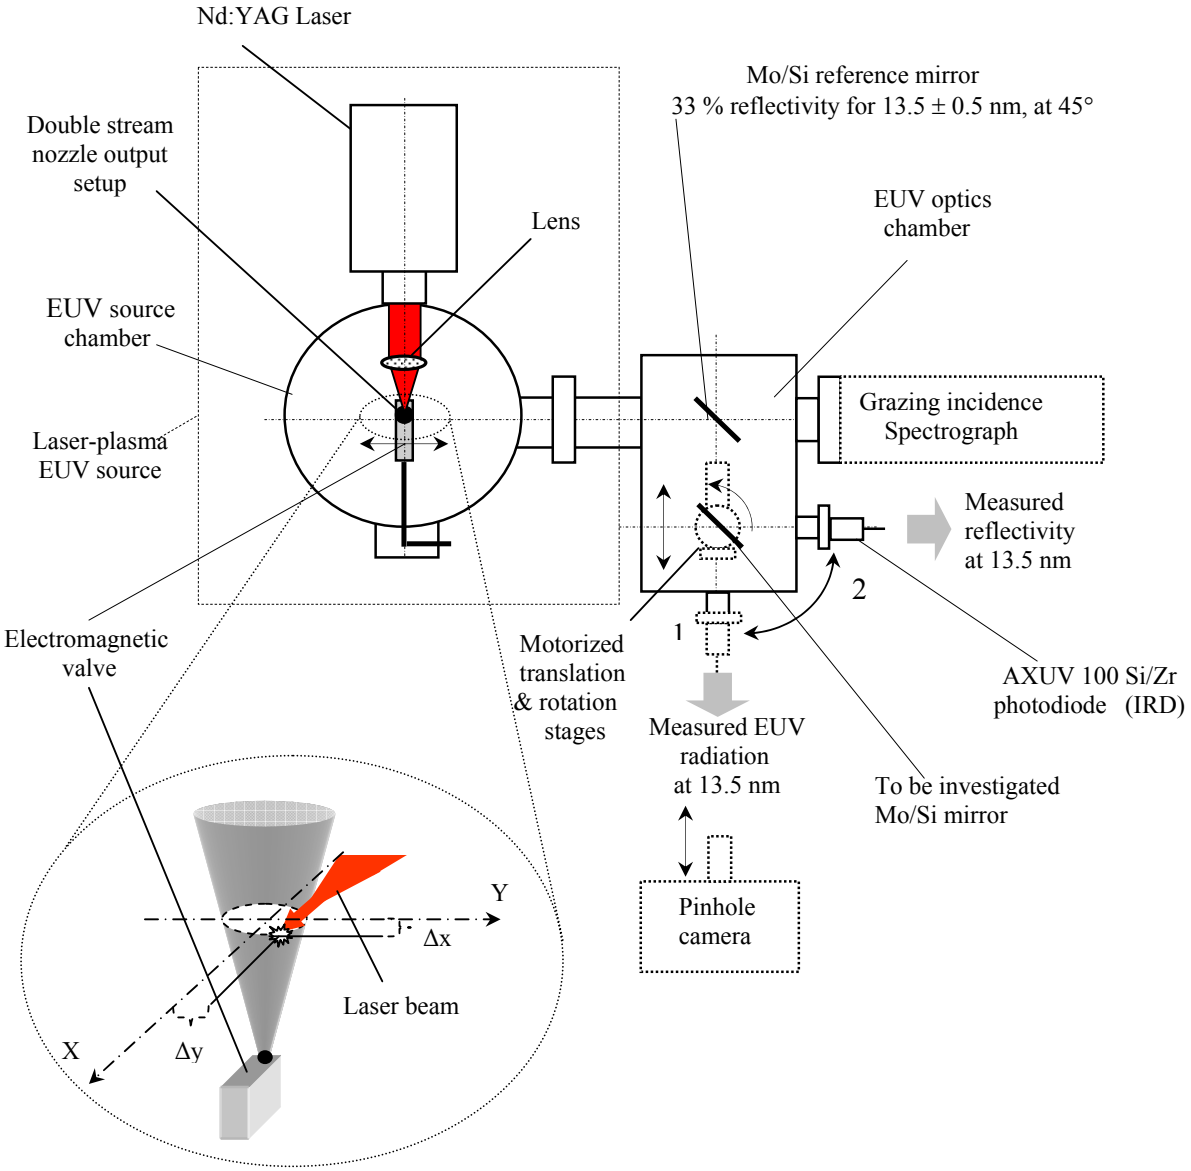

Fig. 1. Scheme of the experimental setup used to investigate EUV optics.

3. Results

3.1. Optimum source parameters

A variety of characteristics of the source were measured in series of experiments in order to obtain the input parameters of the source that lead to the optimum CE. The following input parameters that have meaningful influence on EUV emission can be distinguished: time delay between laser pulse and opening valves, position of laser spot in space in reference to the gas puff target and the backing pressure of the gas in the valves. Time delays: Δt_{Xe} = 800 μs and Δt_{He} = 350 μs for which the emission at 13.5 nm is the highest were chosen. The laser focus spot should be positioned at least H = 1 mm from the nozzle output in order to prevent its thermal degradation. A vertical distance H = 1.2 mm was selected in experiments. A 35 μm diameter laser focus was calculated using the OSLO program and support for this was experimentally confirmed. It was found that the best position of the laser spot, in order to assure the most efficient EUV production at 13.5 nm was located at Δx = 2 mm beyond the axis of the nozzle output of the valve. While the laser focus spot was located at the axis, efficient emission was shifted to the shorter wavelength, but when was at Δx = 2.5 mm condition was not corresponded to enough for xenon ionization and plasma creation. A strong EUV emission dependence on a shift of the laser spot in the gas target perpendicularly to the laser beam axis direction was observed. This shift Δy from the axis of the nozzle output was measured. It was found that the laser focus should be located at the edge of the gas target to obtain the highest EUV emission because of strong absorption of low ionized xe and of neutral xe in the surrounding plasma region. Positioning laser spots at the edge of the gas target causes production of the plasma of relatively large sizes if it is compared to the case when the spot is inside the gas target, but EUV emission observed from this side of the gas target where plasma is created is the highest. Using a AXUV 100 Si/Zr photodiode the highest emission for Δy = 900 μm was measured. Results of this investigation are presented in Fig. 2.

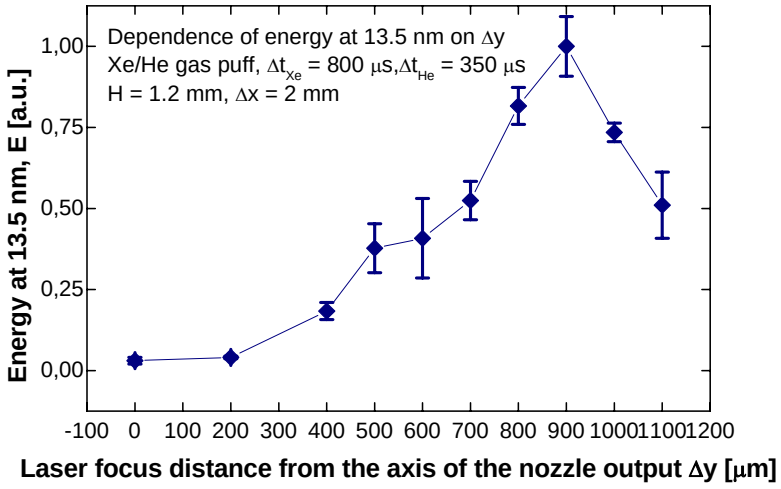

Fig. 2. EUV energy dependence on Δy.

For fixed optimum parameters mentioned previously ($\Delta t_{Xe,He}$, H, Δx and Δy), EUV emission dependence on various backing pressure in the valves was investigated. From this, optimum pressures of P_{Xe} = 1.5 MPa and P_{He} = 0.2 MPa were found. The maximum attainable energy of 1.6 mJ/sr at 13.5 ± 0.5 nm was calculated for optimum parameters and leads to CE of 0.54 % within 2 % BW per 2π sr. In Fig. 3 a pinhole image of the plasma for this case is presented. The plasma is relatively large with its dimensions of the order of 1 mm in comparison to other LPPs. A typical spectrum recorded for the optimum parameters is shown in Fig. 4. The strongest feature belongs to an unresolved transition array (UTA) [5] and for xenon is centered at about 10.85 nm. The spectral distributions for the most interesting Δy, from the significant emission point of view, are presented in Fig. 5. From spectral measurements it is clear that for Δy = 800 μm a feature at 13.5 nm was higher than in the case of Δy = 900 μm and was the strongest feature emission attainable. The Following description can account for this behaviour. Increasing the Δy parameter significantly increases the sizes of the plasma. Moreover in the case of the spectral measurements photons were collected only from the hottest region of the plasma, limited by a slit, while using the photodiodes photons were summed from the whole

plasma surface. For comparison a spectrum for H = 1.1 mm with frozen rest parameters is shown. It is discernible that the peak of the UTA is unaltered while the profile width increases with Δy. Increase of Δy follows growth of plasma dimensions and the decrease of electron temperature. A similar effect for mass limited target was observed when the emission dependence on Sn concentration in tin reach targets was investigated [6]. An explanation of this can be found in [7]. A feature at 13.5 nm which origin is from Xe XI ion stage is marked in Fig. 5 within 2 % BW. It is known that the time duration of the EUV emission corresponds to the laser pulse duration. Measured with the fast photodiode HS1 (τ_{rise} = 0.25 ns), the EUV pulse had a FWHM in the range of 3.7-3.8 ns while a FWHM the laser pulse had a 3.9 ns FWHM.

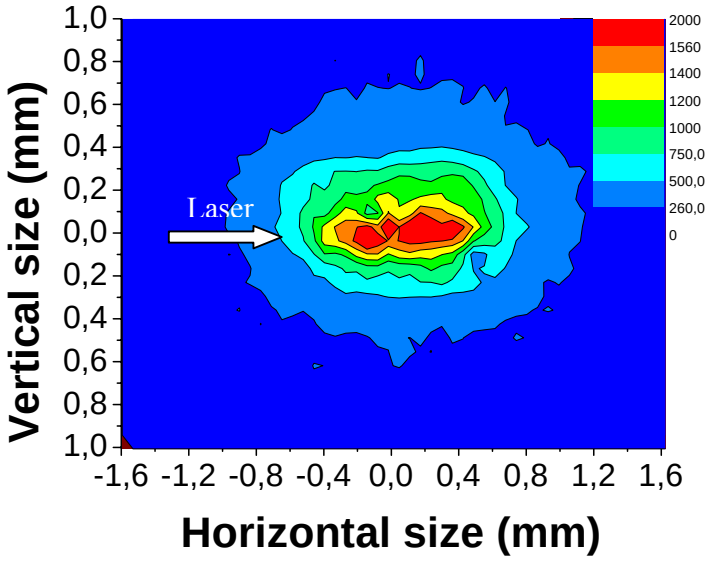

Fig. 3. Pinhole image of plasma emitting at 13.5 nm for optimum condition.

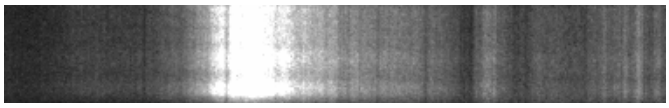

Fig. 4. Spectrum for Xe/He plasma: P_{Xe} = 1.5 Mpa, P_{He} = 0.2 Mpa, H = 1.2 mm, Δx = 2 mm and Δy = 800 μm.

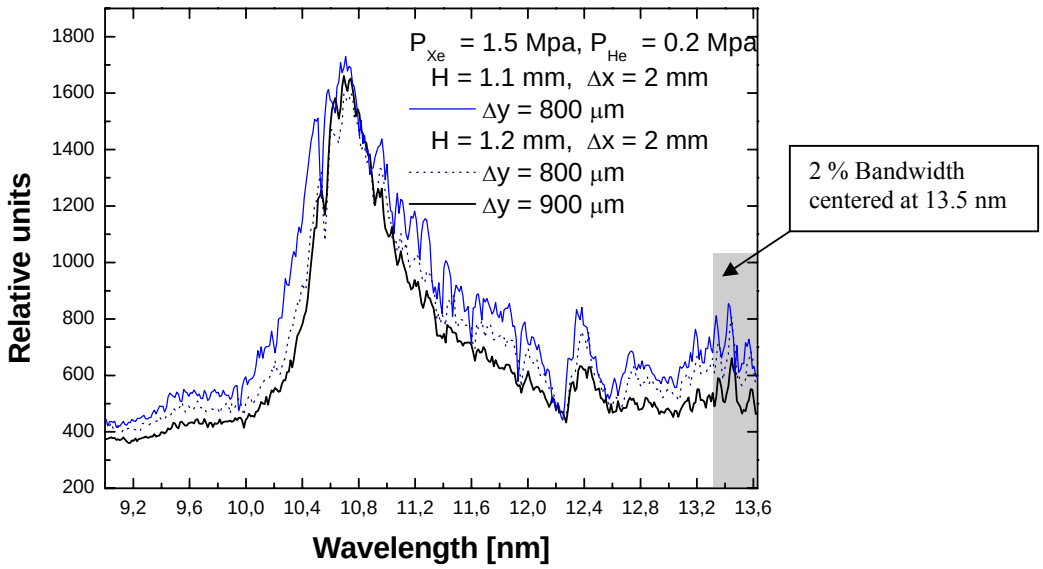

Fig. 5. Spectral distribution for optimum conditions.

3.2. Mo/Si mirrors investigation

An optimised EUV source based on a Xe/He gas puff target in reflectivity measurements of Mo/Si mirrors, was employed. Firstly an EUV average energy for the optimum parameters at 13.5 ± 0.5 nm, with the use of the calibrated photodiode AXUV 100 Si/Zr from 1 flange side, was measured. This yield was used as a reference energy for reflectivity calculations. Next the motorized stages with a mirror to be investigated were located inside the optics chamber. The photodiode from the '1' flange to the '2' flange side (see Fig. 1) was replaced. For each the Mo/Si mirror, for selected grazing angles, after one laser shot, reflected energies have been measured. For each angle position at least 10 independent measurements were performed and averaged with the reflectivity being then obtained. As a result the reflectivity distribution versus grazing incidence angle are presented in Fig. 6a-6c. In the previous experiment the maximum reflectivity at 12.7 nm at 45º in the EUV region for these mirrors was found out. But the maximum was expected for 13.5 nm, because there were so optimised. Thus a peak reflectivity was not expected for the 45º grazing angle. One can see that the peak reflectivity for 52º grazing angle in the case of no etched and for 6 min. etched mirrors and for 49º in the case when mirror was etched for 12 minutes. The maximum reflectivity only at the level of half that is theoretically attainable [8] for no etched mirror was reached. Moreover it is evident that diagrams are not symmetrical. Probably reasoning of all this may dates back to that parameters of the mirror processing such as the layer and the inter-diffusion thickness were not successfully controlled during the deposition process.

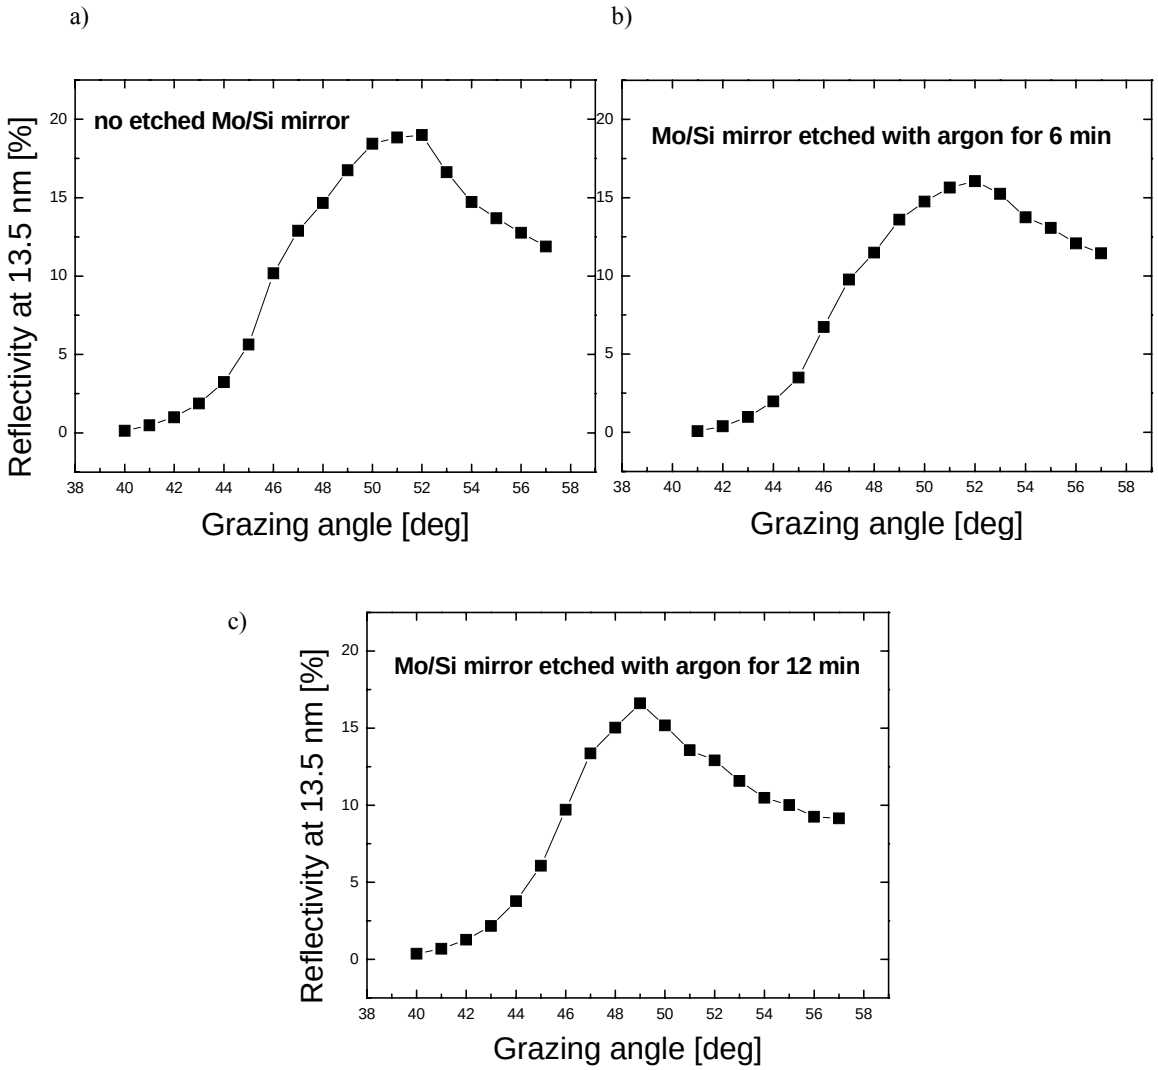

Fig. 6. Spectral distribution for optimum conditions.
a) for no etched mirror, b) for etched for 6 min., c) for etched for 12 min.

4. Conclusion

A significant feature at 13.5 nm up to half of the UTA peak, centered at about 11 nm, was attained. The CE of the laser energy into the EUV for 13.5 nm (2 % BW in 2π sr) up to 0.54 % for the xenon-helium gas puff target, has been reached. The growth of CE should be possible if opacity effects are minimised (by controlling a profitable absorption/emission ratio in plasma) [9]. The Angular distributions of the Mo/Si multi-layer mirrors fabricated by Reflex s.r.o., were performed successfully. The results have proved a usefulness of the source for EUV metrology applications having an effect on a further development of next generation of the EUV technologies.

Abstract
Combustion causes formation of NO_x, which in turn causes acid rain and ozone production when it is released into the air. Reduction of NO_x in the exhaust gas of power plants is therefore of high interest. In our paper we have considered different plasma-assisted techniques for NO_x-reduction: direct treatment of exhaust gases by plasma, injection of N atoms and injection of (stable) reactive species (N_2H_4, O_3). Advantages and disadvantages of these techniques are discussed.
Keywords
$DeNO_x$; ozone; hydrazine; dielectric barrier discharges (DBD); absorption and emission spectroscopy

1. Introduction

The NO_x emission into the atmosphere leads to serious environmental problems. Although the problem of NO_x reduction is quite old, up to now there is no efficient and economical method of NO_x reduction. Non-plasma techniques for NO_x-reduction require ammonia injection and are operated either at a narrow temperature window, 900-1100°C (Thermal $DeNO_x$) [1] or over a catalytic surface at temperatures around 400-500°C (selective catalytic reduction) [2]. Both methods are quite expensive to operate. Non-thermal and thermal plasmas at atmospheric pressure have been widely studied for reduction of NO_x in flue gases. However, non-thermal plasmas seem to be very promising in terms of operation time and costs compared to thermal ones. For instance, a dielectric barrier discharge (DBD) is one of the most attractive plasma sources for this application due to its compactness, low costs, efficiency, and ability to operate in a stable mode at atmospheric pressure at high average power. Combination of a DBD with a catalyst improves the efficiency of NO_x reduction [3], but increases the costs. In general, direct treatment of exhaust gases reduces NO_x, but produces other undesired products [4] which also affect the environment. Therefore, selective NO_x reduction is desirable. Selective NO reduction can be achieved by injection of highly reactive species (atoms, radicals or short-lived molecules) produced by a DBD into the exhaust gas stream. Although sufficient amount of highly reactive species can be produced in DBD plasma, short lifetimes of species cause a limitation of the injection methods. In the paper we consider different plasma-assisted techniques for NO_x-reduction: direct treatment by plasma, injection of N atoms and injection of reactive and stable species (N_2H_4, O_3) into the exhaust gas. Advantages and disadvantages of these techniques are discussed.

2. Experimental set ups

The experimental set up was described in details in our previous work [5]. The DBD reactor consists of two parallel plate metal electrodes. Two alumina (Al_2O_3) discs in contact with each electrode serve as dielectric barriers. The discharge gap between the two alumina discs was 3 mm. The outlet of the plasma reactor is connected to a stainless steel exhaust chamber with a connection to the gas cell of an IR-spectrometer. Both the plasma reactor and the exhaust chamber are equipped with windows for UV- emission/absorption measurements. The DBD is driven by an AC power generator at 15 kHz. Optical emission and absorption measurements were performed by a UV-VIS spectrometer equipped with a CCD-camera and an IR-spectrometer equipped with a multiple-pass absorption cell. A deuterium lamp was used as a light source for UV-absorption measurements in the exhaust chamber. The gas flows were controlled by means of mass flow controllers. In our experiments, the total pressure in the plasma reactor was kept at approximately one atmosphere.
In the experiments with ozone injection, thermal ammonia and hydrazine decomposition stainless steel and quartz reactors placed in a split-oven were used. The temperature in the oven was varied from room temperature to 1000°C. In these experiments the outlet from the reactors was connected to the exhaust chamber and subsequently to the gas cell of the IR-spectrometer.

3. Results and discussion

We performed experiments with different synthetic exhaust gas mixtures and experimental set ups: direct plasma treatment of exhaust gases, treatment of exhaust gases by injection of N-atoms, ozone and hydrazine. These different methods are discussed in this chapter.

3.1 Direct treatment of exhaust gases by plasma

We investigated direct plasma treatment of synthetic flue gases (N_2+O_2(<10%)+NO(<500ppm)+H_2O(<3.5%)+CO_2(<10%)+CH_4(<3%)). Methane is a major constitute of unburned hydrocarbons (UHC) in the exhaust gases from methane fuelled gas engines. The low ionization and dissociation energies of methane compared to those of nitrogen lead to an efficient production of methyl (CH_3) and methylene (CH_2) radicals in the plasmas. These radicals can also be formed by reaction of nitrogen metastable molecules (N_2(A)) with methane [6]. Important radical reactions are:

$$CH_2 + H \rightarrow CH + H_2, \qquad k^{300K} = 4.9\text{x}10^{-10}\ cm^3s^{-1}$$
$$CH + N \rightarrow CN + H, \qquad k^{300K} = 1.7\text{x}10^{-10}\ cm^3s^{-1}$$
$$CN + H \rightarrow HCN, \qquad k^{300K} = 8.9\text{x}10^{-31}\ cm^6s^{-1}$$
$$CH_3 + N \rightarrow HCN + 2H, \qquad k^{300K} = 3.3\text{x}10^{-13}\ cm^3s^{-1}$$
$$CH_3 + CH_3 \rightarrow C_2H_6, \qquad k^{300K} = 2.2\text{x}10^{-26}\ cm^6s^{-1}$$
$$CN + C_2H_6 \rightarrow HCN + C_2H_5, \qquad k^{300K} = 3.0\text{x}10^{-11}\ cm^3s^{-1}$$

All these reactions have high rate constants [7] and even a concentration of hydrocarbons about 2000 ppm leads to a formation of cyanogens in significant amounts on a time scale less than 1 μs. Emission spectra in a N_2/CH_4 DBD show intensive CN emission between 382 nm and 389 nm, Figure 1 (Left panel). The presence of oxygen and water reduces the CN emission intensity due to consumption of CH_2 and CH_3 radicals in competitive reactions, Figure 1:

$$CH_3 + O \rightarrow H_2CO, \qquad k^{300K} = 1.4\text{x}10^{-10}\ cm^3s^{-1}$$
$$CH_3 + OH \rightarrow CH_3OH \qquad k^{300K} = 2.6\text{x}10^{-27}\ cm^6s^{-1}$$
$$CH_2 + OH \rightarrow H_2CO + H \qquad k^{300K} = 3.0\text{x}10^{-11}\ cm^3s^{-1}$$
$$CH_2 + O \rightarrow \text{products (CO, } H_2) \qquad k^{300K} = 1.3\text{x}10^{-10}\ cm^3s^{-1}$$

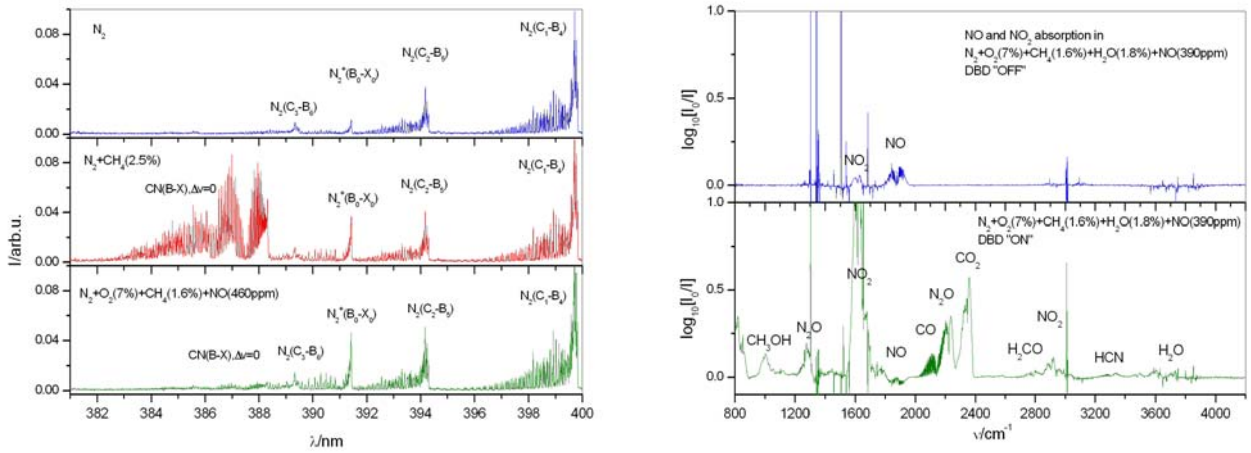

Figure 1.
Left panel: UV-emission spectra from N_2(blue), N_2/CH_4(2.5%)(red) and N_2/O_2(7%)/CH_4(1.6%)/NO(460 ppm)(green) atmospheric pressure DBD.
Right panel: Reference IR-absorption spectrum of NO and NO_2 before plasma treatment (DBD "OFF")(blue) in the mixture N_2/O_2(7%)/CH_4(1.6%)/H_2O(1.8%)/NO(390 ppm) and IR-absorption spectrum of plasma exhaust (DBD "ON")(green).

Water vapors change the plasma chemistry. We have observed an additional production of NO in an N_2+O_2(7%)+NO(400ppm)+H_2O(2.5%) DBD. Addition of ammonia (< 1%) to the mixture inhibits formation of

NO. However, reduction of NO was only achieved with methane addition. When only traces of water vapor are present in the exhaust, nitric acid (HNO_3) is efficiently produced:

$$OH + NO_2 \rightarrow HNO_3, \qquad k^{300K} = 3.4x10^{-30}\ cm^6s^{-1}$$

On the other hand, at a certain water content, nitric acid is consumed by reacting with OH and formation of dinitrogen pentoxide (N_2O_5) as observed in our experiments:

$$OH + HNO_3 \rightarrow H_2O + NO_3, \qquad k^{300K} = 1.5x10^{-13}\ cm^3s^{-1}$$

$$NO_3 + NO_2 \rightarrow N_2O_5, \qquad k^{300K} = 2.1x10^{-30}\ cm^6s^{-1}$$

Direct treatment of exhaust gases causes also formation N_2O, which is difficult to decompose.

$$N_2(A) + O_2 \rightarrow N_2O + O, \qquad k^{300K} = 7.8x10^{-14}\ cm^3s^{-1} \qquad (1)$$

$$NO_2 + N \rightarrow N_2O + O, \qquad k^{300K} = 1.2x10^{-11}\ cm^3s^{-1} \qquad (1a),$$

3.2 Injection of N-atoms produced in DBD plasma

To prevent generation of acids and cyanogens in the discharge, treatment of the flue gases by injection of reactive radicals or molecules is preferable. Injection of nitrogen atoms into the exhaust gas can reduce NO according to the reaction

$$N + NO \rightarrow N_2 + O, \qquad k^{300K} = 2.9x10^{-11}\ cm^3s^{-1} \qquad (2)$$

A typical emission spectrum of an N_2 DBD is shown in Figure 2 (Left panel). Traces of O_2 in the discharge cause the formation of oxygen atoms. Due to recombination of N and O atoms in the afterglow,

$$N + O \rightarrow NO, \qquad k^{300K} = 1.0x10^{-32}\ cm^6s^{-1} \qquad (3)$$

a variety of electronically excited states of NO is expected. In particular, the *B*- and *c*- states of NO are populated. The spectrum in Figure 2 (Left panel) shows emission bands of the β-system of NO in an N_2 afterglow.

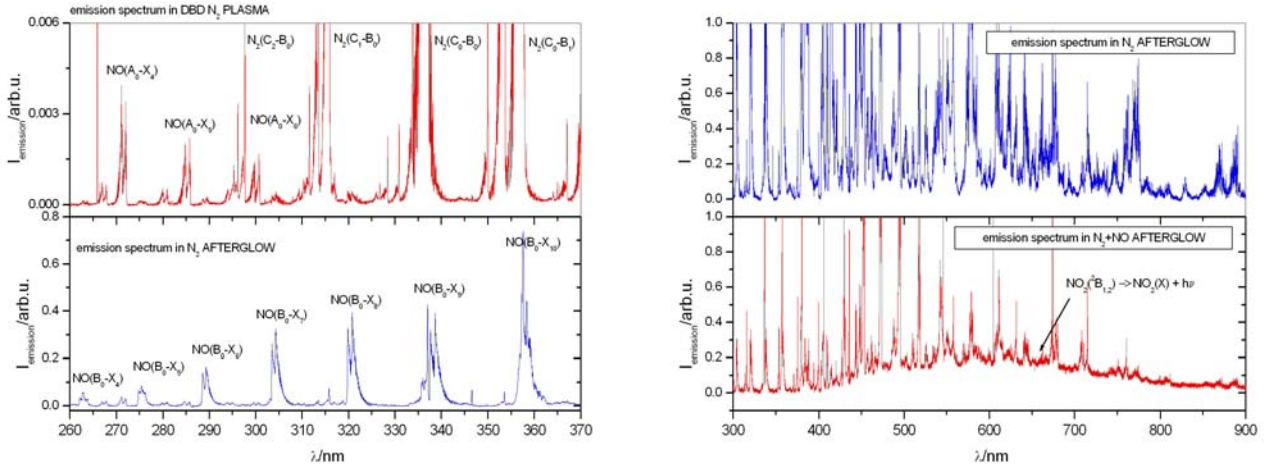

Figure 2.
Left panel: UV-emission spectrum in an N_2 DBD with traces of O_2(red) and its afterglow (blue) at a distance of 10 cm from plasma zone. The flow rate is 40 l_n/min.
Right panel: VIS-emission spectrum in the N_2 afterglow (blue) and in N_2 afterglow in presence of NO(100 ppm) (red).

If the concentration of injected nitrogen atoms is less than the NO concentration, oxygen atoms produced according to (2) will react with NO to form NO_2 in an excited state:

$$O + NO \rightarrow NO_2^* \rightarrow NO_2 + h\nu, \qquad k^{300K} = 8.9x10^{-32}\ cm^6s^{-1}$$

The broad continuum emission in the visible (Figure 2, Right panel) is caused by the decay of excited NO_2 molecules.

When the concentration of nitrogen atoms is larger than the NO concentration, NO is also formed again according to the reaction (3). If the concentration of N-atoms is equal to that of NO, all NO molecules can be consumed and only molecular oxygen will be formed at the end as a product of recombination of oxygen atoms.

The time for transportation of N-atoms into the exhaust gas must be short compared to its lifetime. Nitrogen atoms are consumed in the recombination reaction.

$$N + N \rightarrow N_2 \qquad k^{300K} = 1.3x10^{-32}\ cm^6s^{-1} \qquad (4)$$

Recombination of N-atoms in the afterglow (4) produces mostly $N_2(A)$. The presence of $N_2(A)$ in the exhaust can cause formation of N_2O according to reaction (1).

3.3 Treatment of exhaust gases by injection of hydrazine

A DBD of Ar/NH_3 or N_2/NH_3 can produce NH_2 radicals, which can be used for efficient reduction of NO according to the reaction

$$NH_2 + NO \rightarrow N_2 + H_2O, \qquad k^{300K} = 1.69x10^{-11}\ cm^3s^{-1}.$$

However, at atmospheric pressure, the NH_2 lifetime is short (about a few microseconds) and the final products of ammonia decomposition in a DBD are hydrazine (N_2H_4), N_2 and H_2 [5].

Hydrazine may be decomposed at high temperatures back into NH_2 due to the surface and gas-phase reactions in the exhaust. NH and NH_2 radicals can be also produced by thermal decomposition of ammonia. According to our experiments, ammonia decomposition requires temperatures above 600 ºC and 800 ºC in the heated stainless steel reactor and quartz reactor, respectively. The walls of the stainless steel reactor play the role of a catalyst. Therefore hydrazine decomposition was investigated in the quartz reactor in order to reduce the catalytic effect on the walls. Nitrogen was passed through a hydrazine hydrate, and thus hydrazine vapors were introduced into the quartz reactor where they were mixed with the exhaust gas. It was found that thermal decomposition of hydrazine requires temperature around 300°C. The presence of oxygen accelerates the hydrazine decomposition, but does not reduce NO, Figure 3 (Left panel). It is noted that the UV-absorption spectrum of hydrazine decomposition products is the same as UV-absorption spectrum of ammonia, Figure 3 (Left panel, orange and black lines, respectively) and that the NO reduction starts only at temperatures above 500°C (green line). These observations are in an agreement with previous works [8-10]. If methane is also present in the mixture, NO decomposition becomes more efficient at temperatures around 700°C, Figure 3 (Right panel, red line). However, a complete NO reduction could not be achieved, Figure 3 (Right panel, black line).

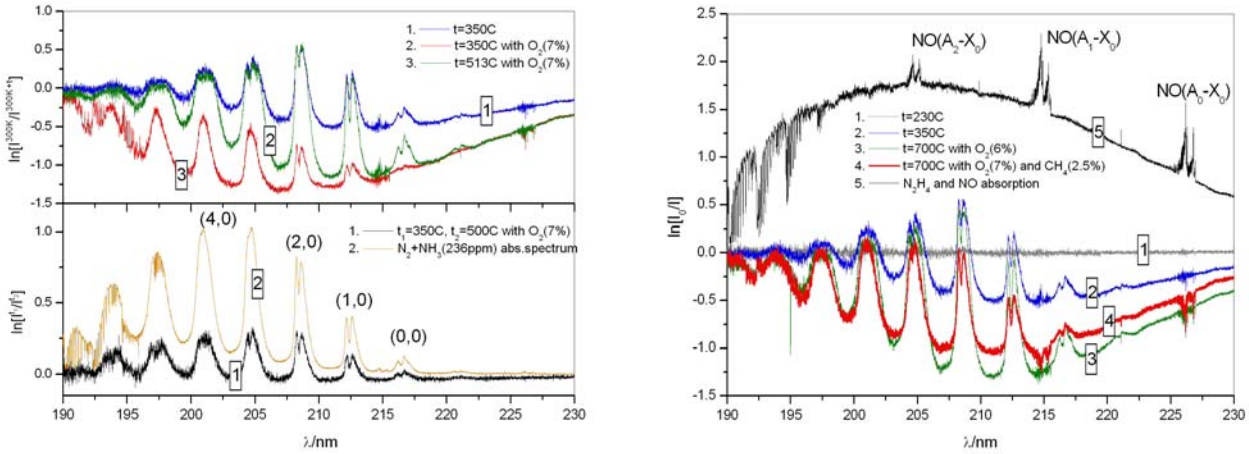

Figure 3.

Left panel: UV-absorption spectra in $N_2/N_2H_4/NO$(190 ppm)(blue) and $N_2/N_2H_4/O_2(7\%)/NO$(180 ppm)(green, red) mixtures at various temperatures in the oven (350°C and 513°C); UV-absorption spectrum of NH_3(orange) and UV-absorption spectrum in $N_2/N_2H_4/O_2(7\%)/NO$(180 ppm) mixture at 500°C with reference spectrum measured at 350°C (black).

Right panel: UV-absorption spectra in $N_2/N_2H_4/NO$(190 ppm)(gray, blue), $N_2/N_2H_4/O_2(6\%)/NO$(190 ppm)(green) and $N_2/N_2H_4/CH_4(2.5\%)/O_2(7\%)/NO$(170 ppm)(red) at various temperatures in the oven. A reference absorption spectrum corresponding to UV-absorption of NO (190 ppm) and N_2H_4 is also shown (black).

3.4 Injection of ozone generated in a plasma

A DBD operated in an oxygen containing gas can serve as ozone generator. Ozone has a typical decay time of 20 minutes at room temperature and therefore it can be easily produced in a cooled DBD and transported into the exhaust. Ozone initiates oxidation of NO to N_2O_5:

$$\begin{aligned} NO + O_3 &\rightarrow NO_2 + O_2, & k^{300K} &= 1.8\text{x}10^{-14}\ cm^3s^{-1} \\ NO_2 + O_3 &\rightarrow O_2 + NO_3, & k^{300K} &= 3.7\text{x}10^{-17}\ cm^3s^{-1} \qquad (5) \\ NO_3 + NO_2 &\rightarrow N_2O_5, & k^{300K} &= 2.1\text{x}10^{-30}\ cm^6s^{-1} \end{aligned}$$

The N_2O_5 can be efficiently trapped by water in a scrubber or bubbler system:

$$N_2O_5(g) + H_2O(aq) \rightarrow 2HNO_3(aq),$$

Oxidation of NO_2 to NO_3 takes typically a few seconds, whereas all other reactions occur fast. Thus a relatively long residence time of the exhaust gases is needed in the reaction volume where NO oxidation takes place.

The other limitation is due to a temperature effect. Exhaust gases usually have high temperatures (> 300°C) which are sufficient for thermal decomposition of ozone. Ozone decomposition leads to inhibition of the NO_x reduction and to formation of N_2O:

$$\begin{aligned} O_3 &\rightarrow O + O_2, & k^{600K} &= 5.6\text{x}10^{-18}\ cm^3s^{-1} \\ O + N_2 &\rightarrow N_2O, & k^{300...568K} &= 5.0\text{x}10^{-38}\ cm^6s^{-1} \end{aligned}$$

Moreover, at high temperatures thermal decomposition of N_2O_5 and NO_3 to NO_2 and NO starts. Therefore low temperatures (< 200°C) of exhaust gases are needed for the NO reduction process.

If ozone is produced from air, N_2O is formed according to reactions (1, 1a) and cannot be trapped by scrubber or bubbler system. The use of pure oxygen overcomes this problem.

We investigated ozone oxidation of $NO \rightarrow NO_2 \rightarrow NO_3 \rightarrow N_2O_5$ and subsequent removal of N_2O_5 by a bubbler system. Ozone produced in an O_2 DBD was injected in the exhaust chamber where the oxidation took place. When the ozone concentration is too low for a complete oxidation of NO to N_2O_5, intermediates will remain in the exhaust, Figure 4 (Left panel, black line). On the other hand, if O_3 concentration exceeds the amount needed, the N_2O_5 and unused O_3 will be detected after NO oxidation, Figure 4 (Left panel, red line). Due to N_2 impurities in O_2 DBD plasma faint admixture of N_2O can be also observed. The bubbler system will remove completely N_2O_5 and mostly all O_3, Figure 4 (Left panel, blue line).

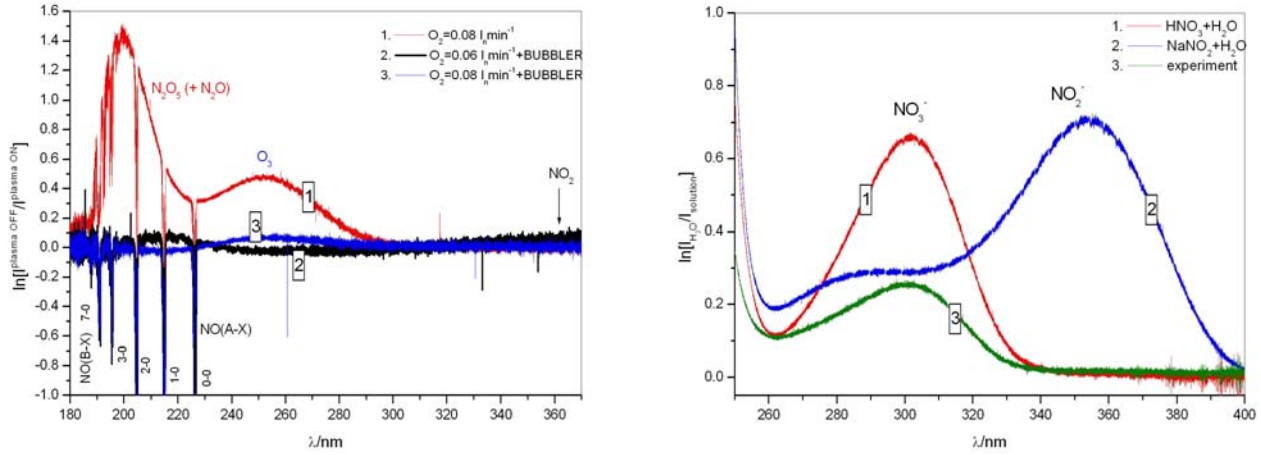

Figure 4

Left panel: UV-absorption spectra in the $O_3/N_2/O_2(6\%)/NO(470\ ppm)$ mixtures at various ozone concentrations with and without bubbler.

Right panel: UV-absorption spectra of aqueous solutions of nitrite (NO_2^-)(blue) and nitrate (NO_3^-)(red) ions in comparison with the UV-absorption spectrum of the water from the bubbler after ozone treatment of a $N_2/O_2(6\%)/NO(470\ ppm)$ mixture (green).

The UV-absorption spectra of water from the bubbler clearly show absorption at 300 nm indicating the presence of NO_3^- ions (HNO_3) in water solution and no absorption at 360 nm indicating absence of NO_2^- ions (nitrous acid, HNO_2). Nitrous acid can be formed in the net reaction [11]

$$2NO_2 + H_2O \rightarrow HNO_3 + HNO_2,$$

However HNO_2 reacts with NO_3 to form HNO_3

$$HNO_2 + NO_3 \rightarrow HNO_3 + NO_2, \qquad k^{300K} < 2x10^{-15}\ cm^3s^{-1}$$

4. Summary and conclusions

Different plasma-assisted techniques for NO_x-reduction, namely: direct treatment of exhaust gases by plasma, injection of N atoms and injection of (stable) reactive species (N_2H_4, O_3) into the exhaust gas have been considered.

- Direct treatment of exhaust gases by plasma oxidizes NO to NO_2 and later to N_2O_5. However, the presence of UHC in exhaust makes the process more complicated and lead to a production of undesirable hydrocarbons and cyanogens whose negative impact into the environment is known. The use of a catalyst in combination with direct treatment will improve the situation, but will increase the costs. Moreover, this method has low selectivity, because a lot of energy is consumed by other processes.
- Injection of N-atoms increases the selectivity in NO reduction. However, high N_2 consumption due to the short lifetime of N-atoms and a possible formation of N_2O makes this technique impractical.
- Hydrazine produced in DBD can be used for reduction of NO in hot exhaust gases. However, the products of thermal N_2H_4 decomposition are NH_3, H_2 and N_2. Therefore, this method is close to the Thermal $DeNO_x$ process which advantages and disadvantages are well established.
- Ozone treatment of exhaust gases seems to be the most promising way for NO reduction. It has a high selectivity for NO reduction, but the oxidation process requires a relatively long reaction time (a few seconds). This limits its applicability when exhaust gases with high flow rates need to be treated. Low reaction temperatures for NO oxidation and oxygen consumption can also be limiting factors for economically reasonable applications.

Abstract

The oxidative conversion of secondary amines to nitrones has been investigated on novel plasma-processed catalytic active membranes. Sodium tungstate, the catalyst, has been immobilized on plasma treated Polyvinylidenefluoride (PVDF) membranes. In particular, the membranes have been modified by means of Ar plasma pre-treatment followed by an NH_3 plasma treatment to produce a surface rich of amino functionalities, active sites for a stable chemical immobilization of the catalyst. Very promising results have been obtained in terms of amine-nitrone conversion in catalytic membrane reactors (CRMs) equipped with the plasma modified PVDF membranes.

Introduction

Low temperature plasma modification techniques appear very attractive in several scientific fields to modify in a controlled way surface chemistry and properties of a wide range of materials [1-5]. Main advantages of plasma techniques are the possibility of modifying only the few topmost layers of materials leaving the bulk totally unaltered, the possibility of functionalization, the negligible environmental impact, and the versatility for industrial processes and substrates. In particular, among plasma techniques, plasma grafting allows to produce surfaces characterized by a tuneable density of functional groups (i.e. –COH; OH; NH_2, etc.) [6-8] which can be conveniently used for the immobilization of various molecules. The grafting process of N-containing groups in NH_3-based RF glow discharge has been described in refs. [7, 8].

The entrapment of homogeneous catalysts in polymer membranes by means of "Van der Waals wrapping" is a rather easy way to heterogenise the catalyst obtaining, in some cases, results comparable to the analogue homogeneous systems [9-13]. However, the absence of strong interaction forces between the complexes and the polymer could represent a failure of this method; in particular, with low molecular weight homogeneous catalysts like sodium tungstate, leaching represents a major lack of the technique. This problem may be avoided by the generation of a stable chemical bond (covalent, ionic, coordinative) between the catalyst and the membrane surface.

In this work we report on the immobilization of sodium tungstate on plasma treated PVDF flat membranes prepared via the inversion phase technique. Modified membranes have been used in CRMs to activate H_2O_2 for the synthesis of nitrones from secondary amines.

Nitrones are versatile synthetic intermediates for the synthesis of heterocycles and natural products and can be synthesized by oxidation of secondary amines or the corresponding hydroxylamines. Enzymes are involved in the metabolic oxidation of amines: mitochondrial monoamine oxidases transforms secondary amines to imines; flavin monooxygenase oxidizes secondary amines to nitrones via hydroxylamines [14,15]. Therefore, the simulation of the activity of such oxidation enzymes, using metal complexes immobilized in polymeric membranes provides mimetic method for catalytic oxidation of amines.

Very promising results have been obtained, in this work, in terms of amine-nitrone conversion in CRMs employing plasma modified membranes loaded with sodium tungstate in presence of H_2O_2. No reaction occurred when plasma modified membranes, not loaded with catalyst, have been employed.

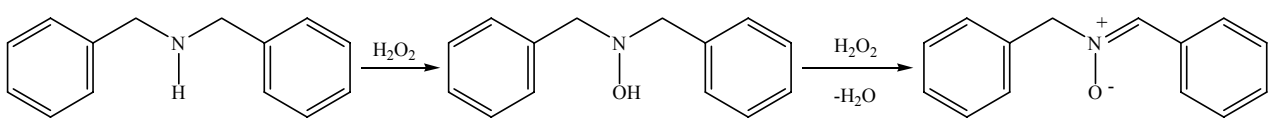
Results and discussion

Flat PVDF membranes have been first plasma treated in a RF (13.56 MHz) glow discharge fed with Ar (20 sccm, 800 mTorr of pressure, 30 W, 1 min), in order to cross-link the surface of the substrate by means of CASING (Cross-linking of Activated Species by Inert Gases) process [16]. The cross-linked top most surface layer becomes much more stable to accommodate the N-groups to be grafted in the following plasma process, and much less sensible to restructuring ageing processes of the fluorinated substrate. This process provided a surface much less prone to ageing. Such approach has been successfully followed for obtaining a permanently wettable polytetrafluoroethylene surface [6] in NH_3 glow discharges. Ar treated membranes have been then plasma treated in a NH_3 RF glow discharge (20 sccm, 800 mTorr of pressure, 20 W, 5 min) to graft N-containing groups grafted on a stable surface. Plasma treatments have been performed in a tubular glass pyrex RF plasma reactor, with internal steel electrodes, in the parallel plate configuration. The chemical composition of modified and native PVDF membranes was determined by X-ray photoelectron spectroscopy (XPS) and Water Contact Angle (WCA) analysis. XPS analysis were performed using a PHI ESCA 5300 spectrometer equipped with non-monochromatic MgK_α rays (1253.6 eV, 300 W). Evidence of the immobilization of the W-based catalysts on plasma treated surfaces (PVDF/Ar/NH3/sodium tungstate) have been obtained via XPS performed after each modification step. Ar pre-treatments caused a severe defluorination of the surface evidenced in the C1s spectrum by a strong reduction of the CF_2 peak component at 294,3 eV and confirmed by the F1s/C1s elemental ratio which decreases drastically from 0.92 to 0.38, attesting a massive fluorine loss.

Soon after the treatment modified PVDF membranes have been immersed in acid solutions of sodium tungstate to allow a chemical interaction between the acid catalyst and the basic sites grafted at the plasma modified membrane.

After sodium tungstate immobilization the presence of W4f peak, in XPS spectra, appeared (C: 61,4%, 13,2%, W4f: 2,9, F: 17,5%, N: 5,0 %). Ageing of modified membranes has been measured over a long period and cross-linking of membranes with Ar appears an effective way to reduce ageing of ammonia treated membranes. The immobilization of sodium tungstate affected also the WCA values. A reduction from 93 ± 2 (unmodified membrane) to 72 ± 2 (PVDF/Ar/NH3) to 64 ± 2 (PVDF/Ar/NH3/sodium tungstate) was recorded.

Catalyst modified membranes have been employed in CRMs and the conversion of dibenzylamine to nitrones has been observed trough the formation of N, N-Dibenzyl hydroxylamine, a reaction intermediate according to the scheme 1.



Scheme 1. Conversion of dibenzylamine to nitrones in presence of H_2O_2, trough the formation of N, N-Dibenzyl hydroxylamine

Stable chemical immobilization of sodium tungstate has been achieved on plasma treated PVDF membranes and this represents a novel efficient catalytically active system for the oxidation of secondary amines. The catalytic membranes have been tested in the experimental apparatus schematically shown in figure 1. Both permeate and retentate have been recyrculated in the system in order to increase the contact time between the unreacted reagent and the catalytic membrane surface. UV-Vis measurements confirmed no leaching of the W-based catalyst confirming that a stable chemical bond occurred trough the basic active sites of the membrane and the catalyst.

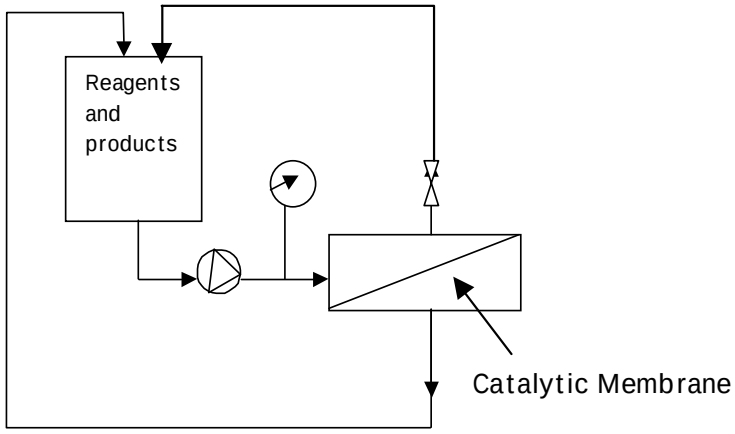


Figure 1-Scheme of the catalytic membrane reactor

The conversion % from dibenzylamine to nitrone and the selectivity of the reaction to nitrone with respect to N, N-Dibenzyl hydroxylamine are shown in Figure 2. Data obtained at 0 and 1 bar of transmembrane pressure in the CRM are reported when plasma modified catalytic PVDF membranes are used. The system efficiently catalyses the oxidation affording the nitrone in good yields (70%) operating at transmembrane $\Delta P=0$ bar in reasonable reaction times, almost comparable to the ones of the homogeneous system [17]. At $\Delta P=1$ the reagent conversion decreased to 60% while the selectivity trend remains almost unvaried.

Future studies will address aspects related to the contact time between the reagent and the catalyst immobilized at the membrane surface. A deeper surface characterization of the plasma modified membranes is also in progress, with the aim of optimizing the combined plasma process and improve the immobilization reaction.

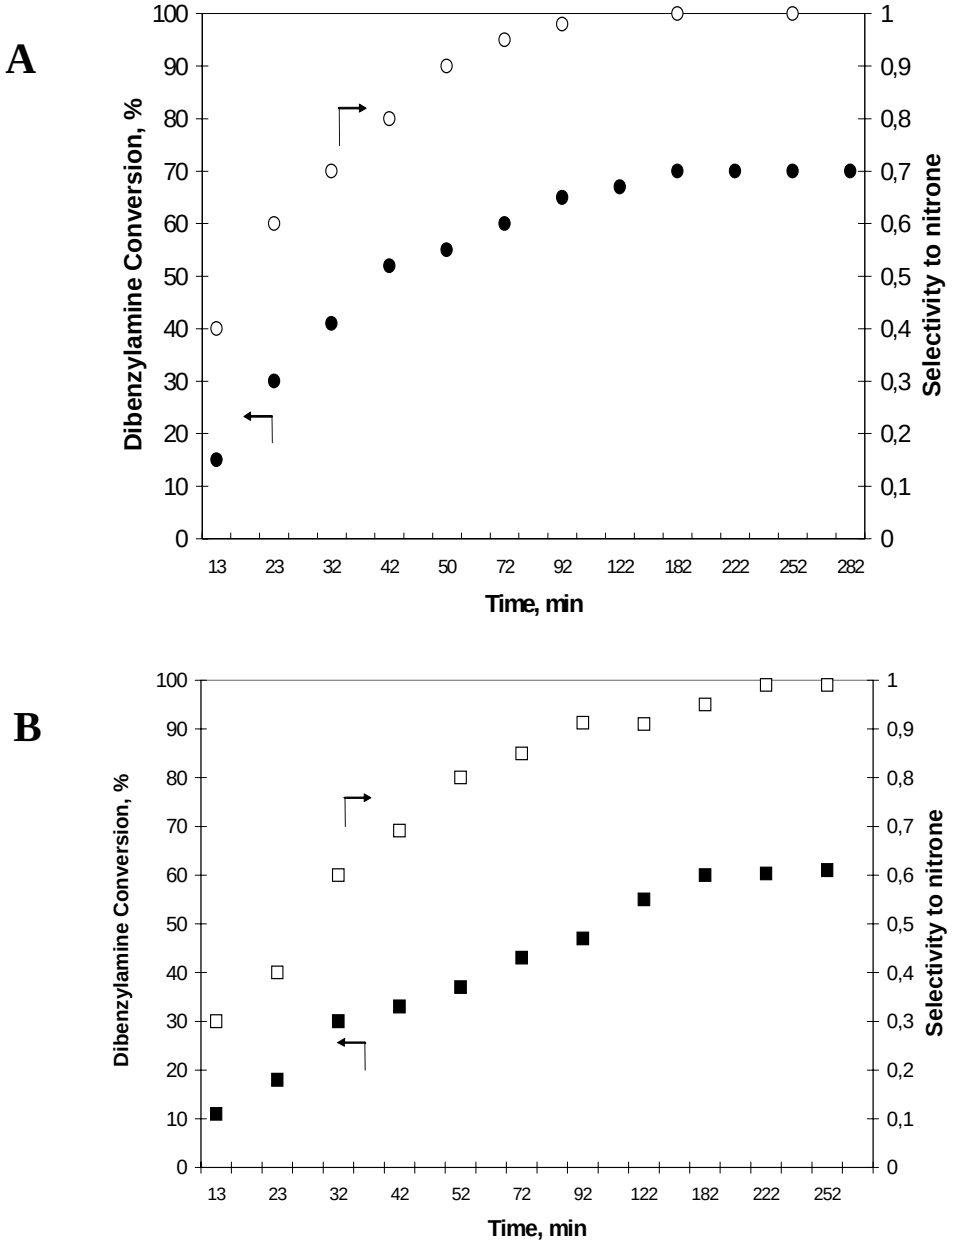

Figure 2 Dibenzylamine conversion % and selectivity to nitrone vs. time at two different transmembrane pressures: (**A**) ΔP=0; (**B**) ΔP=1 bar

.

Conclusions

In this work we have reported for the first time, at the authors knowledge, about the surface immobilization (heterogeneization) of a W-based catalyst on N-grafted PVDF membranes for CRMs. Polymeric catalytic membranes consisting of Na_2WO_4 immobilized on plasma functionalised PVDF are active systems for the oxidation of dibenzylamine to nitrone. The reactivity screening allowed us to select modified PVDF catalytic membrane as the best system in terms of dibenzylamine conversion (operating at low transmembrane pressures) and selectivity to nitrone and exclude the occurrence of competing homogeneous pathways.

VOC Destruction in Atmospheric Pressure Plasma Discharge

H.Grossmannová, F. Krčma, K. Slánská

Faculty of Chemistry, Brno University of Technology, Purkyňova 118, 612 00 Brno, Czech Republic

Abstract
This work is focused on the studies of gliding arc discharge with respect to its use in the decomposition of volatile organic compounds (VOC). The products of decomposition were sampled by Solid Phase Microextraction, which is an innovative, solvent free and economical sampling technique, and analyzed by Gas Chromatography linked to Mass Spectroscopy (GC-MS). During our work, we tried to check up appropriateness of the SPME technique for the destruction products analyzes. The Carbowax/divinylbenzene coated SPME fiber was founded as the best for detection of the highest number of discharge products.

Keywords
Solid Phase Microextraction (SPME), Volatile organic compounds (VOC), atmospheric plasma discharge, gliding arc discharge.

Introduction

The gliding arc reactor is a widely exploited plasma source in many industrial chemical applications, because it is a simple and inexpensive way to generate the non-thermal plasma [1, 2]. The high energy efficiency, reaction selectivity or production of specific species may be achieved in this kind of plasma, and thus for various chemical processes it can be much more effective then in common technologies [3]. The excitation energy can be transported to specific molecules in the reacting gas mixture. Recent studies showed that the reaction stimulation efficiency by the gliding arc discharge plasma is very high [1]. This plasma can be applied in many industrial branches, especially in the surface treatment [4]. One of the applications that are at present widely studied is the emission control of Volatile Organic Compounds (VOC) in the combustion exhaust gas (so called exhaust treatment [5]). Various non-thermal discharge kinds (DC and AC corona discharge or Gliding Arc) were used in several studies on dilute air-pollution control [6]. In these experiments, various aliphatic and aromatic pollutants were presented in order of several hundreds of volume ppm [6].
The in-situ gas chromatography with a simple detector (usually a flame detector) or the active coal sorption tubes were used for the discharge exhaust gas analysis. These techniques have a serious disadvantage in their limited selectivity. The chromatograms contain many different peaks. Their identification is not easy then a flame detector is installed. The use of mass spectrometer as a detector (GC-MS) is more sensitive and selective, and thus many discharge products can be clearly identified even from a complicated exhaust gas mixture. The Solid Phase Microextraction (SPME) technique is a relatively new method (used since 1996) for a sampling Gas Chromatography analysis. It is a very sensitive method for the higher molecular products and it offers a partial selectivity for some kinds of molecules depending on the extraction fiber solid coating (see below). This work is focused on the SPME technique suitability for the discharge exhaust gas analyses.

Experiment

Gliding arc discharge combines the advantages of the thermal and the non-equilibrium plasmas. Most of the plasma in Glidarc exit in the non-equilibrium condition (80%) [2]. The experimental device is schematically shown in Fig. 1. The reactor consists of a single pair of diverging knife-shaped copper electrodes (thickness 1 mm, size 60 mm x 40 mm each), whose minimal distance is 0.6 mm. A pair of ceramic plates was used to limit a gas flow into the active discharge for a higher efficiency of the selected VOCs decomposition. The carrier gas did not scatter the whole reactor area, but the maximum of it was passing through the discharge and the decomposition could be more efficient as it was presented recently [7]. Gliding arc discharge was created in various gas mixtures of nitrogen, oxygen, and argon at the atmospheric pressure. The carrier gas passes through

the mass flow controller and mixes just before entering the reactor with an auxiliary nitrogen flow enriched by toluene or cyclohexane, which were chosen as the model VOCs. The total gas mixture flow rate was typically 1000–1300 ml·min^{-1}. The applied DC voltage was from 3.5 kV up to 4 kV with the discharge current of 35 mA. The exhaust gas leaves the reactor through a special device arranged for the sampling by Solid Phase Microextraction (see Fig. 2).

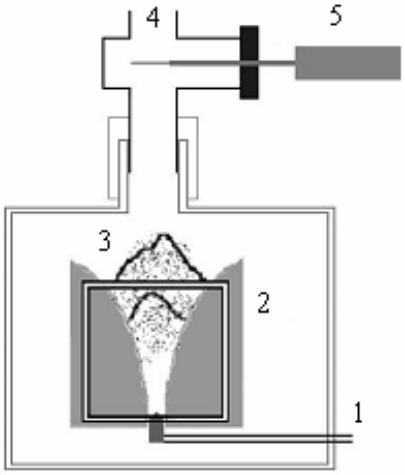

Fig. 2: Discharge reactor: 1 – gases input, 2 – electrodes, 3 – discharge area, 4 – product outlet, 5 – sample collection by SPME.

SPME technique

The solid-phase microextraction is a solvent-free equilibrium extraction method which, with the due calibration, can allow also the quantitative determinations of organic compounds. The sensitivity is very good and usually reaches up to low-to-mid parts per trillion [8] without the use of any organic solvents not only at sampling, but also during the analysis. This technique uses a short thin solid rod of fused silica, coated with a polymeric absorbent for the extraction of volatile compounds. The fiber coating removes the compounds from the gas or liquid sample by absorption or adsorption. The whole analysis using the SPME sampling technique requires only 30 minutes for the sample preparation and analytical separations. It can be easily automated and it is ideally suited for use in the terrain. Although the method was originally developed for the analysis of water samples, now SPME has gained a wide spread acceptance as the technique of preference for many applications including flavours and fragrances, forensics and toxicology, environmental and biological matrices, and product testing, to name a few [9].

The principle of SPME is an equilibrium partitioning of the analyte between the coating fiber and the solution or the headspace. The extraction should be carried out by two methods: direct sampling (the fiber is plunged in the liquid sample) or headspace (sample is collected above the liquid sample from the gas; it is better for volatile compounds). The absorbed (in the case of liquid coatings) or adsorbed (in the case of solid coatings) compounds in (at) the fiber coating are in the thermodynamic equilibrium with the same compounds in the sample [9]. After the extraction, the SPME fiber is inserted directly into the Gas Chromatograph for desorption and analysis.

For the quantitative analysis, it is very important to explore the dependence of the analyte mass in the fiber as a function of the extraction time (see Fig. 3). It is clear the selection of an appropriate SPME fiber is a very important task for obtaining optimal results. There are many important factors which should be considered: polarity of the analyte, volatility and molecular size and shape of the analyte, the effects of analyte size on SPME fibers, capacity of SPME fiber, minimum detection limits or fiber extraction mechanism. Polar analytes are attracted to polar phases (e.g., polyacrylate and Carbowax coatings). Fibers with a thicker coating film (100μm) are better volatile liquids, but also can be used for semi-volatile compound when longer extraction times are recommended.

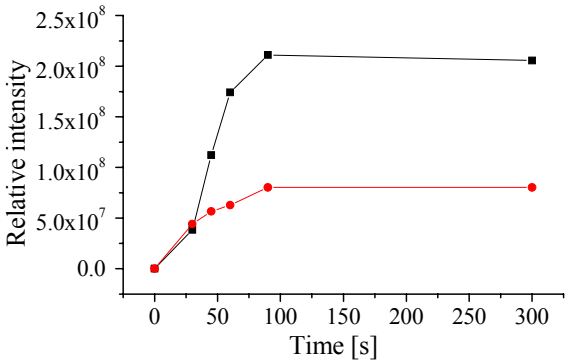

Fig. 3: Time dependence of the relative intensities of cyclohexane and toluene using the sampling by Carbowax/ divinylbenzene SPME fiber.

Porous fibers (Carboxen or divinylbenzene coating) can also retain small analytes as C2 – C6. Thinner coating films (7µm and 30µm polydimethylsiloxane - PDMS) are better for larger molecules. To collect volatile analytes, the Carboxen/ polydimethylsiloxane (CAR/PDMS) fiber is ideal for the extraction of volatile compounds. Adsorption type fibers are also better for extracting analytes presented in low concentrations. The sample heating slightly increases the volatility of the analytes. To ensure reproducibility, the sample must be stabilized at the extraction temperature before inserting the fiber and starting the sample extraction. The absorptive fiber coatings such as PDMS or polyacrylate are recommended for the extraction of semi-volatile compounds in the headspace. Even analytes with high boiling points can be extracted from the headspace, if they have sufficient vapor pressure. Excessive headspace volume reduces the analyte concentration in the headspace and reduces the extraction efficiency [9].

Results

Tree different types of SPME fibers were used for the experiments, namely polydimethylsiloxane (PDMS), Carboxen/polydimethylsiloxane/divinylbenzene (CAR/PDMS/DVB), Carbowax/divinylbenzene (CW/DVB). The toluene and cyclohexane were used as VOC samples for the selection of an appropriate fiber coating for the discharge product analyses.

Fig. 4 shows the chromatographic spectra of toluene destruction products extracted using all three tested SPME fibers. Besides the traces of various compounds generated from the fiber material, the real discharge products were identified. The most abundant higher molecular products of the toluene destruction in the nitrogen – oxygen gas mixture are shown in Table 1.

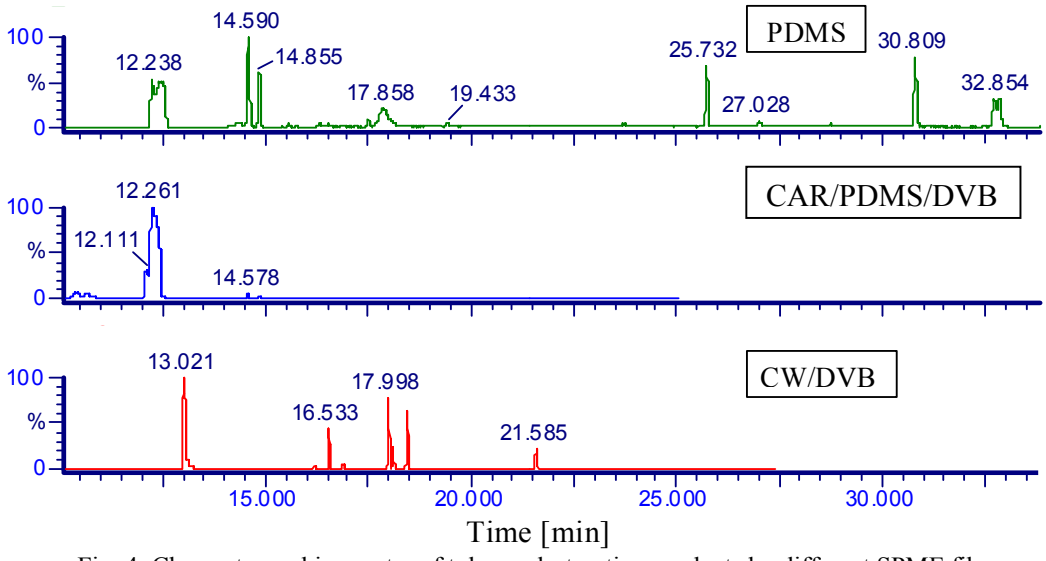

Fig. 4: Chromatographic spectra of toluene destruction products by different SPME fibers.

CW/DVB	PDMS	CAR/PDMS/DVB
toluene	toluene	toluene
methylbenzene	trimethylsilanol (fiber)	2,3-dihydrofuranone
phenol	2,3-dihydrofuranone	benzaldehyde
benzaldehyde	octamethylcyclotetrasiloxane (fiber)	benzenemethanol
benzenemethanol	Benzaldehyde	--------
4-methylphenol	2,4-dimethylimidazol	--------
4-(phenylmethoxy)benzaldehyde	--------	--------
2-methylphenol	--------	--------

Tab. 1: Analysis of toluene destruction products.

Fig. 5 presents the chromatographic spectra of cyclohexane destruction products extracted by the CAR/PDMS and CW/DVB SPME fibers. In the case of PDMS fiber, only cyclohexane and compounds released form fiber material or chromatographic column were observed and thus this spectrum is not presented. The main high molecular products of cyclohexane decomposition are presented in Table 2.

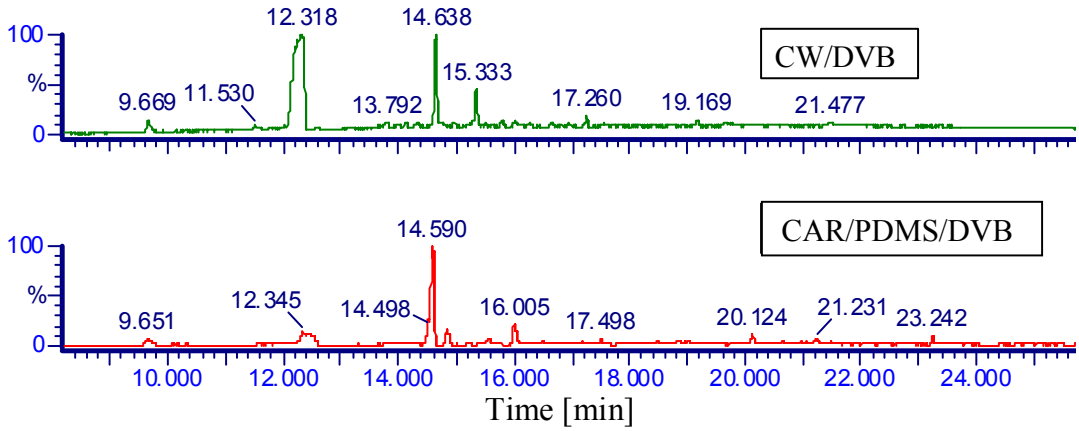

Fig. 5: Chromatographic spectra of cyclohexane destruction products extracted by different SPME fibers.

CW/DVB	CW/DVB	CAR/PDMS/DVB
cyclohexane	2,4-dimethylpentane-3-one	cyclohexane
cyclopenta-1,2-diol	3-methylbutan-2-ol	2,3-dihydrofuranone
benzaldehyde	4-methylcyclohexa-2-en-1-ol	2-ethylhexan-1-ol
heptanale	3-undecene-1-yne	4-phenoxybutanoic acid
2,4-dihydrofuran-2-one	4-decen	2-phenoxyethanol
2-methylcyklohexanol	-------	phenol acetate
2,3-dihydrofuranone	-------	benzenemethanol
3,5-dimethylhexan-3-ol	-------	tetradecane

Tab. 2: Identified cyclohexane destruction products.

These results show that the fiber coated by CW/DVB can extract the highest number of destruction products, the CAR/PDMS coating can be used for the extraction of some other compounds such as phenol acetate or benzenemethanol (C_2 – C_{12} carbons), and the PDMS coating could not be applied for the discharge exhaust gas analysis.

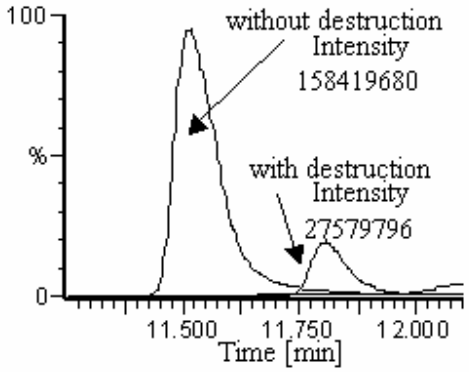

Fig. 6: Chromatographic peak of toluene destruction by CW/DVB SPME fiber.

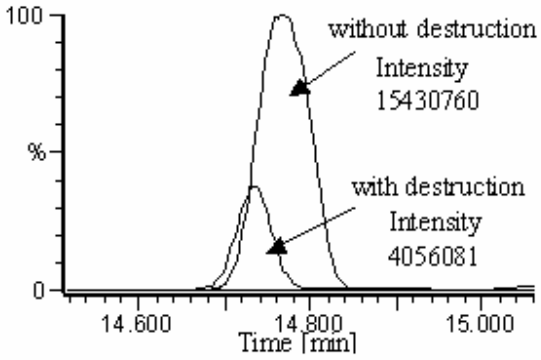

Fig. 7: Chromatographic peak of cyclohexane destruction by CW/DVB SPME fiber.

The total destruction efficiency was studied at the initial concentration of VOC in the range of 100 – 300 $\mu g \cdot l^{-1}$ in the ambient air as a carrier gas. The chromatographic peaks of both studied VOC represents are shown in Figs. 6 and 7. The highest destruction efficiency under the optimal conditions (the power supply of 3,5 kV) was 86 % for toluene and 79 % for cyclohexane.

The destruction efficiency depends of course on the reacting gas mixture composition. The influence of the oxygen and argon admixture in the carrier air based gas mixture was studied in conditions when the best decomposition in ambient air was observed. The increase of the oxygen content in the gas mixture plays a relatively small role, the destruction efficiency increases only by about 20 % when the oxygen content is increased from 20 % up to 60 % (see Fig. 8). The role of the argon admixture is negative because the argon adding rapidly decreases the efficiency down to 8 % at about 12.5 % of argon in the gas mixture [7].

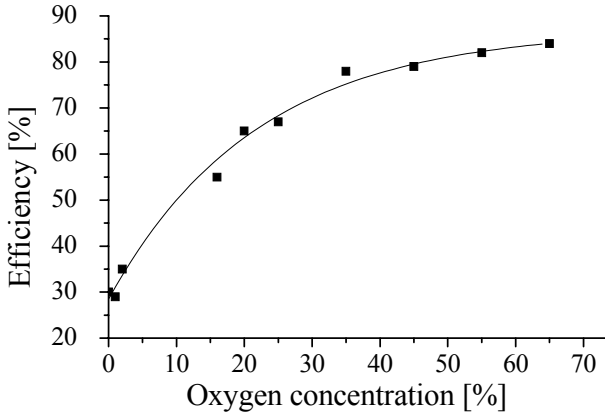

Fig. 8: Dependence of toluene decomposition on the oxygen concentration in nitrogen carrying gas.

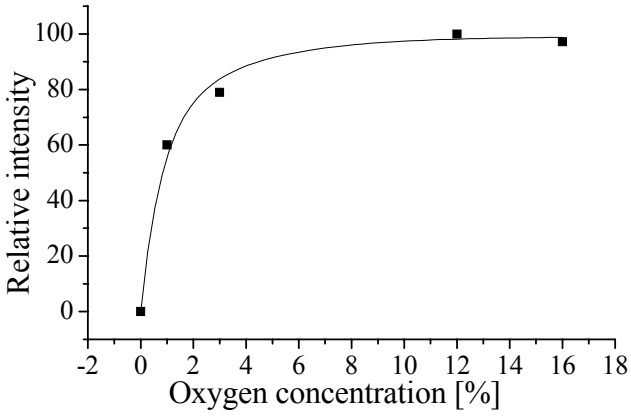

Fig. 9: Dependence of the benzaldehyde concentration on the oxygen concentration in nitrogen carrying gas (the maximum value was chosen as a reference).

The concentrations of various extracted compounds are also dependent on the gas mixture composition. The dependence of benzaldehyde was chosen as an example. Fig. 9 demonstrates the significant production of this compound even in oxygen pure gas mixture (about 3 % only) and it is not too dependent on further increase of oxygen presence. On the other hand, the concentration of benzene decreses with the increase of oxygen presence. The exact study of these dependencies for more or less all discharge products will be the subject of further studies that will be extended by the measuring of the carbon conversion into its inorganic form.

Conclusion

The presented work gives the first results about applicability of the Solid Phase Microextraction in the analysis of Volatile Organic Compounds destruction in the non-thermal plasma. Using this technique, better results can be obtained in comparison with the classical Solid Phase Extraction (sorption tubes with an active coal). Three different SPME sorption fibers were tested, the Carbowax/divinylbenzene coated fiber was found as sensitive to main part of discharge products, the Carboxen/polydimethylsiloxane can be used as an additional extraction medium. On the other hand, the polydimethylsiloxane fibers cannot be used for the discharge exhaust gas analyses due to their negligible sensitivity to products. The analysis using Carbowax/divinylbenzene fibers showed that the total destruction efficiency of toluene and cyclohexane reach up to 86 %, resp. 79 %. Many different higher molecular weight products were analyzed by the GC-MS analysis. Their concentrations as well as the total destruction efficiency are dependent on the discharge conditions, mainly on the oxygen content. The destruction is more effective than oxygen presence in the carrying gas mixture increases and concentrations of the more oxidized products increases, too.

The following experiments will be focused on the estimation of concentration dependencies for more or less all discharge products on the discharge conditions. The organic carbon conversion measurements with CH-meter and low molecular products analysis will be completed, too.

The Parameters and Conditions of Appearance of Branching Streamer

A.V. Krasnochub, M.M. Nudnova, A.Yu. Starikovskii.
Physics of Nonequilibrium Systems Laboratory (NEQ-Lab),
Moscow Institute of Physics and Technology, Dolgoprudnyi, Russia, krasnochub@neq.mipt.ru

Abstract
In this paper the experimental results of research of a branching streamer discharge in an mixture (N_2:O_2 4:1) both cathode-directed and anode-directed streamer in plane – plane gap at 26 – 42 kV and pressure 300 - 1200 torr are shown. Experimental data are supplemented with results of numerical modeling of solitary cathode-directed streamer. The method of measuring of electro-dynamical diameter of the streamer's head is offered. The pattern of radiation of the streamer's head is observationally restored.

1. Introduction

Plasma of pulsed discharges is widely used in different applications [1] - from radiation sources to plasma chemical reactors - due to the main advantage in comparison with stationary and quasistationary discharges, namely - minimal rate of thermal heat. This leads to a high efficiency of the energy input to the channels with high energy thresholds [2]. Another important characteristic of plasma generator is a large bulk which could be filled with of plasma. The branching streamer gives such possibility. The comprehension of mechanism of branching and knowledge of parameters and conditions which influence on bifurcation of streamer allow us to predict optimal characteristics of plasma chemical reactors.
The aim of the paper is the investigation of conditions of appearance of branches both for cathode and anode streamer.

2. Experimental setup.

On fig. 1 the block scheme of the experimental installation is shown. Investigations were carried out in cubic discharge chamber with an edge of 220 mm. The construction of the chamber allowed us to carry out investigation both at the reduced (300 torr) and at increased (1200 torr) pressure. In the present research we analyzed distribution of a streamer in synthetic air (mixture N_2:O_2 4:1) in a plane - plane gap with distance between electrode of 30 mm. During experiment we controlled electro-dynamical and optical parameters of a streamer. Optical diagnostics was carried out through windows with diameter of 100 mm, made of quartz QU-1. The high-voltage electrode is made of brass as a disk with diameter of 80 mm, the earthed electrode is made of an aluminum disk with diameter of 100 mm. For initiation of streamer at the centre of the earthed electrode is set a needle with diameter of 0.8 mm, with height of 8 mm. Current of streamer's flash was measured by means of the current shunt which was built in between a needle and the earthed electrode.

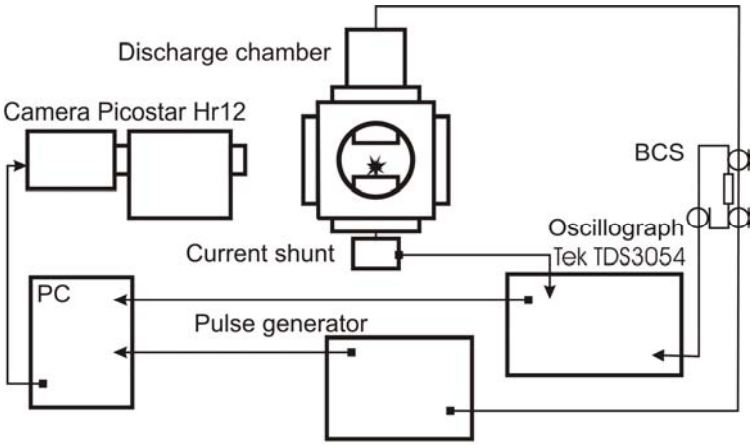

Fig. 1. The block scheme of the experimental installation.

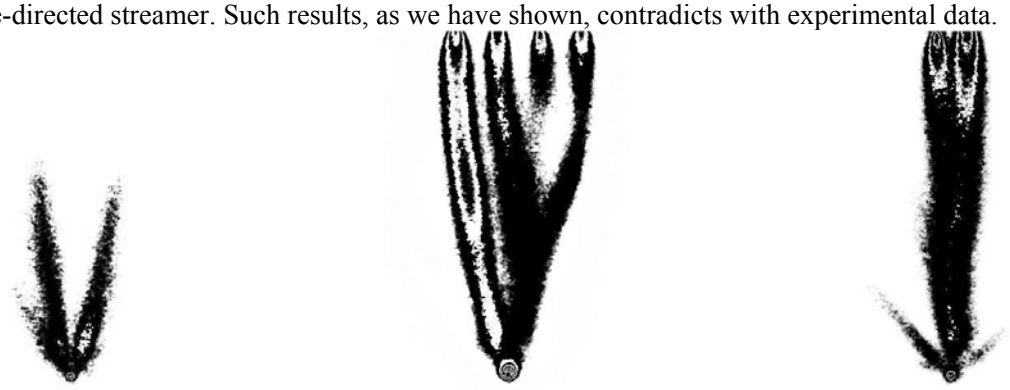
For getting of the discharge pulses both of positive, and negative polarities with amplitude in a cable line from 12 up to 24 kV (24-48 kV on a discharge gap) with front of increase 5 ns, duration on half-height of 20 ns were given. Frequency of following pulses was 40 Hz. Parameters of the incident pulse were measured using a back-current shunt placed in a break in the cable braiding such as to make possible the separation of the incident pulse from generator and the pulse reflected from the chamber. During the experiment were carried out [3] the experimental measuring of parameters of a streamer at pressure in the discharge camera 300÷740 torr and voltages in a cable of 12 kV. In this paper the range of pressures is dilated up to 1200 torr, voltages up to 22 kV.
For definition of spatial and temporal characteristics the camera PicoStar HR12 of company LaVision with a spectral range of sensitivity 300÷700 nm and temporal exposure up to 200 ps was used. The camera ICCD was focused on the needle of the low-voltage electrode thus, so the upper and lower electrodes could hit in the picture. Photos of a streamer discharge were received in two modes of work of the high-speed camera: an integral and stroboscopic mode. By working in an integral mode the amplifier of the high-speed camera was switching on simultaneously with coming of a high-voltage pulse on an electrode. Time of exposure was 50 ns and included the duration of a high-voltage impulse. For working in a stroboscopic mode, on the amplifier of the camera is set a starting sine signal with frequency of 300 MHz, time of exposure of the camera's amplifier is set by the program and in our experiments it was 300 ps.

3. The experimental results and discussion.

During the work photos of a streamer were received at voltages on electrodes 26÷48 kV and pressure 300÷1200 torr for both polarities. For the specified voltages within a range of pressures 300÷740 torr 200 photos of anode-direct streamer were analyzed, typical Fig. 2a, 2c, 5c. In pictures it is visible, that the single streamer channel or some channels, starting from an initiating needle can be observed. From 200 images of anode-directed streamer we received, only in one picture (fig 2b), was obtained the image which can be interpreted as branching anode-directed streamer, thus in our opinion indeterminacy is maintained: there was a branching or channels will start from the needle of the cathode. The statistical weight of this image is very small. Also we concluded that branching is not typical for anode-directed streamer in the explored range of pressures and voltages. This result should be especially underlined because in articles [4,5] devoted to numerical model operation of the anode-directed streamer, it was drawn a conclusion that there is an opportunity of branching of the anode-directed streamer. Such results, as we have shown, contradicts with experimental data.



a) – 30 kV b) – 36 kV c) – 42 kV

Fig.2 Images of anode-directed streamer in an integral mode at pressure of 740 torr

To determine how the parameters (P, U) influence on occurrence of branches of cathode-direct streamer, the following procedure was done. For each applied voltage and for each pressure it was received not less than 20 pictures. For each picture the amount of apparent branches of a streamer was counted and then the received data were statistically handled. The results of this processing are shown in Fig. 3

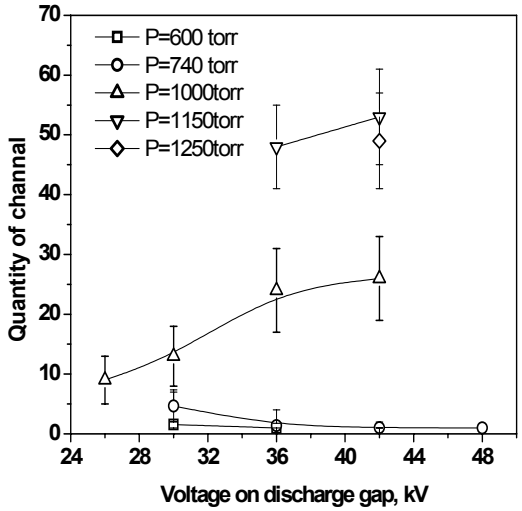


Fig.3. Dependence of branches on value of pressure and voltage on a discharge gap.

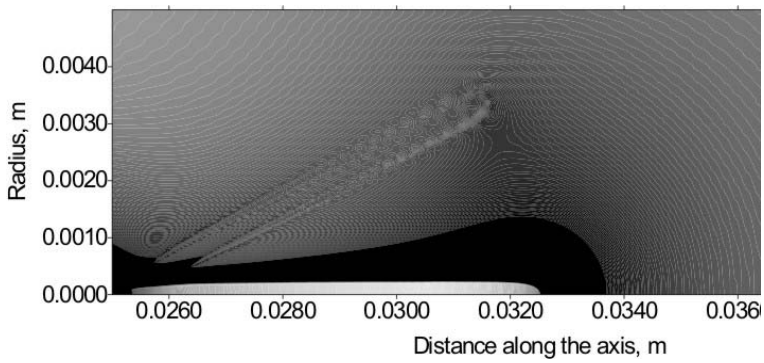

Fig.4. Electric field distribution in the gap ($\log_{10}(E/n)$). One additional "conical branch" is added.

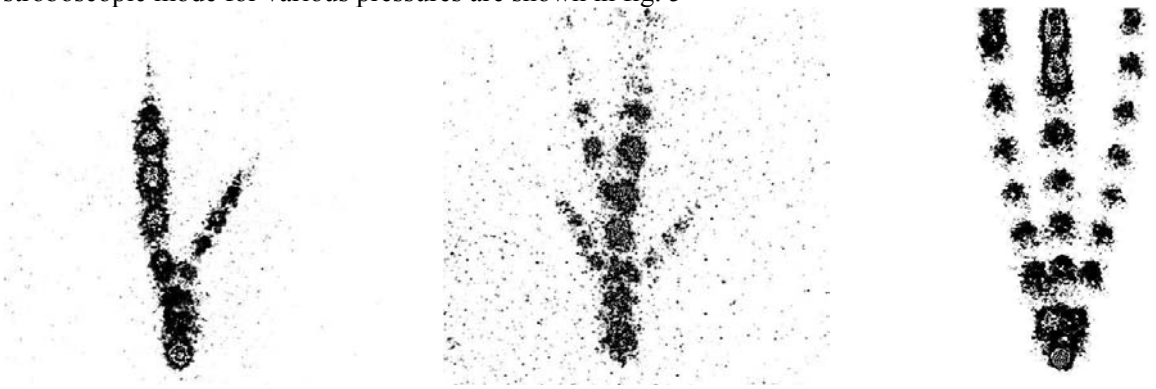
We developed a numerical model, which allowed us to calculate the influence of branches on each other. We have performed the calculations for two different regimes: single channel propagation, and simultaneous propagation of two "branches". In the axially symmetric geometry this means that we add charge, equal to the charge of the main channel, into the cone with the deviation angle α =0.5 rad (Fig.4). For initial configuration we have observed streamer channel with radius $R_{streamer}$=0.282 mm, current I =14 mA, total charge in the discharge gap Q =$7.4 \cdot 10^{-10}$ Cl, streamer velocity V =5.06 10^5m/s. For simultaneous propagation of two streamer branches we have I =10 mA, Q =$5.5 \cdot 10^{-10}$ Cl, V =$4.85 \cdot 10^5$m/s. So, strong influence of the streamer branching on the channel parameters is shown. It follows from the received numerical data, first, that at the given pressures and voltages velocity of a streamer hardly depends on presence or lack of branching, second, that the branching influences most of all on a current of a streamer.

Thus, for more detailed studying of mechanisms leading to the branching of streamer, it is necessary to synchronize the moment of a streamer start, with the beginning of shooting of its spreading and with the moment of recording of a current and the voltage enclosed to a discharge gap. To start with we have investigated spreading of a streamer in stroboscopic mode, without synchronization with a current of a streamer. Photos in a stroboscopic mode for various pressures are shown in fig. 5



a) – cathode-direct streamer at a voltage of 30 kV and pressure of 600 torr

b) – cathode-direct streamer at a voltage of 30 kV and pressure of 740 torr

c) – anode-direct 30 kV 740 torr

Fig. 5 Image of development of a streamer received in a stroboscopic mode.

Velocity of cathode-directed streamer were measured in a wide range of pressures and voltages. Velocity was

determined, as the ratio of a distance between two positions of the streamer's head to the time interval between the exposures. The distance between positions of the streamer's head was determined by the maximum or minimum of intensity of a side view of radiation. On fig. 6 the diagram of dependence of streamer's velocity on a voltage is shown. At pressures 740 and 600 torr, where the experimental points are added with the diagram received by results of numerical modeling of solitary cathode-directed streamer in a hydrodynamic approximation in a two-dimensional formulation, description of model see [6]. The results of modeling of velocity must transmit the tendency of rising of velocity with the raising of voltage at the fixed pressure.

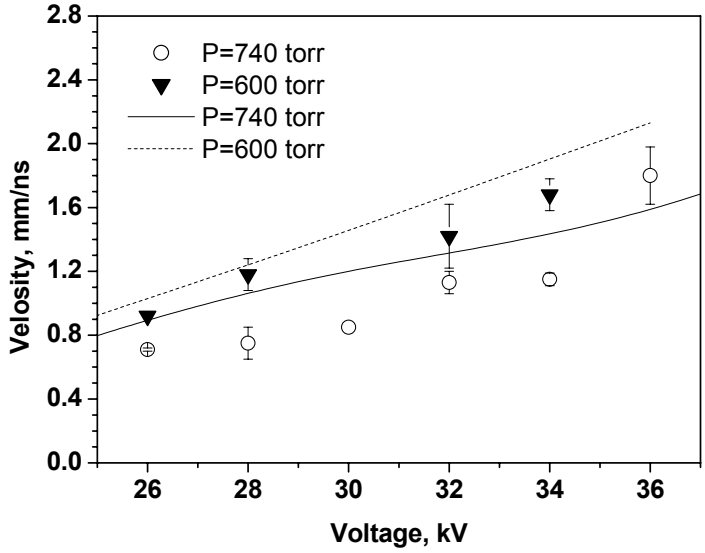


Fig. 6 Diagram of velocity's dependence of a streamer on voltage between electrodes for pressure 740 and 600 torr. The experimental points and the relevant to them diagrams re-constructed by means of numerical model [6]

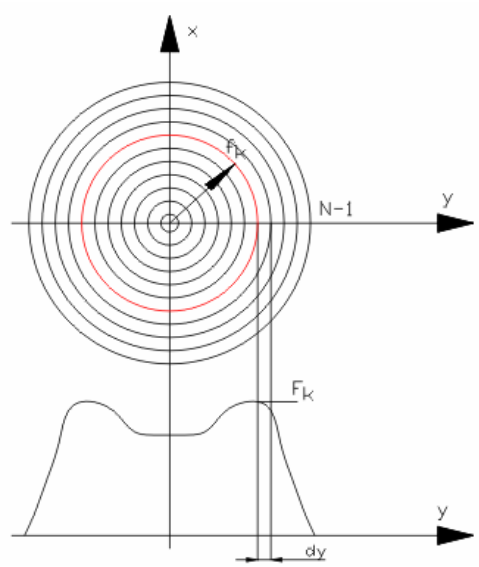

Fig. 7 Scheme of transformation of two-dimensional section of the streamer's head in the one-dimensional profile view of emission

In article [7] we supposed that the accumulation time of the active particles happens exclusively at the head of a streamer. In a spectrum of radiation N_2-O_2 under one influence of nanosecond discharge in a visible range the basic contribution imports emission of the second positive system of nitrogen in transition $N_2(C^3\Pi_u \rightarrow B^3\Pi_g)$.
On fig. 8 the profile view of radiation of the streamer's head P=740 torr, U=30 kV is shown, which is removed with exposure interval of 300 ps (curved line 1), 2 shows a lateral view after FFT-transformation. This two-dimensional lateral view is gained by summation of radiation of three-dimensional cylindrical rotationally symmetric object on fig. 7. To restore a picture of distribution of radiation along the radius of the streamer's head, we have used the inverse transformation of Abel:

$$f_k = \left[\frac{F_k}{2} - \sum_{j=2}^{N-k} f_{k+j-1} \times \Delta y \left(\sqrt{(k+j)-k} - \sqrt{(k+j-1)-k} \right) \right] \times \frac{1}{\Delta y \sqrt{2k}},$$

where f_k - required emission along radius of object, F_k - apparent emission after summation on chords.
The curved line 3 on fig. 8 shows distribution of emission on radius of a streamer which is received by means of transformation of Abel. The distance between maximums of radiation is required diameter of a streamer. The radius of the streamer's head, which is received by means of photos with picosecond's endurance, counted on maximums of radiation, makes 0.3÷0.4 mm, that approximately is twice less, than the lateral view which has been removed on half-height. On fig. 9 typical profiles of radiation after inverse transformation of Abel are shown, which were removed in different parts of the head (by virtue of axial symmetry of the head only half of lateral view of radiation is given).Actually, the profile 2 has the peak of intensity on an axis of the streamer's head while the profile 3 which is removed apart of 0.2 mm from a profile 2 on axis of the head aside the anode, has two peaks of radiation. The profile 1 is removed apart 0.2 mm from a profile 2 aside the cathode where with reduce of a field intensity of radiation decreases. On fig.9 the picture of emission of the streamer's head is

shown, which is restored on profiles of radiation in different sections of the streamer's head.

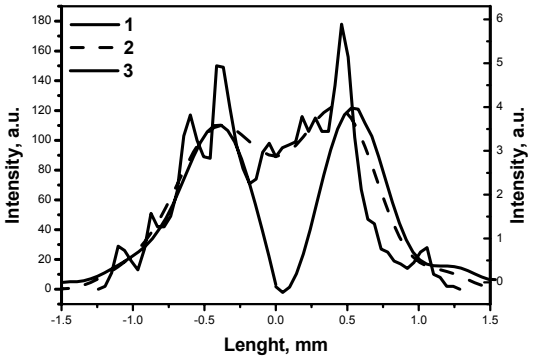

Fig. 8. 1-profile of radiation of the streamer's head P=740 torr U=30 kV, 2-profile after transformation Fourier, 3-profile after inverse transformation of Abel.

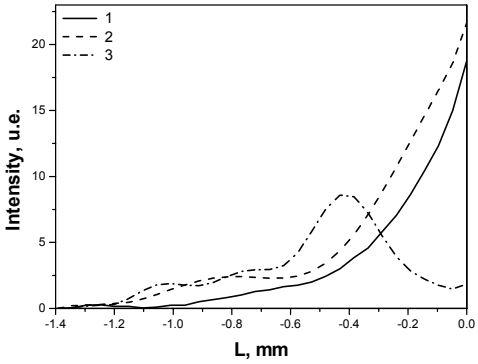

Fig. 9. Profiles of radiation on section of the head of a streamer: 2- a pique of radiation of the head, 1-on distance 0.2 mm from 2 aside the cathode, 3-apart 0.2 mm from 2 aside the anode.

Observationally filed radiation with the ICCD camera is proportionally to concentration of emissive transition $N_2(C^3\Pi_u)$. On fig. 11 it is shown the instantaneous image of concentration of excited states $N_2(C^3\Pi_u)$ for pressure P=740 torr U=30 kV, received by means of numerical model [6]. Whereas the concentration of the excited particles is proportional to quantity of a field on the streamer's head, diameter of the streamer's head is determined on a location of maximums of radiation

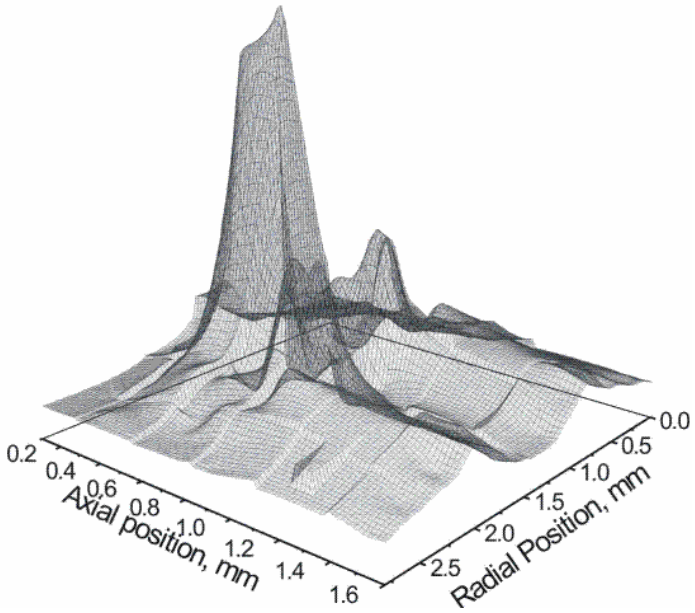

Fig. 10. A picture of radiation of the streamer's head, restored on lateral views of radiation in different sections of the streamer's head. P=740 torr U=30 kV

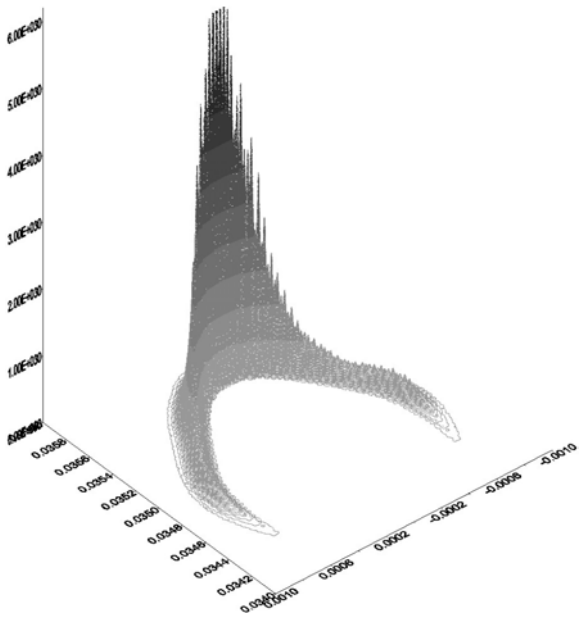

Fig. 11. The instantaneous image of concentration of excited states $N_2(C^3\Pi_u)$ for pressure P=740 torr U=30 kV, constructed by means of numerical model [6].

Conclusions.

In this work the data on branching of a streamer are received at voltages on electrodes 26÷42 kV and pressure 300÷1200 torr for both polarities. It is shown, that anode-directed streamer does not branch. Comparison of the experimental values of velocity's distribution, diameter of a streamer with results of numerical modeling [6] is carried out. It is shown, that the numerical model may predict velocity (radius, diameter) of a streamer in a wide range of pressures and voltages.
Profiles of emission of the streamer's head, received in a stroboscopic mode of operation of the high-speed camera, prove the guess that in basic points the operating time of the active particles occurs on a surface of the streamer's head. Also it is shown, that the numerical model offered before, also allows to predicting correctly the structure of the streamer's head.

Modelling for Characteristics of Dielectric Barrier Discharge Lamp

Yoshio Watanabe, Hideto Kurimoto and Takayuki Nitta
Dept. of Electrical, Electronics and Information Engineering, Kanagawa University, Yokohama, Japan

Abstract

The model for the barrier discharge lamp has been studied. First, the coefficients in the model are estimated. Good agreements between the calculated and measured waveforms are obtained by this model. Next, the distribution of electron density, ion density, electric field and ionization amount per second are calculated at each current phase. Then, ionization mechanism in the barrier discharge lamp is investigated.

Keywords: barrier discharge, numerical model

1. Introduction

Dielectric barrier discharge (**DBD**) is employed in various fields, such as LASER, ozonizer, plasma display panel and so on. Recently, **DBD** lamp filled with xenon gas has been investigated as a mercury free light source. **DBD** lamp also has advantages of full light output from the start of operation and independence of ambient temperature because of mercury absent. It has been known that **DBD** shows unique voltage-current characteristics due to the electrification on the discharge tube wall and its efficacy is strongly depend on the applied voltage waveform [1]. To analyse this unique characteristics, the numerical model for **DBD** lamp has been studied in this study [2].

2. Objective DBD Lamp

The objective **DBD** lamp is as follows. The cylindrical discharge tube with diameter of 10 mm and length of 345 mm is filled with gas mixture of Xe (30%) and Ne (70%) at 4.4×10^4 Pa. Phosphor is not coated inside the tube. A pair of stripe electrodes is printed on the outside of the tube. The lamp is operated at 50 kHz. The waveforms of the discharge current, I, and output light, Φ, are measured at various waveforms of applied voltage, V, and compared with the calculated waveforms by the model.

3. Model

The discharge tube configuration assumed in the model is shown in Fig.1. The model is one-dimensional model with infinite length in the axial direction. The continuity equations for electron density, n_e, and ion density, N_i, are given as follows,

$$\frac{\partial}{\partial t} n_e = -\mathrm{div}(\mu_e n_e E - D_e \mathrm{grad} n_e) + \nu_i n_e - \frac{D_a}{\lambda^2} n_e \quad (1)$$

$$\frac{\partial}{\partial t} N_i = \mathrm{div}(\mu_i N_i E) + \nu_i n_e - \frac{D_a}{\lambda^2} n_e \quad (2)$$

where μ_e: electron mobility, E: electric field, D_e: diffusion coefficient for electron, D_a: ambipolar diffusion coefficient, λ: characteristic diffusion length, and μ_i: ion mobility. Ionisation frequency, ν_i, is given by using the Townsend coefficient of primary ionisation.

$$\nu_i = \mu_e E A p \exp(-\frac{Bp}{E}) \quad (3)$$

where p: filling gas pressure, A and B: coefficients determined by gas condition.
The continuity equation for current density, i, is given as follows,

$$i = q(n_e \mu_e E - D_e \mathrm{grad} n_e) + q N_i \mu_i E + \varepsilon_0 \frac{\partial}{\partial t} E \quad (4)$$

where q: electron charge and ε_0: dielectric constant.

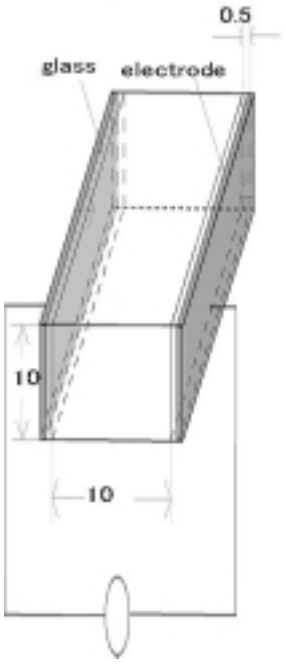

Fig.1 Assumed discharge tube configuration

The boundary condition on the wall during cathode cycle is given as follows,

$$i = (1+\gamma)qN_{i0}\mu_i E_0 + \varepsilon_0 \frac{\partial}{\partial t} E_0 \qquad (5)$$

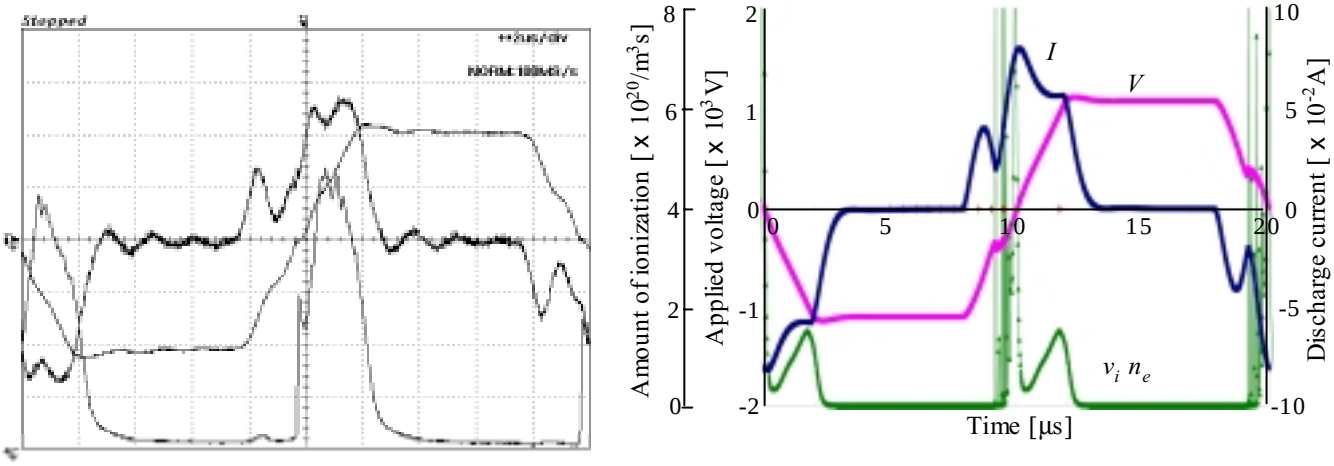
where γ: the secondary coefficient of the glass wall.

4. Calculation Result

The values of the coefficients are estimated by the try-and-error method. The coefficients, μ_e, μ_i and *Bp,* are sensitive to the characteristics while D_a/λ^2 and γ are insensitive. The values for trapezoid waveform of applied voltage by which the most similar waveform of *I* is obtained are shown in Table 1. The calculated waveforms of discharge current, *I*, and ionisation amount per second, $\nu_i n_e$, by these values are shown in Fig.2 together with the measured waveforms. Since output light from plasma is produced by electron impact as well as ionization, the calculated $\nu_i n_e$ waveform and the measured output light waveform should be somewhat resemble to each other.

Table.1 Selected coefficient values for *the* applied voltage with trapezoid waveform

μ_e	6.0×10^{-2}m^{2}V^{-1}s^{-1}	μ_i	4.0×10^{-5}m^{2}V^{-1}s^{-1}
D_e	3.6×10^{-2}m^{2}s^{-1}	D_a/λ^2	10^2s^{-1}
Ap	6.0×10^{8}m^{-1}	*Bp*	11.4×10^{6}m^{-1}V
γ	10^{-4}		



(a) measurement (b) calculation

Fig.2 Waveforms obtained under trapezoid waveform of applied voltage

The result shows good agreement between the calculated and the measured waveforms. The calculated characteristics depend on μ_e are also agree with those shown in the reference [3].

Calculations are continued for the case of sinusoidal and triangle applied voltage waveforms. The agreement between the calculated and the measured current waveforms for sinusoidal and triangle applied voltage waveforms were not so good when the values in Table 1 were employed. Thus, the coefficient values are modified for sinusoidal and triangle waveforms. The modified coefficient values for sinusoidal and triangle waveforms are shown in Table 2. The calculated waveforms by these coefficients are shown in Figs.3 and 4, respectively. Good agreement between the measurement and the calculation are obtained by these coefficient values.

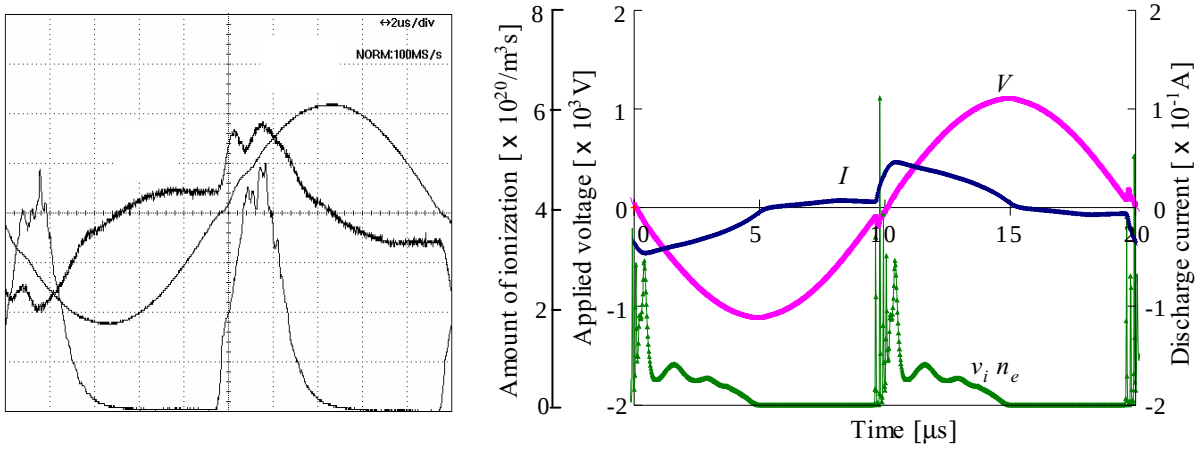
Table.2 Selected coefficient values for *sinusoidal* and triangle applied voltage waveform.

μ_e	3.0×10^{-2}m^{2}V^{-1}s^{-1}	μ_i	6.5×10^{-5}m^{2}V^{-1}s^{-1}
D_e	3.6×10^{-2}m^{2}s^{-1}	D_a/λ^2	10^2s^{-1}
Ap	6.0×10^{8}m^{-1}	*Bp*	6.8×10^{6}m^{-1}V
γ	10^{-4}		

The case of triangle waveform of applied voltage with absent period at zero-cross phase is calculated using the values shown in Table 2. The calculation results are shown in Fig.5 together with the measured waveforms. The agreement between the calculation and the measurement are fairly good.

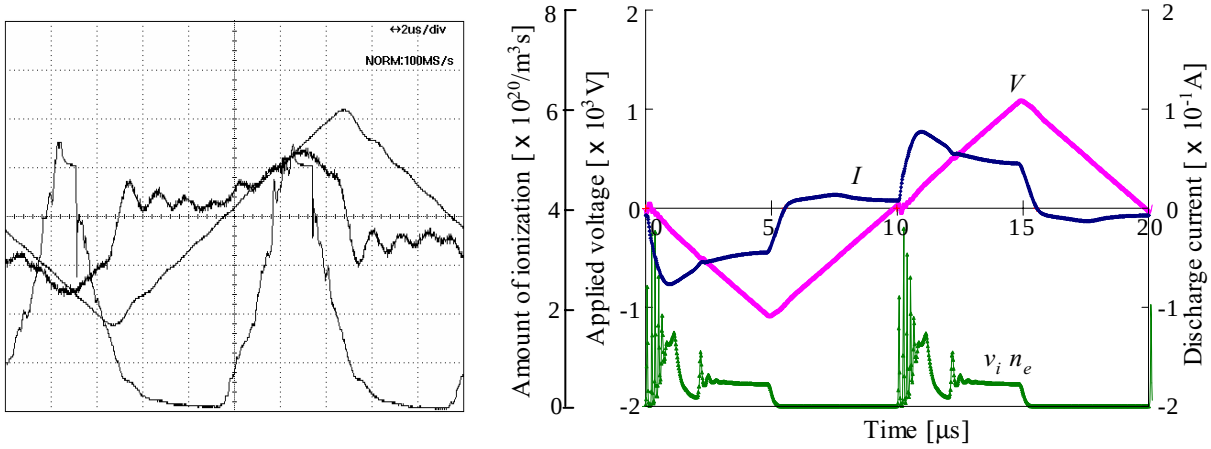
Up to now, the reason why the appropriate coefficient values are a little bit different between trapezoid waveform and sinusoidal/ triangle waveform is not clear yet. The problem might be existed in the

assumption that the plasma coefficients are taken as constant in this study.



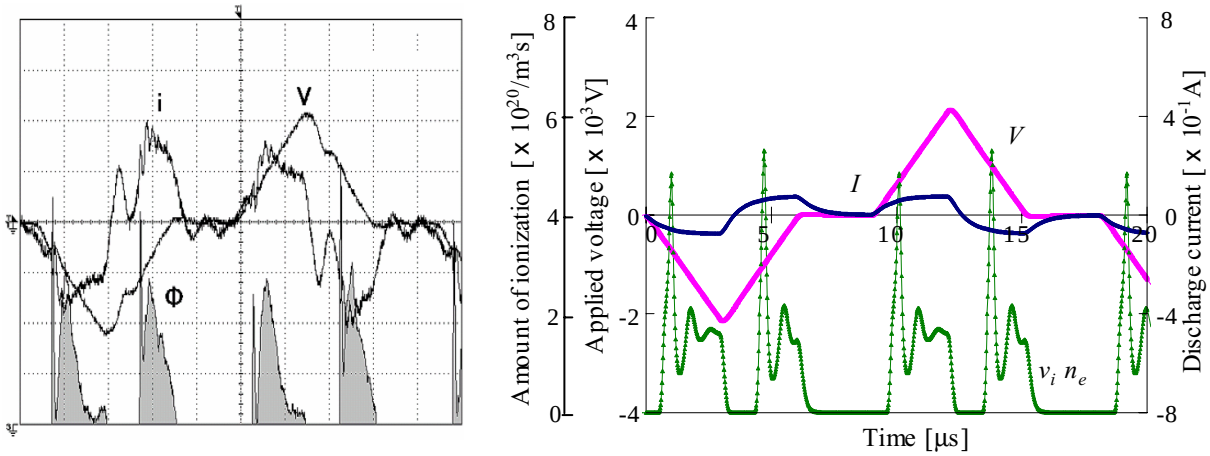
(a) measurement (b) calculation

Fig.3 Waveforms obtained under sinusoidal waveform of applied voltage



(a) measurement (b) calculation

Fig.4 Waveforms obtained under triangle waveform of applied voltage



(a) measurement (b) calculation

Fig.5 Waveforms obtained under triangle waveform of applied voltage with absent period

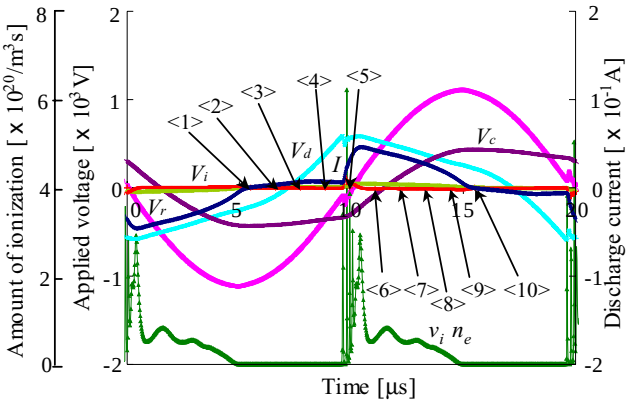


Fig.6 Calculated waveforms by sinusoidal waveform of the applied voltage. The number in the figure indicates the phase when the figures in Fig.7 are calculated.

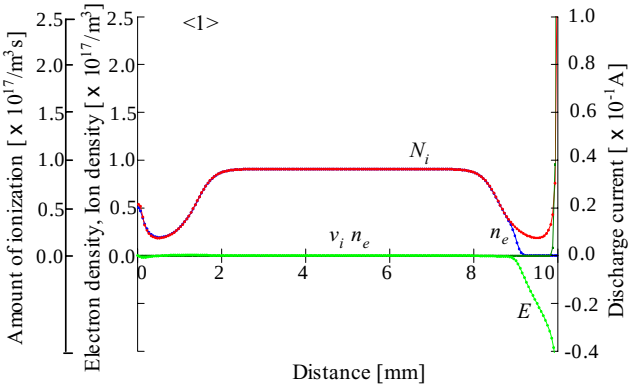
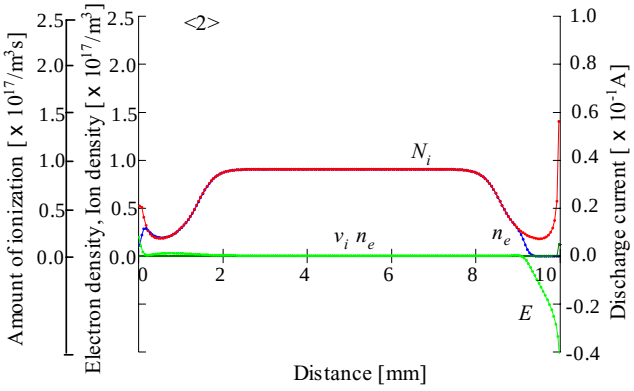
Next, the distributions of electric field, E, electron density, n_e, ion density, N_i, and ionization amount per second, $\nu_i n_e$, at each phase designated in Fig.6 are calculated and shown in Fig.7. The calculated voltage across the plasma, V_d, and the voltage across the glass wall (barrier), V_c, are also shown in Fig.6.,

Electron density n_e in the central part which is almost equal to ion density N_i is nearly constant during the cycle. Thus electric field E in the central part changes proportionally with discharge current I. Even though electron density in the central part is high, the electric field there is low to produce intense ionization, while ionization mostly takes place in the space charge layers formed on the glass walls.

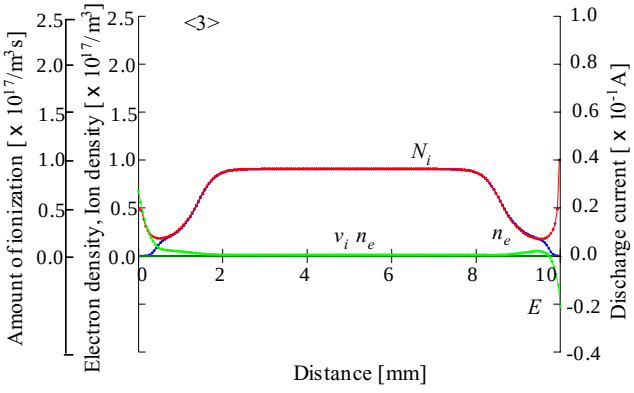
Fig.7<1> shows the distribution of E, n_e, N_i and $\nu_i n_e$ at t=5.5μs. At this phase, discharge current takes zero cross as shown in Fig.6. The most part of discharge voltage V_d is the voltage across the space charge layer formed on the right side glass wall. At t=6.6μs shown in Fig.7<2>, the discharge current is increasing while discharge voltage remains at negative polarity. This condition indicates that the space charge layer acts as a capacitor and its impedance is much larger than the impedance at the central part of the plasma at this phase. At t=7.7μs shown in Fig.7<3>, the discharge voltage polarity turns to inverse in accordance with the formation of space charge layer on the left side. At t=8.8μs shown in Fig.7<4>, the space charge on the left side becomes to grow rapidly, since electrons are enforced to move to right direction by electric field. At t=9.9μs shown in Fig.7<5>, intense ionization takes place in the space charge layer. Since electrons and ions are enormously produced in the space charge at the phase, the impedance of discharge plasma sharply decreases. Then discharge current becomes to increase abruptly.



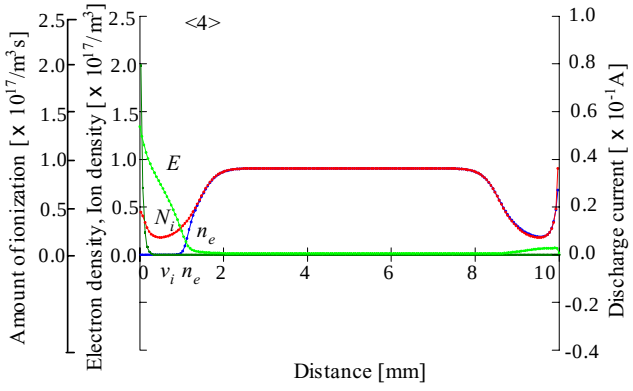
<1> t=5.5μs



<2> t=6.6μs



<3> t=7.7μs



<4> t=8.8μs

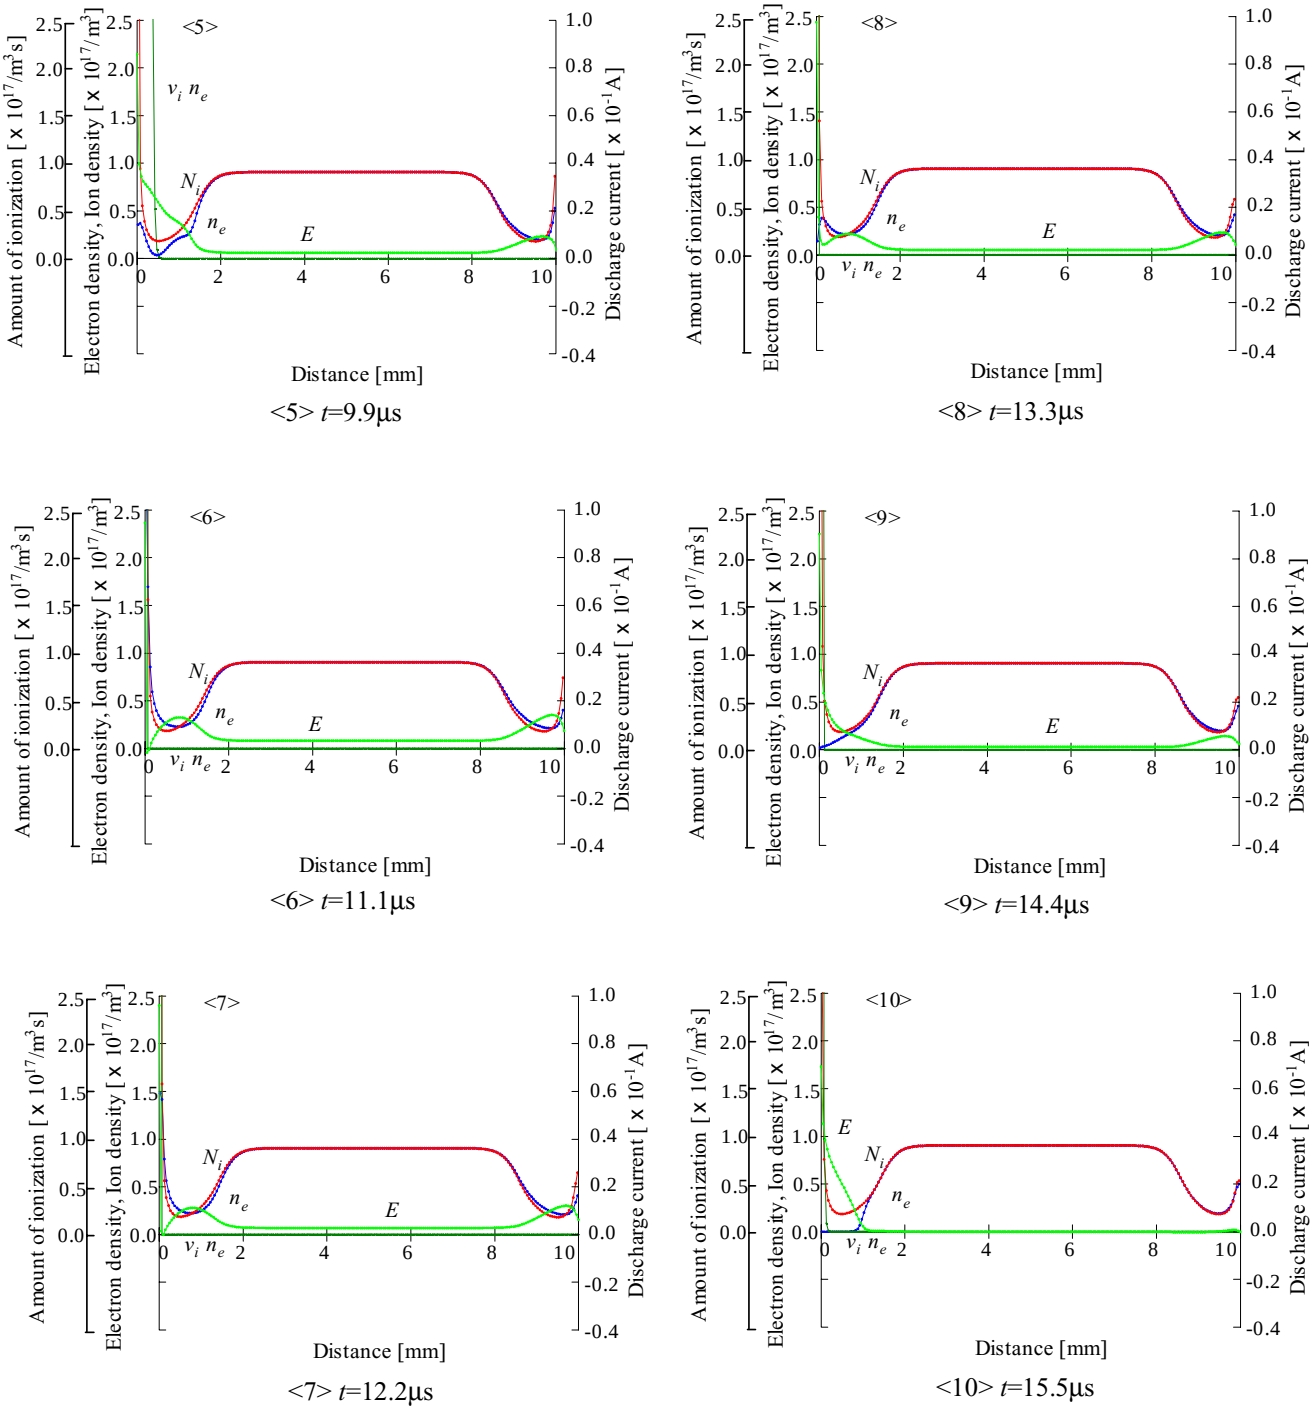


Fig.7 Distribution of electric field, E, electron density, n_e, ion density, N_i, and ionization amount per second, $\nu_i n_e$, at each phase designated in Fig.6.

At t=11.1μs shown in Fig.7<6>, the space charge on the left side is almost banished since the electron produced by the intense ionization neutralizes the space charge. Then the electric field in the space charge almost is vanished and intense ionization will cease. At t=15.5μs shown in Fig.7<10>, the space charge becomes to form again on the left side wall. Since electron density on the left side is nearly zero at this phase, intense ionization will not produce due to the lack of electron. However, if the applied voltage has absent period at zero cross phase, electron can diffuse into the space charge layer from near plasma region during the absent period. Then intense ionization might be produced when the applied voltage begins to increase

again. This mechanism may explain the phenomena shown in Fig.5.

5. Conclusion

Good agreements between the calculation by the model and the measurement are obtained for **DBD** lamp. The appropriate coefficient values for the model should be modified for each applied voltage waveform up to now. The reason is not clear yet. The distributions of electron density, ion density, electric field and ionization amount per second at each phase are calculated by the model. It is shown that ionization in **DBD** lamp mainly takes place in the space charge layer on the glass wall and it strongly depends on the applied voltage waveform.

PRODUCTION OF HYDROGEN GAS AND CARBON BLACK BY DECOMPOSITION OF HYDROCARBON USING THERMAL PLASMA

Sun-Hee Park and Dong-Wha Park

Department of Chemical Engineering and RRC- ETTP(Regional Research center for Environmental Technology of Thermal Plasma) , Inha University, 253 Yonghyun-dong, Nam-gu, Incheon 402-751, Korea

Abstract

On the basis of the thermodynamic equilibrium calculations, the optimum condition of methane decomposition by thermal plasma was investigated. Methane was found to be decomposed mainly into hydrogen and solid carbon in the temperature range between 1000 and 2000 K. The amount of hydrogen produced increased with increasing the methane flow rate. Methane conversion was higher than 90% and decomposed carbon was solidified to amorphous carbon black. The particle size of carbon black was observed to be strongly dependent on methane flow rate.

Keywords

Thermal Plasma, Methane decomposition, Thermodynamic equilibrium calculations, Hydrogen, Carbon black

1. Introduction

Hydrogen has long been considered as an alternative, renewable, and clean energy source to replace fossil fuels [1]. A hydrogen energy based fuel economy is fast becoming interesting and it is certain that automobiles and electrical energy generation facilities will begin to use hydrogen in the very near future. Hydrogen has been produced mainly through steam reforming or partial oxidation of natural gas. Because the hydrogen produced by these processes inevitably contains CO and CO_2 beyond a tolerable range, the removal of CO is required. An alternative for hydrogen production is water electrolysis using renewable energy, which is not presently cost competitive. Methane, which is the main component of natural gas, is being used in a variety of fields. Direct thermal decomposition of methane can produce high purity of hydrogen without CO_2 and other pollutants (SOx, NOx, etc)[2], although it requires quite a high temperature (1500−2000℃) in order to obtain a reasonable hydrogen yield. Thermal plasmas have been suggested and considered as a promising heat and radical source for the direct decomposition of methane, because of its high temperature property and flexibility. Besides the high purity of hydrogen produced, carbon can be recovered as carbon black without emission of CO_2 [3]. When methane is heated to high temperature, the methane is decomposed or cracked into carbon and hydrogen:

$$CH_4 \rightarrow C + 2H_2 \qquad \triangle H^{o}_{298} = 76 \text{ kJ/mol}$$

Decomposition of methane is endothermic reaction and 38 kJ/mol H_2 produced is required, which is considerably lower than that for the steam reforming process (63 kJ/mol H_2). Compared with methane combustion, it can save 10% of energy required to operate the process [4-6].

Carbon produced by thermal decomposition can be either sequestered or used as a law material and it is much easier to be separated, handled, transported, and stored.

2. Experimental

Thermal plasma system has been developed for the decomposition of methane. The experimental system consists of D.C plasma torch, plasma reactor and filter assembly, as shown in Fig 1. All the experiments were carried out at atmospheric pressure with 6 kW electric powers. The feed gas (CH_4) flow rate was varied from 3 ～15 l/min depending on the operating conditions. All gaseous products were analyzed by gas chromatography equipped with TCD and molecular sieve 13X column.

Table 1 Experimental conditions

Plasma formation gas		Nitrogen(7~12 l/min)
Reforming source gas		Methane(99.9%, 3~15 l/min)
Plasma input power		6kW
Analysis	Gas composition	Gas chromatography (TCD, molecular 13X)
	Carbon black	SEM (S-4200, Hitachi Co.)
		BET (ASAP 2010, Micromeritics)
		PSA (LS230, COULTER Co.)

The specific surface areas of carbon produced were measured by the BET method (ASAP 2010, Micromeritics). Morphology and particle size of the formed carbon were investigated by the scanning electron microscopy (SEM: S-4200, Hitachi Co.) and particle size analyzer (PSA: LS230, COULTER Co.). The experimental conditions are summarized in Table 1.

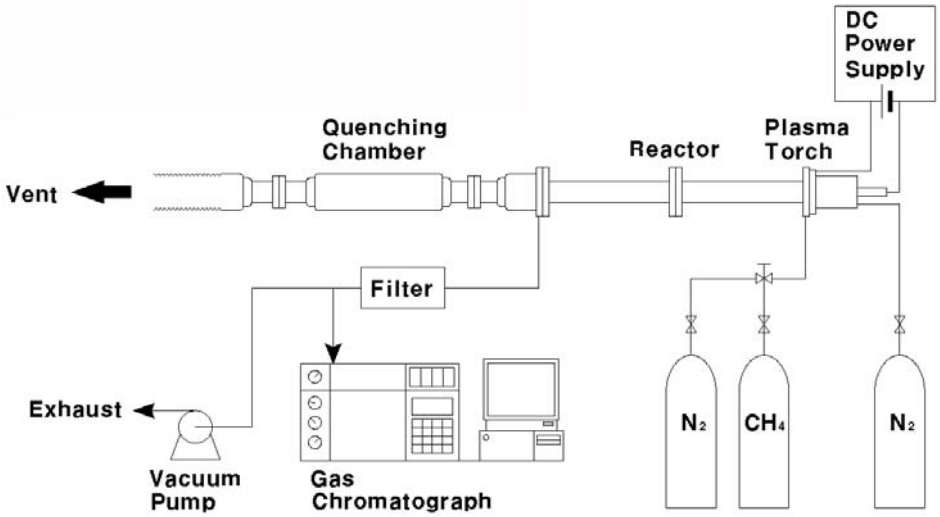

Fig. 1 Schematic diagram of experimental equipment

3. Results and Discussion

For comparison, thermodynamic equilibrium concentrations of reactant and products for both steam reforming and thermal decomposition were calculated using Fact sage (Version 5.3.1, GTT-TECHNOLOGIES) and the results are shown in Fig 2. This calculation was based on the Gibbs free energy minimization.

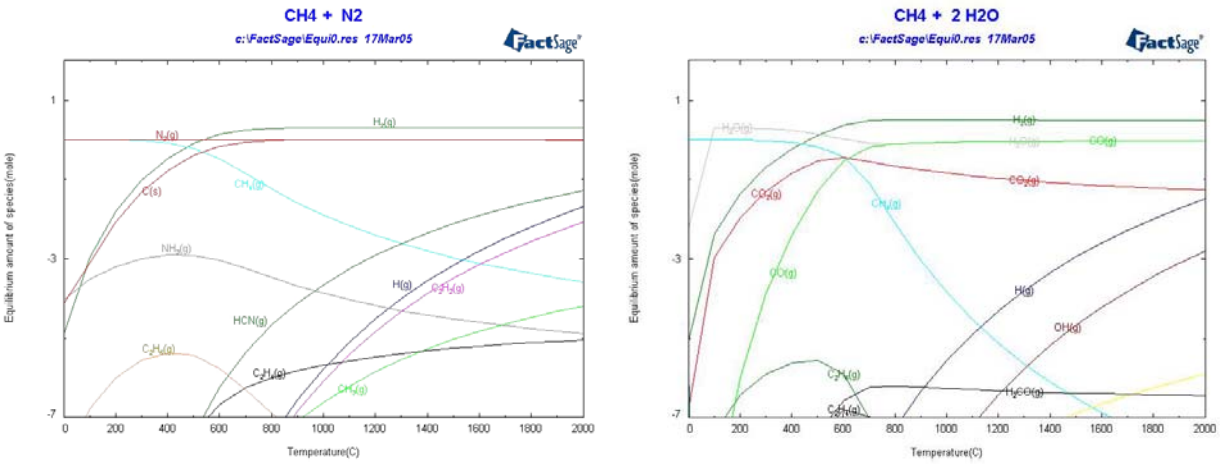
In the case of steam reforming, as expected, major products were H_2, CO and CO_2 at above 500℃ (Fig. 2-(a)). In thermal decomposition, major products were H_2 and solidified carbon at the similar temperature range, which can be easily separated from each other. These calculations imply that high purity of hydrogen can be easily achieved by thermal decomposition without separation process.

The feed gas (CH_4) and all gaseous products were analyzed by gas chromatography (GC) and the methane conversion and hydrogen yield were calculated from the area of each peak. The results with respect to methane flow rate are shown in Fig 3. The methane conversion was defined as:

$$\text{Decomposition of } CH_4\ (\%) = \frac{\text{In } CH_4 - \text{Out } CH_4}{\text{In } CH_4} \times 100$$

Where In CH_4: Amount of the methane gas before the plasma reaction

Out CH_4: Amount of the methane gas after the plasma reaction



(a) (b)

Fig. 2 Calculations of equilibrium chemical composition
(a) in steam reforming process (b) in thermal decomposition of methane

As shown, methane conversion was very high (above 90%) all over the ranges investigated. At very high methane flow rate (when the flow rate was 15 l/min), the conversion slightly decreased, probably due to the decrease of residence time. Because the hydrogen selectivity is very high, as evidenced from Fig 2, the hydrogen yield was very close to the methane conversion all over the ranges. No other gaseous product was detected even by FT-IR analysis, which means all the products from methane decomposition by thermal plasma are hydrogen and solidified carbon.

The morphology of the carbon was characterized by SEM and particle size was determined by particle size analyzer. For comparison, carbon was taken from several parts, reactor, quencher, and filter. Fig. 4 shows SEM photographs of the carbon blacks formed at different locations of the process. As shown, all carbons from three places under the same flow rate of methane have the similar particle size, although they form aggregates rather than isolated form. For accurate determination of particle size, particle size analyzer was used and particle sizes of carbons synthesized are compared with commercially used carbon black (N700 and N800, KCB) in Table 2.

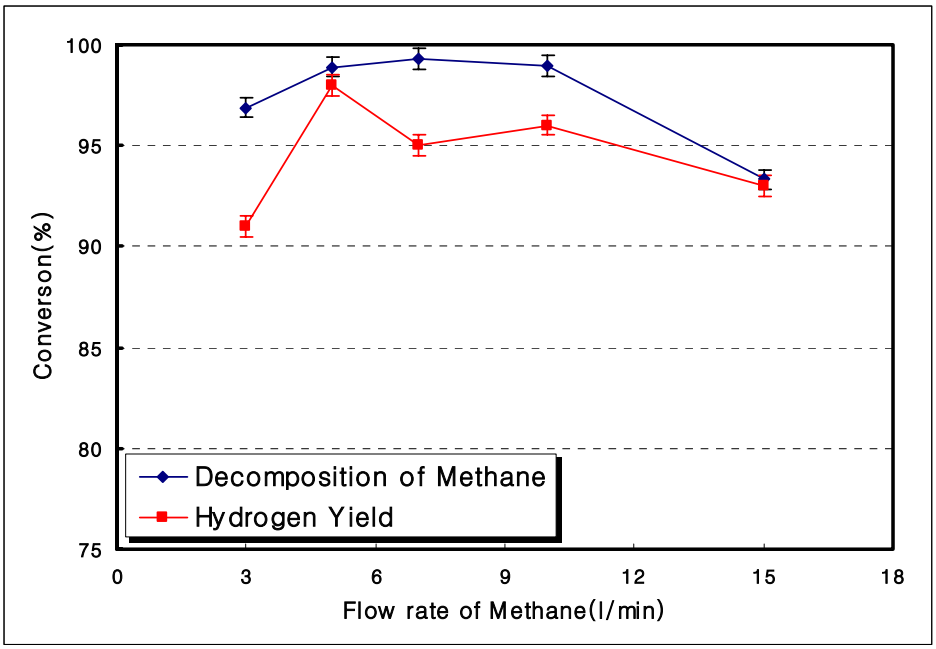


Fig. 3 Methane conversion and hydrogen yield as a function of methane flow rate

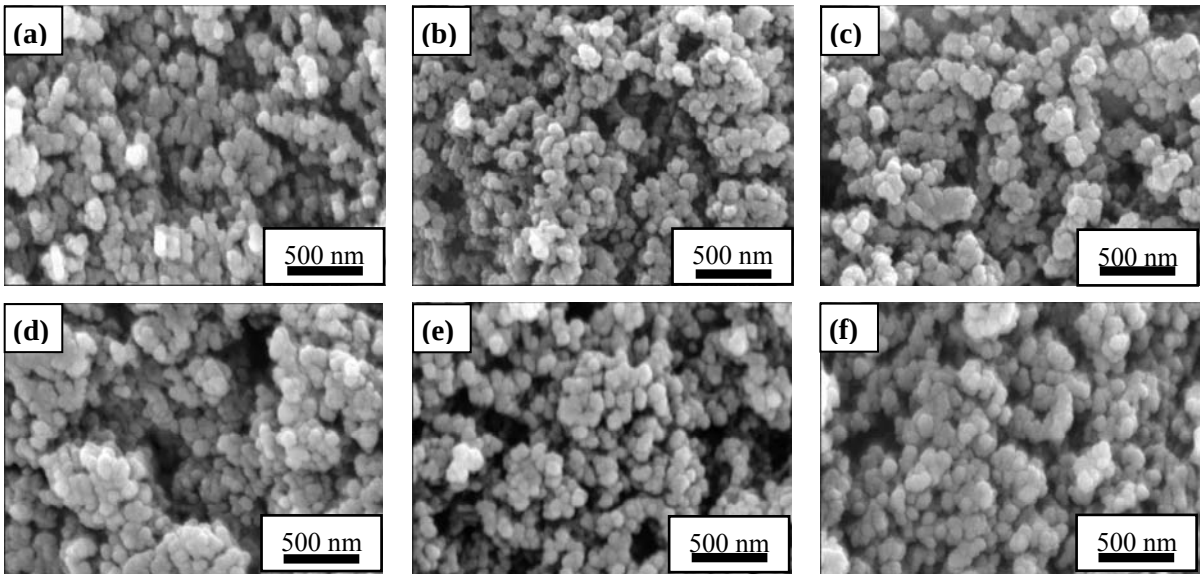

Fig. 4 SEM images of the carbon black
(a) Reactor part under CH_4 3 l/min (b) reactor part under CH_4 5 l/min (c) reactor part under CH_4 7 l/min
(d) Reactor part under CH_4 10 l/min (e) filtering part under CH_4 5 l/min (f) quenching chamber under CH_4 7 l/min

Table 2 Size of carbon black by particle size analyzer

Flow rate of methane (l/min)	N700(SRF)	N800(FT)	3	5	7	10
Particle diameter(nm)	61~100	101~200	84	109	113	116

N700(SRF) : Semi Reinforcing Furnace
N800(FT) : Medium Thermal

It was confirmed from particle size analysis that particle size of carbon increased with increase of methane flow rate, as also evidenced from SEM analysis. The particle size increase with methane flow rate can be explained by the increase of the number of carbon in the reactor for unit time with increase of flow rate. These results imply that particle size can be easily controlled by the methane flow rate. It varied from 80 to 120 nm. BET surface areas of carbon as a function of methane flow rate were compared with those of commercially used carbon blacks in Table 3. BET surface area ranges from 58 to 100 m^2 /g with methane flow rate and this decrease is due to the increase of particle size. Carbon black which has lower surface area (30~100 m^2 /g) can be used in rubber industry, while high surface area (> 700 m^2 /g) carbon black is like activated carbon.

Table 3 Nitrogen Surface Area of carbon blacks by CH_4 flow rate

	Corax® Hard Grade	Corax® Soft Grade	Exp.1	Exp.2	Exp.3	Exp.4
Feed gas (l/min)	Natural gas, Tar, Oil Pyrolysis	Natural gas, Tar, Oil Pyrolysis	CH_4 3	CH_4 5	CH_4 7	CH_4 10
Nitrogen Surface Area (m^2/g)	100±10	50±10	193	191	100	81

Corax® Hard Grade , Corax® Soft Grade : Used to rubber industry

4. Conclusion

Thermal plasma system has been developed and direct thermal decomposition of methane was carried out, which is an environmentally favorable process. For comparison, thermodynamic equilibrium concentrations were calculated by Fact sage software for both steam reforming and thermal decomposition. In case of thermal decomposition, high purity of hydrogen and solidified carbon can be achieved without any contaminant.

Methane conversion and hydrogen yield were investigated with respect to methane flow rate and both of the two was very high (above 90%) Particle size and surface area of synthesized carbon were strongly dependent on methane flow rate and it was observed that particle size decreased with increasing methane flow rate. Hydrogen produced from thermal plasma can be applied to fuel cell due to its high purity and carbon black can be applied for the synthesis of rubber industry.
It could be concluded that thermal plasma process for methane decomposition is very effective in terms of production of high purity of hydrogen as well as synthesis of carbon black.

Abstract

Cu dispersed C-S dielectric thin film was fabricated by simultaneous process of plasma CVD of CH_4, SF_6, and Ar mixture gas, and sputtering of Cu plate discharge electrode. The C-S film was supposed to be formed by HF dissociation reaction in the plasma CVD process. Effect of substrate holder temperature on the deposition was studied. With increasing the temperature, sulfur content was decreased and oxygen content was very large for all samples. At 400℃, the sulfur content became negligibly small. Atomically distribution of Cu in the dielectrics was expected from no X-ray diffraction peak for the Cu dispersed C-S dielectric thin film. The large oxygen content was referred to oxidization of atomically dispersed Cu atom in the film in the air.

Keywords: plasma CVD, sputtering, HF dissociation, C-Cu-S, X-ray diffraction

1. Introduction

Metal containing dielectric is studying variously as an optical memory [1], large refractive index material [2], large non-linear electro-optic effect [3, 4] and semi-conductive film [5]. For the metal containing dielectric film formation, there are wet and dry processes [4, 6]. For the dry process, co-evaporation method of metal and dielectric and co-operation method of plasma CVD and sputtering.

We are forming gold (Au) atom containing C (carbon)-S (sulfur) film by co-operation process with plasma CVD of CH_4, SF_6, and Ar mixture gas and sputtering of discharge electrode with gold plate on graphite plate electrode [2,5]. The gold atom was observed to be distributed atomically in the C-S dielectric film caused on chemical bond between gold atom and sulfur atom [7]. Therefore the co-operation method of plasma CVD and sputtering is unique and useful method, because the large refractive index more than 3.5 and other interesting properties were realized [2].

However there is a question that other metal can also be distributed uniformly in the C-S dielectrics like as the gold atom.

In the plasma CVD that used the CH_4-SF_6-Ar mixed gas, chemical reaction between C and S atom was realized by dissociating H and F atom from CH_4 and SF_6 and by forming HF molecule if the stoichiometrical condition is maintained [5]. Under the self-bias condition, the sputtering of metal atom from upper metal plate discharge electrode is performed, and it mixes into the C-S dielectrics.

Pyrite-type CuS_2 is known to show superconductivity with T_S = 1.5 K, which is formed by synthesis under high pressure [8-11]. For the Cu dispersed C-S (C-Cu-S) by plasma processes, it is interesting to know the chemistry on C-Cu-S synthesis. In this work, the effect of substrate temperature was studied. In order to study the effect of substrate holder temperature on the deposition, a new substrate holder was prepared which can heat the substrate up to 1000℃.

2. Experiments

The reactor for the co-operation process of plasma CVD and sputtering are shown in Fig. 1, which was used for our C-Au-S film formation. However the reactor was changed like as Fig. 2 for the study of substrate temperature effect on the deposition. But the gap between the parallel plate electrodes was extended from 15 mm to 22 mm in order to insert the substrate heating system. The metal target for the sputtering was a Cu plate electrode (200 mm diameter), which has numerous small holes in order to introduce the reaction gases in the discharge plasma space between the parallel plate electrodes.

The deposition was performed at a constant discharge power of 100 W for 30 min discharge period at 13.56 MHz. The substrate temperature was controlled to be 66 (no heating), 200, 300 and 400℃. For the characterization of the films, ESCA spectrum and X-ray diffraction pattern measurement were performed.

3. Results

When the gas flow rates of CH_4, SF_6 and Ar were 5, 3, and 20 sccm respectively at 0.07 Torr, the atomic composition was measured as shown in Table 1 by ESCA measurement. The result was obtained after Ar plasma sputtering of the surface layer. By the Ar plasma sputtering for 3 min, the surface atomic layer was supposed to be taken off. Fluorine and oxygen atom content were negligibly small. Copper, carbon, and sulfur content were almost same as 30 %.

For the substrate temperature effect on the deposition, the deposition was performed with using the reactor as shown in Fig. 2. The flow rate of CH_4, SF_6 and Ar were 10, 6, and 10 sccm, respectively. The discharge power and the pressure were set as 100 W and 0.07 Torr, respectively. The atomic composition of the film was measured as shown in Table 2, which surfaces were not cleaned by Ar sputtering.

Fluorine atom content was negligibly small for all samples. This fact means that the stoichiometrical condition was maintained during the deposition. With increasing the substrate temperature, sulfur atom content was decreased. For all samples oxygen atom content was significantly large. The sulfur atom content was not observed at 400℃. Oxygen was not mixed with the reaction gas, whereas the oxygen content was referred to oxidization of the film while the sample was keeping in the air.

The x-ray diffraction pattern of the film was measured as shown in Fig. 3. The observed single peak was referred Si wafer. Whereas, the Cu dispersed C-S dielectric film did not show any X-ray diffraction peak. This fact means Cu is expected to be distributed uniformly in the film same as the gold atom in the C-Au-S film.

It is concluded that the large oxygen content in the film will be referred the atomically distributed Cu in the film because the atomic Cu will be oxidized easily in the air.

The sulfur content was decreased with substrate temperature and the sulfur was disappear from the film formed at 400℃. This fact means that plasma process has some possibility to synthesize sulfide compounds in the evacuated system. However substrate temperature is negatively affected on the sulfide.

These experimental results are important, because the proposed process has a possibility to realize atomically distribution of metal atom in the dielectrics.

4. Conclusion

With using the co-operation process of plasma CVD of CH_4, SF_6, and Ar mixture gas and sputtering of copper discharge electrode, Cu dispersed C-S dielectrics film was formed. The Cu atom was expected to distribute uniformly in the film because the X-ray diffraction peak on the Cu cluster was not observed.

The sulfur atom content was decreased with increasing the substrate temperature and the sulfur was not observed at 400℃.

Transferred-arc in flight evaporation of Al for the production of AlN nanosize powder

O.W. Bender, A.C. Doring, H. Toku and A.C. da Cruz

Institute for Technological Research (IPT), São Paulo- SP, Brazil

Abstract

A thermal plasma synthesis reactor aimed at nanosize metal and ceramics synthesis has been studied at our lab at IPT in the past years. Applied to the vapour phase synthesis of aluminum nitride (AlN), the results presently reported refer to the study of gas flow at nozzle and a sequence of modifications introduced in the anode assembly intended to increase energy and productivity efficiencies.

1. Introduction

Thermal plasma vapor-phase synthesis of ceramics of many different compositions has been demonstrated on the lab scale in the past years. Although thermal plasmas present many important features needed in this field (e.g. suitability to carrying out high temperature reactions, promotion of fast quenching which invariably conducts to the production of finely dispersed particles, and provision of easy means to control process atmosphere, all of which are of the interest of production of high purity materials), scaling up of plasma reactors still meets major problems. In particular, the availability of gas phase metal precursors is a major technical barrier. Although the use of metal halides is possible in most cases, these are expensive and one has to deal with the inconvenient production of undesirable contaminants and non-environment-friendly by-products. Transferred-arc evaporation of pure metal precursors is an interesting alternative which has been studied [1].

The work we carry out is focused on the development of a plasma reactor concept for the vapor-phase synthesis of fine particles, of both pure metal and ceramic compositions. For most of the development work, aluminum nitride (AlN) has been adopted as a study case.

Previous work on transferred-arc evaporation of aluminum (Al) from a molten anode [2] showed that only about 7% of the aluminum vapor (Al(v)) produced (anode mass balance) came out the evaporation chamber (sampling probe measurement). The remaining 97% condensed on the plasma chamber walls. Also it was observed that because of the anode high temperatures, reaction between metal and anode material was a major practical problem to be solved.

With the main objective to produce greater amounts of final product powder, in order to overcome the difficulties pointed out, a modification of the initially proposed reactor concept was introduced [3]. Instead of using a molten precursor metal anode from which its vapor phase is produced, the material is introduced in the form of a powder directly into the arc at the cathode assembly. In the electrical configuration, an annular anode is used to transfer the arc. Previous report on this work also includes the theoretical study of particles nucleation and growth in the reaction section [4-6].

The presently reported results refer to a study of gas flow at nozzle and a sequence of modifications introduced in the anode assembly intended to increase energy and productivity efficiencies.

2. Experimental

Fig. 1(a) shows a schematic drawing of the experimental setup. A general description of the whole assembly was given elsewhere [3]. Fig. 1(b) physically shows the arc circuit, which includes a multi-gas and powder injection cathode assembly and a hollow anode.

Compared to the previously reported experiments [3], a main modification to be noted is the simplification of reactor assembly introduced by mounting the reaction section right below the plasma chamber (intermediate hot gas chamber removed).

Metal vapor is produced in the upper section, under inert (argon) atmosphere by injecting atomized Al powder into the arc [Fig. 1(b)], through the cathode assembly, using a SULTZER-METCO Dual Powder Feeder 4MP 800. Vapor phase reaction takes place at the outlet of the evaporation section as the hot metal vapor carrier gas is cooled by NH_3/N_2 gas jets. Powder is collected at the reactor walls, heat exchanger, and on a bag house

filter. Pressure drop in the filter is compensated by a vacuum pump in order to control reactor internal pressure.

Commercial atomized Al powder (Höganäs MG-300) was used as metal precursor. Tab. I shows the general plasma operating conditions used. Three different anode assemblies were tested to verify the effect of increasing degree of anode insulation (referred as Steps A, B, and C) on reactor performance, evaluated in terms of Al conversion to AlN: A) a single water cooled cooper ring, 100 mm i.d. (Exp. #32 - #38); B) a graphite tube, 80 mm i.d. x 115 mm long, supported by a water cooled cooper ring (Exp. #39 and #40); and C) a graphite tube, 90 mm i.d. x 120 mm long (no cooling water, Exp. #41).

After each experiment, the reactor was carefully cleaned and all the powder produced and condensates collected for the purpose of mass balance. The powder collected in the bag house filter was characterized for composition using x-ray diffraction and for average particle size using BET specific surface area (SSA) and transmission electron microscopy (TEM). Carbon content was analyzed by direct combustion using infrared detection.

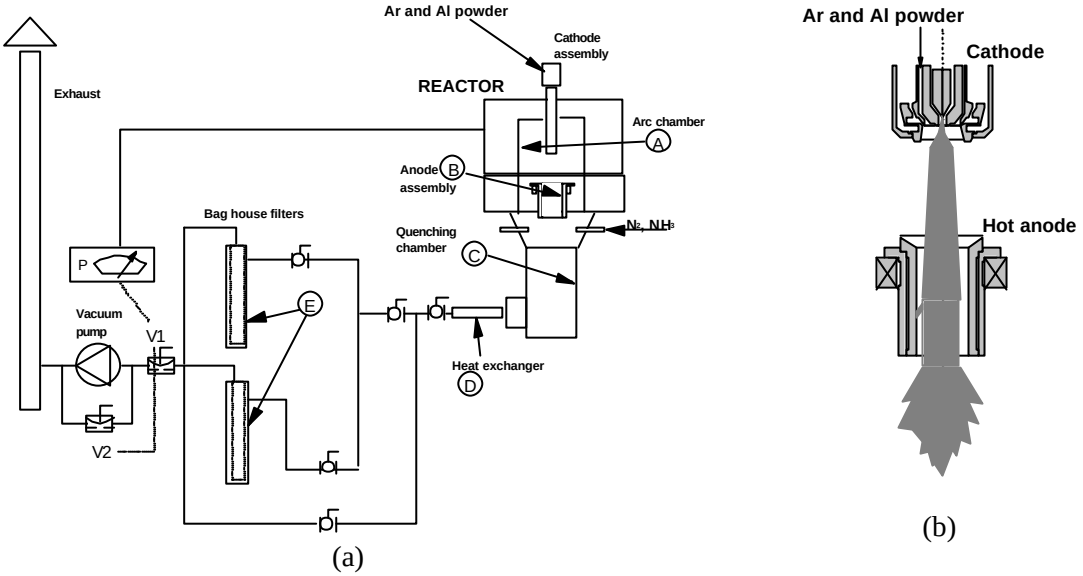

Fig. 1 – Schematic diagram of the synthesis reactor: a) hot anode assembly with bag house powder collection; letters indicate powder collection points for mass balance purpose; and b) illustration of the transferred-arc, showing the cathode and anode assemblies.

Total cooling gas flow rate (Ar/15%NH_3)	115 lpm

1) Arc length referred to the top of anode.

3. Results and discussion

Fig. 2 shows nozzle details, computational and experimental results for the near nozzle and evaporation chamber gas flow pattern. Given the nozzle design [Fig. 2(a)], the theoretical study focused on determining the most appropriate operating conditions in order to avoid as much as possible gas recirculation in the

vicinity of the water cooled nozzle. In practice, gas recirculation brings metal vapor laden hot gas into contact with cold, water cooled walls, which ultimately results in metal condensation in this region. A strong recirculation will result in the blockage of powder injection ports and interruption of metal powder supply.
The schematic drawing of Fig. 2(a) indicates the different gas injection ports: central hole (Q1); annular aperture around the cathode through which powder is injected using carrier gas (Q2); and a second annular aperture forming a gas sheath around the arc (Q3). The computational study using CFX shows the velocity vectors inside the nozzle [Fig. 2(b)].

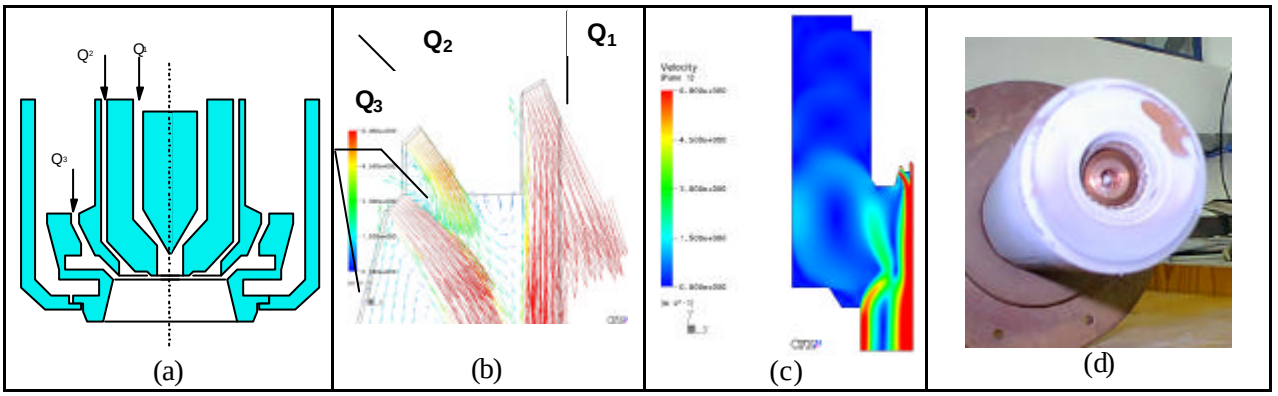

Fig. 2 – Schematics of the gas injection ports in the nozzle (a); velocity fields in the nozzle vicinity (b); and in the evaporation chamber (c); photograph of nozzle after experiment (d). Modeling results refer to: Q1 = 30 lpm (17.7 m/s); Q2 = 40 lpm (5.2 m/s); and Q3 = 30 lpm (11.8 m/s).

Tab. II – Operating data, mass balance considering the material collected in different regions of reactor according to Fig. 1(a), and powder specific surface area (SSA) of AlN powder produced.

Operating data and powder collecting place		Experiment Nr.						
		#32	#33	#37	#38	#39	#40	#41

Mass (%)	A (Al)	0.0	3.6	0.0	0.0	0.0	0.0	0.0
	B (Al)	76.4	59.9	76.8	55.0	38.1	7.3	57.5
	C (AlN)	25.3	22.0	22.1	44.4	43.5	18.5	26.5
	D (AlN)	8.4	8.6	9.4	19.5	67.3	22.4	5.3
	E (AlN)	5.2	4.1	6.6	7.1	6.7	5.4	7.1
Al converted (%)		25.4	22.8	25.1	47.0	77.4	30.5	25.6
xAl(plasma chamber) [1)]		0.031	0.050	0.018	0.027	0.033	0.043	0.047
xAl(reaction chamber) [2)]		0.008	0.012	0.005	0.013	0.025	0.013	0.012

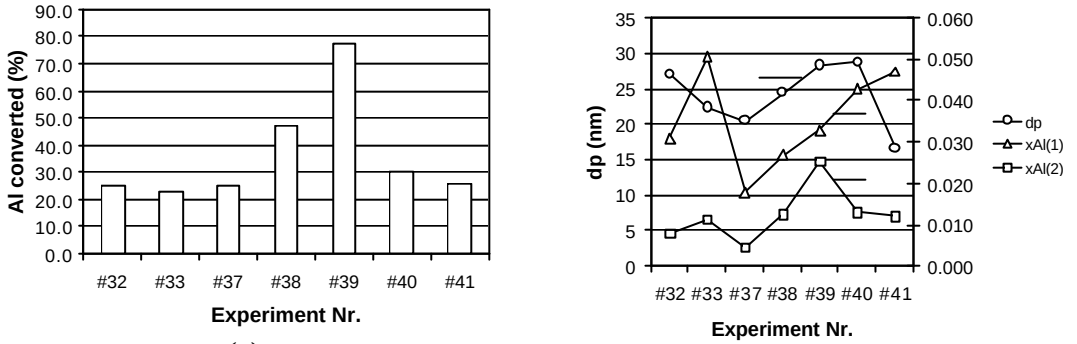
SSA (BET) (m^2/g)	68	82	90	75	65	64	110
Average particle size BET (nm)	27	22	20	24	28	29	17

1) xAl(plasma chamber)=gas mole fraction inside arc chamber, before condensation at anode;
2) xAl(reaction chamber)=gas mole fraction that enters reaction chamber;
3) Material collected above reaction chamber (A and B): predominantly condensed Al; reaction chamber and below: predominantly AlN (C, D, and E);
4) BET analysis refers to the powder collectedin the bag house (E).

Different flow conditions where simulated. Only the one with flow rates closer to the ones adopted for all the experiments reported is shown [Fig. 2(b)]. At the vicinity of nozzle cold wall the model indicates little gas recirculation. The cold flow pattern inside the plasma chamber indicates a strong central flow, directed

towards the tubular anode; and a lower intensity recirculation inside the chamber that brings hot gas into contact with the external wall of the cathode assembly [Fig. 2(c)]. Although plasma flow and temperature effects were neglected, the visual observation after the experiments indicates that little material deposition is observed inside the nozzle, and some deposition is verified on the external wall of the cathode assembly. These observations demonstrate a good agreement between modeling predicted results and practice [Fig. 2(d)], at about same gas flow rates. For the stated analysis purpose, the cold reactor simplification is considered to underestimate the potential of the present nozzle design (the results seen from the theoretical analysis are to the safety side). The plasma arc will in principle enhance both the flow outward the nozzle and in the plasma chamber due to cathode jet and gas expansion effects.

Data on operating variables for each experiment, the resulting mass balance considering the material collected in different regions of reactor according to Fig. 1(a), the evaluation of amount of converted Al, and powder specific surface area (SSA) of AlN powder produced are all shown in Tab. II. The operating time shown in this table refers only to the period during which AlN production is carried out. The total experiment time includes up to 1 h operation without powder and NH_3 injection, until steady state condition monitored by gas and water temperature measurement is reached. Converted aluminum percentage was determined as the ratio between total AlN collected and the total amount of Al feed into the reactor. The aluminum mole fraction (xAl) in the vapor phase shown was determined for the plasma chamber (before anode condensation), and reaction chamber (aluminum which in fact is brought to react), considering the total amount of gas fed through the cathode assembly and, respectively, the total amount of Al introduced and amount of AlN collected. The Al powder feed rate shown is the average figure determined from the given operating time and mass balance of aluminum in the powder feeder vessel before and after each experiment. The feed rates thus determined is in very good agreement with the value adjusted and made constant during each experiment.



(a) (b)

Fig. 3 – a) amount of aluminum converted in aluminum nitride for each of the experiments considered; b) specific surface area average particle size and aluminum mole fraction in the plasma [xAl(1)] and reaction [xAl(2)] chambers.

The bar plot shown in Fig. 3(a) indicates that Al conversion first increased with a more intense anode insulation (increase of anode temperature), from Step A to B, but decreased when the anode was even better insulated (from Step B to C). This decrease of conversion might be possibly result from intensified reaction between anode material and metal vapor as a consequence of a higher anode temperature. Average BET particle size and metal vapor concentrations of each experiment are shown in Fig. 3(b). For the set of experiments carried out with the Step A anode preparation, it is observed that the changes of Al concentration inside the plasma chamber [a direct consequence of the range of powder feeding ratio (2 to 5.8 g/min) tested] reflects on the Al(v) concentration determined for the reaction section. Because of a more intense Al(v) condensation on the anode, and eventually in the plasma chamber walls with greater feeding rates, a narrower correspondent range of change is verified in case of the reaction chamber Al mole fraction. Also, because of the interdependence of effects of both temperature and metal vapor concentration on supersaturation, and consequently on the definition of particle diameter, the data plotted in Fig. 3(b) do not allow any dear conclusion on this aspect.

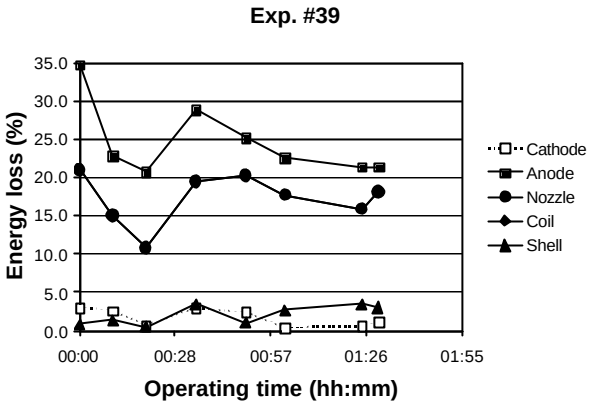


Fig. 4 - Energy loss to each of the water cooled parts of reactor (Exp. #39 shown as a typical case), expressed in percentage of total plasma arc power.

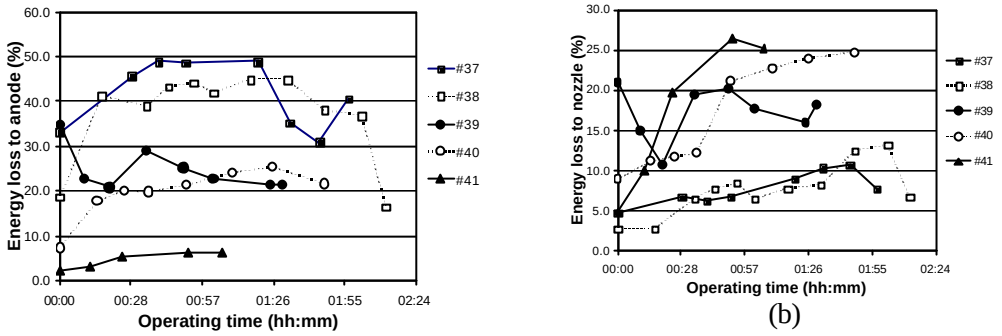

Fig. 5 – Energy losses for different degrees of anode insulation, shown as a function of operating time; Exps. #37 and #38 refer to insulation Step A; Exp. #39 and #40 to Step B, and Exp. #41 to Step C: (a) energy loss to anode; and (b) energy loss to the nozzle assembly.

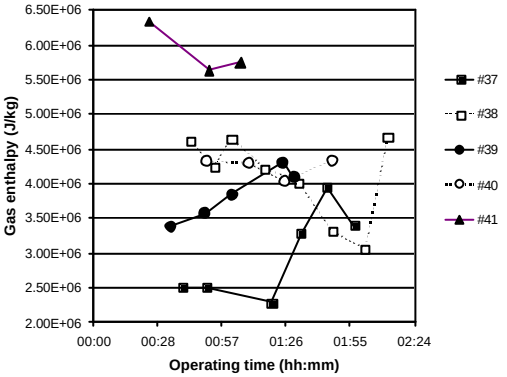

Fig. 6 – Gás enthalpy at the entrance of reaction section, evaluated base on calorimetric measurements.

As a typical example, heat losses determined based on calorimetric measurements for Exp. #39 are shown in Fig. 4. The most import losses are verified in the anode and nozzle assemblies. Considering experiments under different anode insulation levels as discussed before, energy losses to anode and nozzle assemblies are shown in Fig. 5 (a) and (b), respectively. Because of the progressive better insulation, energy loss to anode decreases from 30%-50% in Step A to 20%-30% and under 10%, Step B and C, respectively. Because a hotter anode results in more radiation loss, its heat losses to the water cooled nozzle assembly increases going inversely from Step C to Step A. The gas enthalpy evaluation based on calorimetric measurement is shown in Fig. 6.

A TEM micrograph and a x-ray diffraction pattern from a typical AlN produced is shown in Fig. 7. Samples of powders collected at the filter for Exp. #39 e #41 were analyzed for carbon: 0.38±0.1 %C (#39) and 0.61±0.02 %C (#41). Compared with Exp. #38, the greater C content observed for Exp. #41 possibly results from a greater amount of C sublimation.

4. Conclusion

A study including theoretical and experimental work focused on the development of a plasma reactor concept for the vapor-phase synthesis of fine particles was carried out. The theoretical study aimed to predict gas flow inside the cathode assembly nozzle in order to identify conditions which would led to metal vapor condensation and consequent blockage of gas and metal injection ports well agreed with experiment. Although plasma flow and temperature effects were neglected, the visual observation after the experiments indicates that little material deposition is observed inside the nozzle, and some deposition is verified on the external wall of the cathode assembly.

For three different anode cooling conditions tested, Al conversion was observed to reach a maximum with the increase of anode insulation. The decrease in conversion with higher anode insulation might be a possible consequence of increased reaction between anode material and the metal present in the gas phase resulting from a higher anode temperature.

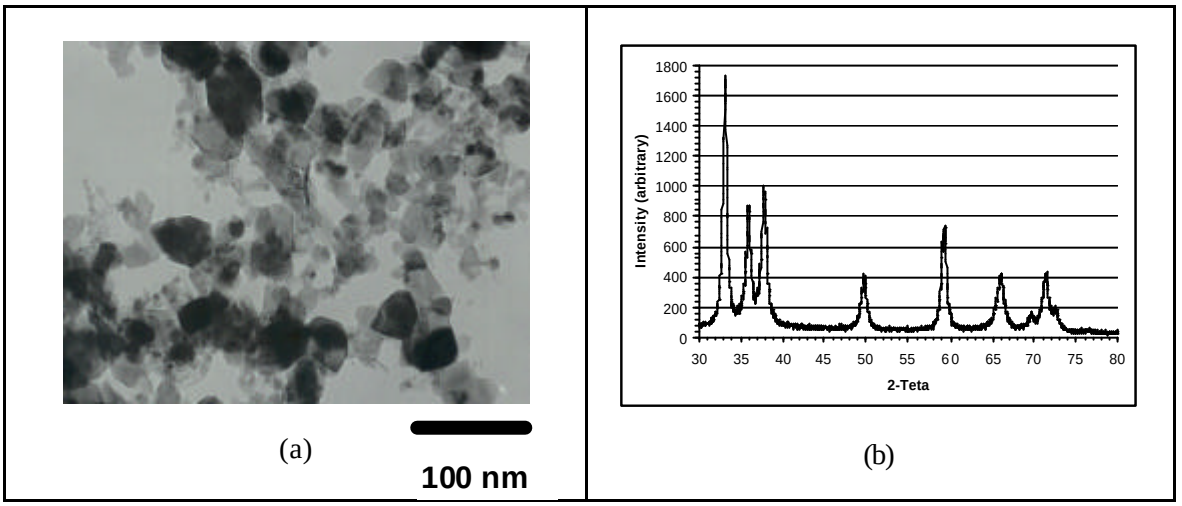

Fig. 7 – TEM micrograph (a) and x-ray diffraction pattern (b) of one of the AlN powder produced.

Abstract

Poly(ethylene terephthalate) track membranes were exposed to radiofrequency plasma generated in ammonia gas for different power and pressure values. The influence of the plasma treatment conditions on the surface topography, thickness, chemical composition, contact angle is studied. The transport properties (water permeability) of the plasma modified track membranes are presented and discussed in relation with the mechanisms affecting the chemical composition and structure of the membranes.

Keywords: Poly(ethylene terephthalate) track membrane, Plasma treatment of polymers, Water permeability;

1. Introduction

Among the technologies for separation of complex mixtures of liquids and gases that based on filtration through membranes are the most promising. The nuclear track membranes, obtained by irradiation of polymer films with high-energy ions and subsequent chemical etching of ions trajectories, play a key role in the separation processes [1]. Owing to certain properties, such as small thickness and high uniformity of pores, track membranes are responsible for their wide use in medicine, biotechnology, microelectronics and other engineering areas. The manufacturing technology of track membranes has recently developed in a new direction, the surface modification of membranes: the change in composition and structure of the surface layer, aiming to improve the filtration properties. There are various methods for surface modification of polymer materials by physical and chemical means. Plasma treatment is superior to other methods, as it allows a wide variety of compounds to be used. The new properties of the membranes produced in this way depend mainly on the chemical compound used. Related to that, a number of studies published recently were devoted to understanding of the plasma discharge effects on polymeric membranes [2-4], including the nuclear track ones [5-10]. These previous studies showed that the low temperature plasma of both non-polymerizing and polymerizing gases in various discharge conditions lead to modification of the membrane surface layer accompanied by the change of a number of properties, namely the adsorption, selectivity and the transport ones. Therefore the studying of these processes which depend on the plasma discharge parameters and the composition of the plasma-forming gas, aiming to the membrane properties improvement, is dictated by practical and scientific challenges.

In this paper the properties of poly(ethylene terephthalate) track membranes (PET TM) exposed to ammonia plasma were investigated. The influence of plasma treatment the conditions on the basic characteristics of the membranes, namely surface topography, chemical composition, thickness, water permeability, is reported and discussed.

2. Experimental

PET TM obtained by a standard procedure [1] with the thickness of 9.5 μm and the effective pores diameter of 0.220 μm (pore density $2 \cdot 10^8$ cm^{-2}) were under study. The plasma treatments were performed in a discharge chamber with two plan parallel electrodes, the upper electrode being RF powered (13.56 MHz, max. 500 W) and the lower being grounded. The electrodes were situated in a grounded stainless steel chamber (60 cm diameter, 30 cm height) provided with quartz windows allowing visual and spectral inspection. The gas (ammonia) was admitted through the perforated RF electrode (acting as a gas shower) via a mass flow controller. A mechanical pump, insuring a background pressure of 10^{-2} torr, pumped down the system. Membrane samples shaped as disks with area of 5.6 cm^2 were positioned on the grounded electrode, at 3 cm distance from the powered electrode. The schematic view of the experimental set-up can be found in reference [11]. The discharge parameters (gas

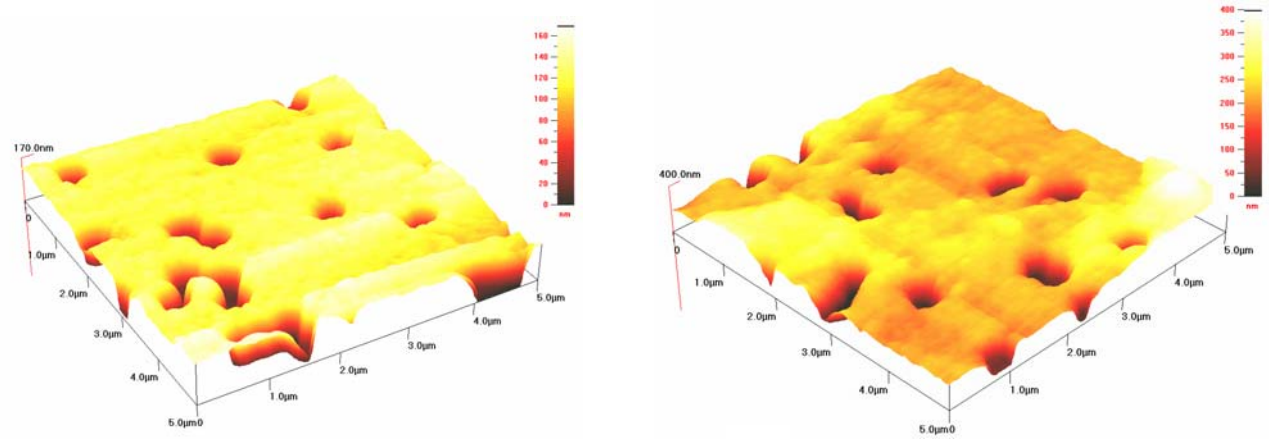
pressure in the vacuum chamber, discharge power) and the duration of the plasma action were varied. Only one side of the membrane was exposed to plasma.

The characteristics of the initial and modified membranes were determined through a series of complementary methods described in more detail in [8, 9]. The topography of the membranes was characterized by Atomic Force Microscopy (AFM, Q-Scope^{TM} Nomad^{TM}). The membranes thickness was determined with an electronic meter for thickness measurements (Unit Tesa, Austria). The contact angle was measured by the goniometric method. The ESCA spectra were recorded with the spectrometer Riber SIA-100 with MAC-2 analyzer (MgK_a, 100 W, 15 kV, 20 mA). The position of peaks (the binding energy values) was calibrated against the C_{1s} standard peak (284.6 eV). The permeability of water solutions was measured with a standard filtration installation FMO-2 (Russia) at a pressure drop $7 \cdot 10^4$ Pa on samples having an area of 254 mm^2.

3. Results and discussion

Surface topography

The modification of the membranes surface due to the plasma exposure was studied by AFM. Images of untreated (a) and ammonia plasma treated (b) PET track membranes are presented in Figure 1. The ammonia plasma exposure leads to a moderate increase of the surface roughness. The pores shape is modified as well, but not in a significant manner. These results can be compared with the results obtained in the case of similar treatments in air [11]. In that case the appearance of numerous craters on the originally smooth polymeric surface was revealed, the occurrence of which was explained by the difference in the etching rates of the amorphous and crystalline areas of the polymer [9]. The membrane surface got rough. The crater sizes varied with treatment conditions and increased with treatment duration. The comparative results indicate that the ammonia plasma is much less aggressive as compared to the plasma containing oxygen, and conserves better the surface topography.



a) b)

Fig. 1. AFM images of PET TM of 0.4 µm pore diameter for a) untreated membrane, b) treated in ammonia plasma at the discharge power 60 W , 10 min treatment time; gas pressure is 13.3 Pa.

Dependence of the membrane characteristics on the process parameters

The results of the measurements of the membranes thickness, effective pores diameter, and porosity for membranes treated for different time values and different power values are presented in Table I. Here, each value represents an average of at least three measurements. One can observe a slight increase of the effective pore diameters for the samples subjected to plasma. It testifies that during the plasma treatment there is an etching at the surface inside the pores. From the data represented in the table, it follows that the etching rate depends on the values of the discharge power: increase of the discharge power leads to an increase in the etching rate. Similar studies showed that the etching rate depends also on the pressure of plasma-forming gas. Increase of pressure

results in increase of the etching rate. More detailed analysis of the etching process in the ammonia plasma showed that the process develops in two stages: a first stage (short treatment time) when the etching rate is high and a second stage with lower etching rate [11].

Table I. Parameters of PET TM subjected to the ammonia plasma treatment at gas pressure 13.3 Pa

Discharge power, W	Plasma treatment time, min	Thickness, μm	Effective pore diameter, μm	Porosity, %	Water contact angle, deg
–	–	9.5	0.220	7.6	65
20	5	9.5	0.230	8.3	50
20	10	9.4	0.235	8.7	75
40	5	9.6	0.230	8.3	80
40	10	9.7	0.230	8.3	90
60	5	9.7	0.235	8.7	100
60	10	9.8	0.240	9.1	95
80	5	9.7	0.230	8.3	95
80	10	9.8	0.240	9.1	100

The process of PET TM etching by plasma containing oxygen was investigated in detail previously. In the previous studies of the effect of air [6] and oxygen [10] plasma on PET TM an increase in the diameter of the membrane pores was observed, as well. In those studies has been also shown that the plasma generated in these gases causes the etching of the polymer surface that leads to a reduction of the PET TM thickness. The data from the present experiments show that the effect of ammonia plasma on track membranes leads to a more complex dependence. In this case two competing processes are indicated by the results: etching of the polymeric matrix and re-deposition of a polymeric layer on their surface. At small treatment durations and low values of the discharge power the process of plasma etching is basically observed – a reduction of the membrane thickness testifies it (Fig. 2, curve 1). This is related to a rapid removal from the surface of the low weight material, which is formed on surface during the membrane fabrication by caustic etching and probably of the amorphous PET materials. At longer plasma treatments and a higher discharge power, a process of deposition of a polymeric film gets appearing. Increasing of the thickness of the membranes (Fig. 2, curve 2) and changing their color proves it. Reduction of the growth rate of the effective pore diameter at longer plasma treatment can be then, at least partially, connected to the re-deposition of a cross-linked polymeric film on the pore surface, whose formation is caused by polymerization of the products of etching the membrane matrix.

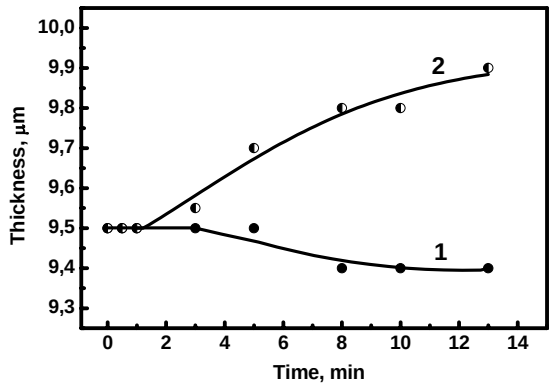


Fig. 2. Dependence of the thickness of PET TM on the treatment time in ammonia plasma at the discharge power 20 W (1) and 60 W (2); gas pressure is 13.3 Pa.

Chemical composition

The analysis of the ESCA spectra of the modified membranes shows the change of the chemical composition of their surface. The O_{1s}, N_{1s} and C_{1s} peaks belonging to the respective species were identified in the spectra. The presence of O_{1s} peak testifies that the oxidation of the polymer surface occurs. Most likely the oxidation appears when carrying the samples out on air.

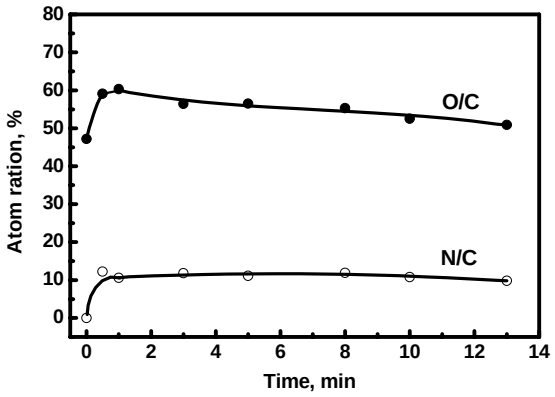

Fig. 3. The dependence of the relative content of atoms on the treatment time in ammonia plasma at the discharge power 40 W and gas pressure is 13.3 Pa.

In Figure 3 one can observe the behavior of the intensity of O_{1s} /C_{1s} and N_{1s}/C_{1s} ratios with the treatment time. At long times the ratios decrease somewhat with the plasma treatment duration. The abstraction of oxygen from the surface at long plasma treatment can be made due to ammonia plasma species, for example H atoms and NH radicals. The presence of N_{1s} peak proves that in the process of PET TM treatment in ammonia plasma, a fixing of nitrogen with formation of nitrogen-carbon bonds takes place. For long treatments the content of nitrogen, practically does not change with the treatment time. Thus, the treatment of PET TM in ammonia plasma leads to membrane functionalization.

Water permeability

The experiments showed that the water permeability usually decreases during the filtration process, with final values after 30 minutes in the range of 16 to 40% from the initial values. Both the initial values and the decrease rate are depending on the treatment conditions, as follows.

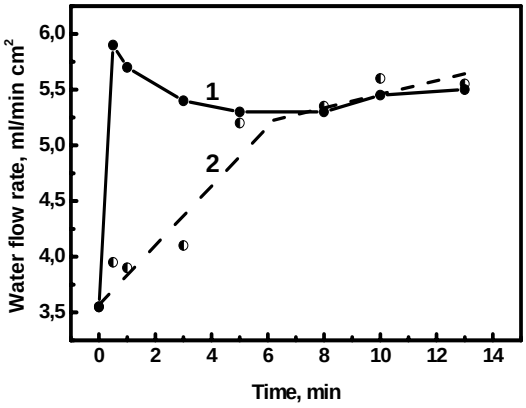

Fig. 4. Dependence of the water flow rate of PET TM on the treatment time, for discharge power 20 W (1) and 60 W (2); gas pressure is 13.3 Pa.

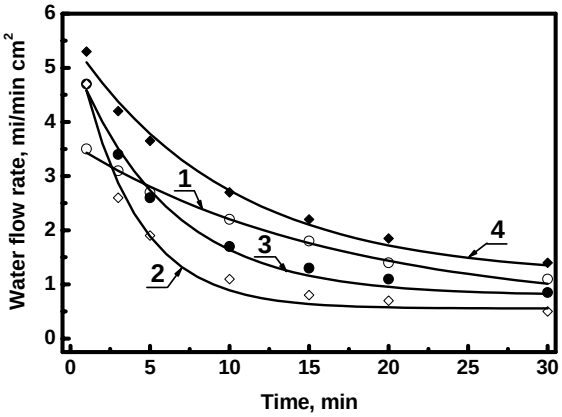

Fig. 5. Dependence of the water flow rate in time for initial PET TM (1) and membranes treated in ammonia plasma during 5 min at gas pressure is 13.3 Pa and the discharge power 20 W (2), 40 W (3) and 60

The initial water permeability dependence upon the treatment time exhibits a rapid growth at low discharge power (20 W) and short treatment times (Figure 4, curve 1), which is correlated with the increase of the pores size (Table I). This growth is followed by a slight decrease at longer treatment time which relates to the change of the hydrodynamic properties owing to the decrease of the membrane wettability [11]. At higher discharge power (60 W) one observes a gradual growth of the water permeability, reaching a plateau toward the long

treatment time region.
The curves describing the behavior of the water permeability during the filtration time, for membranes treated 5 minutes at different power values, are shown in Figure 5. The curves profiles depend strongly on the surface properties. A drastic decrease (to 16 % from the initial value) of the water flow rate in time (30 min) is observed in case of the membranes for which a reduction of the contact angle was produced by the treatment (power 20 W, Figure 5, curve 2). The decrease is slower for the membranes treated at higher power (Figure 5, curves 3 and 4), for which the increase of the contact angle was obtained by treatment, reaching up to 40% from the initial permeability value in case of membranes treated at 60 W. It results that the decrease of the hydrophilicity (reduction of the concentration of polar functional groups) in the surface layer leads to a higher filtrate volume in the course of filtration process. Thus, the results show that improved filtration performances as compared to the untreated samples are obtained for membranes containing smaller numbers of polar groups after the plasma treatment (Figure 5, curve 4).

4. Conclusion

Radiofrequency ammonia plasma treatments of PET TM were performed with various power levels and exposure times. The AFM investigations proved that ammonia plasma produces a moderate roughening of surface and a slight pore size modification. The ammonia plasma is less aggressive as compared to the plasma containing oxygen (air plasma), and conserves better the surface topography. The chemical analyses proved that functional groups are attached to the surface, mostly containing O and N atoms. These functional groups and the surface topography play a determinant role in changing membrane wettability, leading to surfaces which can be more or less hydrophylic in comparison to the initial ones.

The modification of surface properties entails the changing of the transport characteristics. In particular conditions of treatment the water permeability raises above that of the untreated samples. The use of such type of membranes can lead to considerable increase of the filtration processes efficiency.

Design and optimization of a miniature He-O_2 atmospheric pressure glow discharge torch for bio-applications

V. Léveillé, S. Coulombe and S. Yonson
Department of Chemical Engineering, McGill University, Montréal, Canada

Abstract
We report on the design and optimization of a novel miniature atmospheric pressure glow discharge torch (APGD-*t*) aimed at bio-applications. The APGD-*t* produces a 500 μm-diameter plasma jet which is ~3 mm-long with a gas temperature of ~45-55 ºC when operated at ≈1 W with 1-1.5 SLM He as the plasma-forming gas. We demonstrate that the use of a central capillary electrode to inject the source of reactive species in the He plasma afterglow is a more efficient way to produce the excited reactive species (O from O_2). Our optimization study reveals that the optimum O_2/He flow rate ratio is 0.3 v/v%.

1. Introduction

The interest in atmospheric pressure non-thermal plasma sources for bio-applications has grown considerably over the last decade (sterilization [1,2], surface functionalization [3], cell removal [4], and microcontact printing of protein on polymers [5]). In the field of local bio-applications, Stoffels *et al* [4,6,7] developed an atmospheric pressure unipolar RF "plasma needle", operating at power levels ranging from 10 to 100 mW. The plasma needle involves electrical coupling of the plasma source with the surface, and relies on diffusion to transport the reactive species to the substrate. To inhibit the electrical coupling between the plasma source and the surface under treatment, and to facilitate the transport of reactive species, we designed a miniature atmospheric pressure glow discharge torch (APGD-*t*). The design challenges associated with the APGD-*t* were the need to maintain a non-thermal equilibrium state in the plasma to minimize the thermal load to the substrates while maintaining a high degree of chemical reactivity, and to limit the rapid recombination of the reactive species in the plasma afterglow. The principal design characteristics of the APGD-*t* are: 1) the use of an amplitude-modulated high-frequency excitation source (RF), 2) the use of helium as the plasma-forming gas, 3) the injection of the source of reactive species through a central capillary electrode downstream of the plasma-forming region, and 4) the use of a torch configuration permitting the rapid transport of reactive species to the remote substrate. In this proceeding, we present the torch design, reveal the advantage of adding O_2 separately from the plasma-forming gas, and present the results of an optimization study aimed at enhancing the production of atomic oxygen.

2. Torch construction

A schematic of the APGD-*t* is presented in Fig. 1. The torch is made of two concentric electrodes; the central powered electrode is a stainless steel capillary tube while a silver epoxy painted on the plasma confinement quartz tube serves as the grounded electrode. The quartz tube also acts as a dielectric barrier in this DBD configuration. The outside and inside diameters of the quartz tube are 4 mm and 2 mm, respectively. The capillary electrode is 0.3556 mm-outside diameter by 0.1778 mm-inside diameter. The entire torch is approximately 10 cm long and held together with a Swagelok® tee. The downstream end of the quartz tube is shaped into a converging nozzle with an exit diameter of 500 μm. The plasma-forming gas, helium, is injected through the side arm of the tee and O_2, the source of reactive species used in this study, can be injected either in the capillary electrode or with the plasma-forming gas. This torch design allows easy translation of the capillary electrode by sliding it inside the lower Teflon fittings.

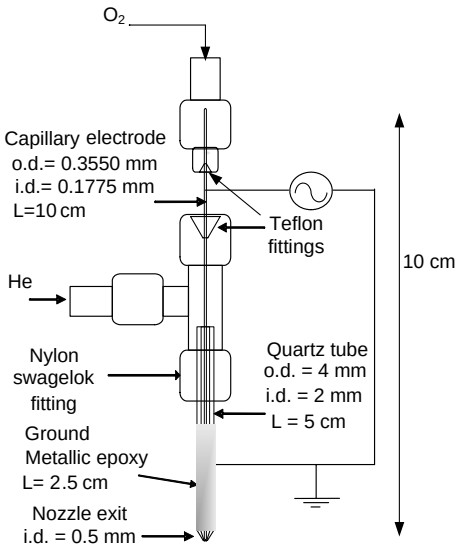

Figure 1: Schematic of the APGD-*t*

Under a typical configuration, the capillary electrode tip is recessed by a few 100's µm from the nozzle exit plane (see Fig. 2 - left). Fig. 2 (right) shows the beveled capillary electrode tip as well as some degree of melting at the capillary tip due to local heating (the capillary electrode was translated to the left for clarity). The position of the capillary electrode along the torch axis is crucial for the formation of a relatively long and straight jet, and for the efficient generation of O atoms. If the capillary electrode is located outside of the nozzle, the strong electrical field created at the capillary electrode tip favors the excitation of air molecules at the expense of dissociating O_2 into O, freeing electrons, and exciting He atoms to metastable states (i.e. excited radicals are formed by electron-impact dissociation and excitation, and by other collisional processes involving He metastables). When the tip of the capillary electrode is slightly recessed inside the nozzle exit, the gap delimited by this electrode and the inside surface of the quartz confinement tube becomes very small (72 µm when perfectly aligned in the middle of the nozzle exit) thus favoring the acceleration of the plasma flow and the excitation of the plasma-forming gas. This position also favors the mixing of the reactive species injected through the capillary electrode with the flowing plasma-forming gas and thus, with the plasma electrons and He metastables. Finally, since most of the plasma volume is occupied by the main plasma-forming gas (He), the electrical characteristics and stability of the plasma torch are not significantly affected by the nature of the gas used as the source of reactive species. The breakdown voltage of the APGD-*t* is relatively low due to the geometrical amplification of the electric field (~ 220 $V_{peak\text{-}to\text{-}0}$ in He [8]).

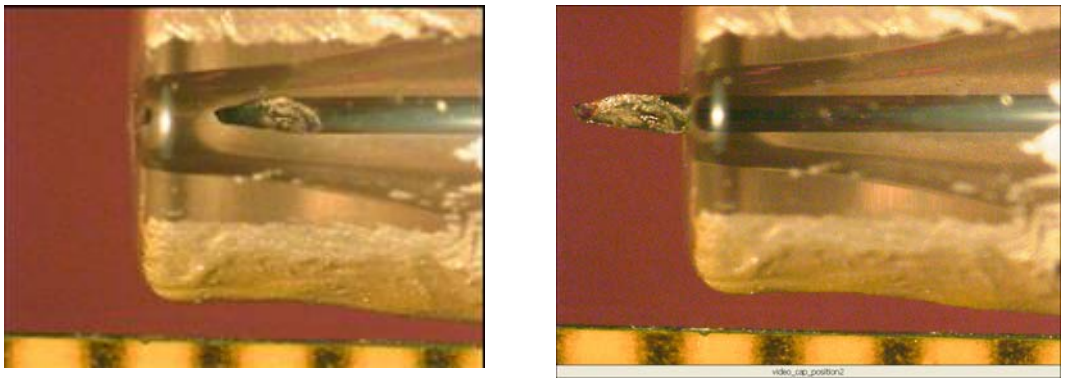

Figure 2: Left - Picture of the nozzle end of the APGD-*t* with the capillary electrode ending ~600 µm upstream of the nozzle exit plane. Right - Same picture but with the capillary electrode translated outside the nozzle. Scale is in mm.

3. Experimental considerations

The APGD-*t* is powered by a RF signal generated using an arbitrary waveform generator (HP 33120A, 15 MHz bandwidth) set at a carrier waveform frequency of 13.56 MHz, and amplitude-modulated (10-50% duty cycle) by a variable duty-cycle square wave generator (Racal-Dana model F64 AM-FM-sweep-trig/pulse-function generator). The use of a 10-50% duty cycle allows a continuous modulation of the APGD-*t* power over the ~1-5 W[8] range. A 10% duty cycle is used in the present study. The signal is amplified with a broadband RF amplifier (Amplifier Research 75A250, 75W, 10 kHz-250 MHz, 50 Ω input/output impedances). A homemade series inductor is used as matching network and provides near-resonance circuit conditions. The electrical power delivered to the APGD-*t* is deduced from measurements [8] of the torch voltage, circuit current and phase angle between both signals using a fast digitizing oscilloscope equipped of two probes (Passive voltage probe: Tektronix P6139A, 10X, 500 MHz, 10 MΩ, 8 pF; Current probe: Tektronix CT-2 current transmitter, 1mV/1mA into 50 Ω, with a Tektronix P6041 probe, 1X; Digital oscilloscope: Tektronix TDS3054B, 500 MHz, 5 GS/s). The voltage and current measurements are transferred to a PC through a GPIB interface and displayed on a LabView™ interface. A PID control loop is used in order to regulate the torch power and monitor the operating parameters. Helium (99.998 % purity) or a certified mixture of He + 1 v/v% O_2 (±5 %) is used as a plasma-forming gas. Extra dry oxygen (99.6 %, 5 ppm impurities) can also be injected through the capillary electrode as

a source of reactive species. The gas flow rates are regulated using thermal mass flow controllers (Qualiflow, AFC 80 MD). The plasma jet temperature is measured using a 0.5 mm-OD, ungrounded and shielded type K thermocouple. Pictures and optical emission spectra of the plasma jet were captured with a telemicroscope (Edmund Optics, 16X) and a low-resolution UV-VIS spectrometer (Ocean Optics USB2000). A bi-convex lens (50 mm-diameter, 15 cm focal length) was used to collect the plasma emission and to focus it onto a 400 μm optical fiber attached to the spectrometer.

4. Results and discussion

4.1. Telescopic images of the plasma jet

In figure 3, pictures of the jet are presented for three different flow rates of helium and a torch power of ≈1W (no O_2 added). Under typical operating conditions, the plasma jet is approximately 2 to 4 mm-long (the jet diameter at the nozzle is 500 μm). One can distinguish a bright (whitish) plasma core surrounded by a blue plume. The whitish plasma core is characteristic of the He plasma emission while the bluish afterglow is attributable to the optical emission from species produced from the N_2 and O_2 molecules present in the ambient air and entrained in the plasma afterglow. The pictures reveal that an increase of the He flow rate elongates the jet. Higher axial plasma flows are beneficial to the transport of excited reactive species to a remote substrate since the ratio of the recombination time scales over the convective transport time scale is higher. On the other hand, larger flow rates involve higher He consumption and more momentum transfer to the substrates which, in the case of bio-applications, might not be mechanically strong (ex. cells attached on a petri dish). The picture of the plasma jet on Fig. 3a best reveals a structure near the nozzle exit that might originate from sonic flow conditions. To verify this hypothesis, we used the one-dimensional adiabatic flow approximation (assuming a local isentropic flow, no friction) to determine the flow conditions prevailing at the nozzle exit. We found that a 0.5 SLM He annular flow passing through the nozzle exit with a gas temperature up to 315°C gives Mach numbers < 0.06, thus discarding, *a priori*, the sonic flow hypothesis. Additional STP flow calculations revealed that an annular flow rate of 6 SLM He at the nozzle exit is required to reach a Mach number of 1. It is not clear at this point if other mechanisms such as the thermal expansion of the gas or some sort of EHD or MHD pumping can contribute to the flow acceleration. Future work will focus on a more detailed analysis of the plasma jet hydrodynamics. Nevertheless, it is important to note that supersonic flow conditions would be beneficial in the context of the applications sought: the excited reactive species would be transported further downstream than under subsonic conditions.

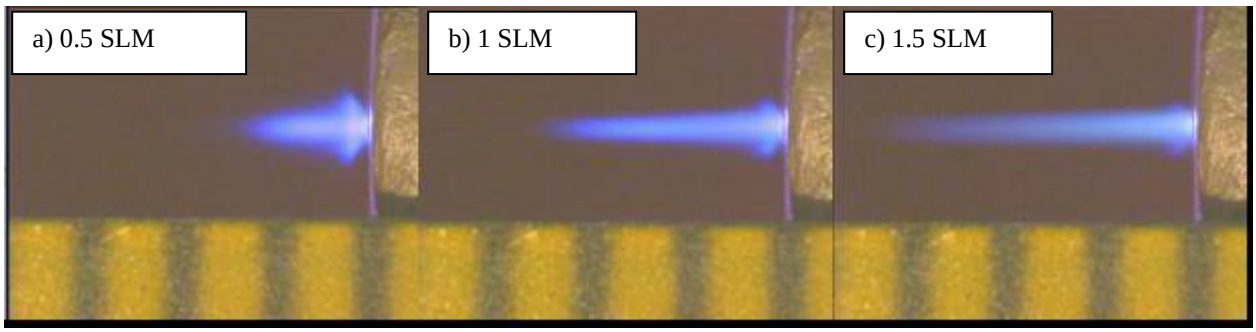

Figure 3: Pictures of the plasma jet produced by the APGD-*t* operating at ≈1 W for different He flow rates.

Fig. 4 presents a comparison of the visual appearance of the plasma jet when O_2 is injected in the capillary electrode (10 SCCM O_2, Fig. 4b) or added to the plasma-forming gas (1v/v% of O_2 in He is equivalent to 10 SCCM in the capillary electrode, Fig. 4c) with an helium flow of 1 SLM (He only, Fig. 4a). The injection of 10 SCCM O_2 in the capillary electrode leads to a slight reduction of the plasma jet length, while the injection of an equivalent amount to the plasma-forming gas leads to a drastic reduction of the length. Such decrease in optical emission implies a decrease in the density of excited atomic and molecular species having radiative transitions in the visible range. Since several excitation channels involve collisions with electrons and He metastables, the

decrease of the optical emission can be seen as a reduction in the density of those populations. The actual situation is slightly more complex though. Our preliminary investigation of the jet using optical emission spectroscopy [8] revealed that the emission from excited atomic O increased with O_2 injection through the capillary electrode and collapsed with the injection of O_2 with the plasma-forming gas. We infer from this that the electrons and He metastables are used to dissociate and excite the O_2 injected through the capillary electrode at the expense of N_2 (ambient air) dissociation/excitation. With O_2 injected with the He flow, a drastic overall reduction of the optical emission is observed suggesting that the plasma in the plasma-forming region is quenched.

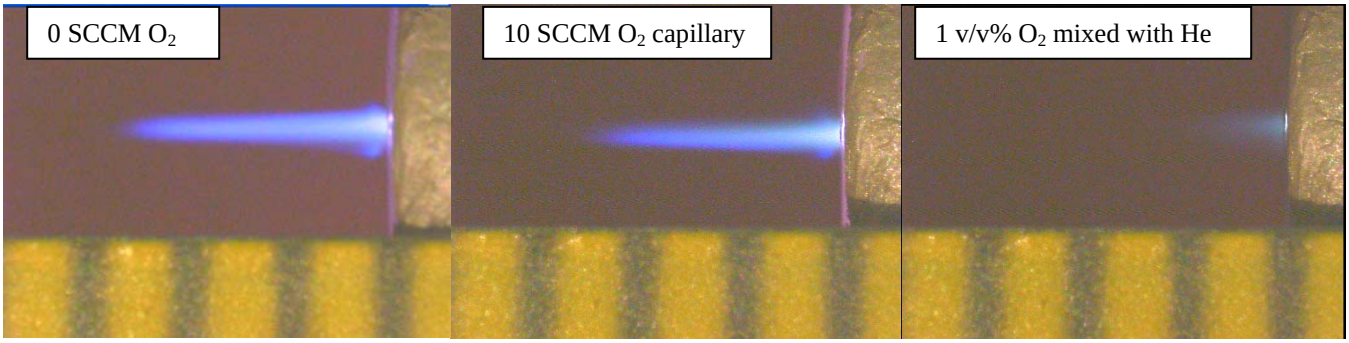

Figure 4: Pictures of the plasma jet at ≈1 W and 1 SLM He (left) with 10 SCCM O_2 injected through the capillary electrode (center) or with 1 v/v% O_2 added to the plasma-forming gas (right).

4.2. Optical emission spectroscopy analysis

From the telescopic image analysis and the preliminary spectroscopic investigation [8], we found that adding O_2 through the capillary electrode was more efficient than adding it with the plasma-forming gas. We then optimized the amount of O_2 added in the capillary electrode in order to get the maximum generation of O atoms. We used as a measure of the atomic O production the peak intensity of the excited O line at 777 nm, measured in the nozzle exit plane along the jet axis. Figure 5 shows the relative intensity profiles of the O (777 nm) line along with some other monitor lines of He and N_2. All emission intensities are normalized with respect to the maximum emission intensity of the O (777 nm) line. As can be seen in Fig. 5a (1 SLM He at ≈1 W), 3 SCCM of O_2 injected in the capillary electrode produced an emission maximum from the O (777 nm) line. This flow rate corresponds to a O_2/He volumetric ratio of 0.3%. The gas temperature under those conditions is ~55°C. (Note that this gas temperature can be slightly too elevated for bio-applications - i.e. skin and cells treatments - and thus, a continuous movement of the torch over the surface of interest might be required in order to reduce the local thermal load).

The He gas flow rate too was optimized to reach the maximum emission from the excited O atoms. During this series of experiments, the O_2/He volumetric flow rate ratio of 0.3% was kept constant independently of the He flow rate and torch power. As can be seen in Fig. 5b, the increase in He flow rate causes an increase of the excited O emission (777 nm line) at the nozzle exit. One can attribute this phenomenon to a more significant axial transport: the isolines for the particle densities are stretched further downstream with the increase of the plasma gas flow. At 1.5 SLM He, the production of excited O atoms is highest and the gas temperature is slightly lower than at 1.0 SLM due to the increased convective cooling (~45 °C versus ~55 °C). It is interesting to note that the intensity of the He (706 nm) line seems to saturate around 1.5 SLM while the O (777 nm) line does not. This phenomenon can be attributed to the fact that the upper energy level of the He (706 nm) transition is much larger than the O (777 nm) transition (22.72 eV versus 10.74 eV). By optimizing the production of excited He atoms we, in turn, optimize the production of metastable He atoms (upper energy levels ~20 eV). Since the metastable states have much longer lifetimes, those species will be found even further downstream the plasma jet and potentially, contributing too to the formation of excited O. The increase of the He flow rate has another positive effect: the reduction of air entrainment in the plasma jet (see Fig. 5d). At a flow rate of 0.5 SLM

He, the spectral emission of one of the strong emission lines of air, N_2 at 357 nm, is as strong as the spectral emission lines of He (706 nm) and O (777 nm) reported in Fig. 5b and Fig. 5c, respectively. However, for He flow rates of 0.75 SLM and higher, the emission from the N_2 line becomes much less significant than for the He and O lines.

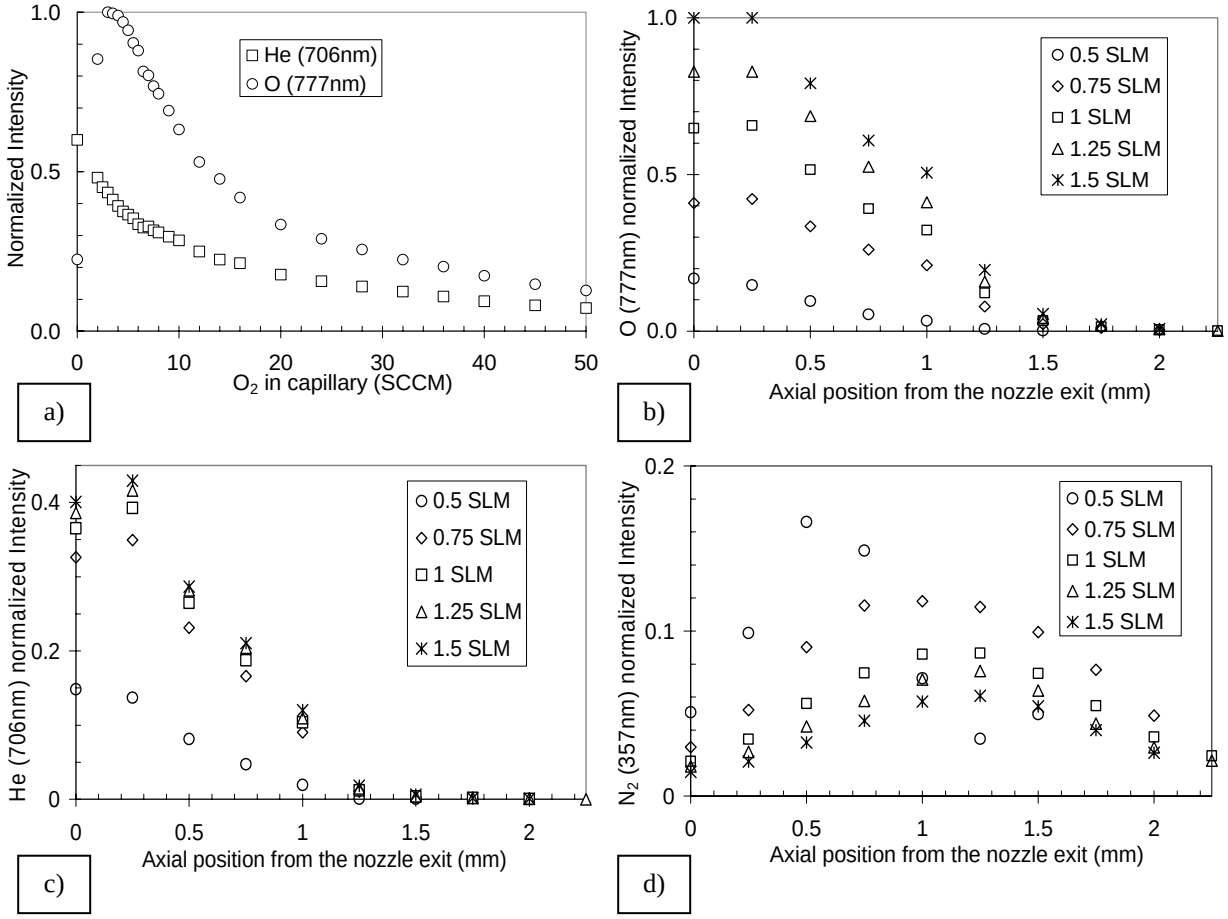

Figure 5: Normalized peak line emission intensity of a) O (777 nm) and He (706 nm) at the nozzle exit for different flow rates of O_2 in the capillary electrode. Axial distribution of the normalized peak line emission intensity of b) O (777 nm), c) He (706nm) and d) N_2 (357 nm) for different He flow rates.

5. Concluding remarks

The main goals of this report were to present the design of a novel atmospheric pressure glow discharge torch (APGD-*t*) specifically designed for bio-applications, and to reveal the advantages of injecting the source of reactive species (O_2) downstream of the plasma-forming region (He) and the operating conditions which optimize the production of O atoms (reactive species). The APGD-*t* operating at ≈1 W in a 1.5 SLM flow of He produced a small-scale plasma jet (~3 mm long by 500 μm diameter at the nozzle exit) with a gas temperature of ~45 ºC, which is suitable for bio-applications. A volumetric O_2/He ratio of 0.3% gave rise to the maximum production of excited O atoms. In future work, He metastable and ground state O atoms will be monitored by laser-induced fluorescence spectroscopy in order to validate/invalidate the assumption that He metastable atoms participate in the production of ground state O atoms, and to see if the highly reactive O atoms reach the bio-surface of interest.

Acknowledgments
The authors wish to thank Luciano Cusmich, Frank Caporuscio, and Alain Gagnon for their technical assistance. The project was funded by the National Sciences and Engineering Research Council of Canada (NSERC), through the Discovery and Canada Research Chairs programs, the Fonds québécois de la recherche sur la nature et les technologies (FQRNT), and McGill University.

Plasma-Assisted Synthesis of Pre-Coated C_{60} Nanopowders from a Mixed Fullerenes Source

S. Coulombe, A. Tariq and J. –L. Meunier

Department of Chemical Engineering, McGill University, Montreal (QC), Canada

Astract
C_{60} nanopowders were produced by in-flight exposition of C_{60} molecules sublimed from a C_{60}-rich mixed fullerenes source to a continuous flow ethane plasma sustained by RF capacitive coupling. TEM et SEM micrographs of the deposits reveal nanopowders of size ranging from 30 to 50 nm, and agglomerates of those nanopowders. Conversely, micrographs of powders produced in an inert argon plasma show large μm-sized crystallites.

1. Introduction

There is a growing interest for the development of synthesis techniques for the production of coated nanoparticles. The driving force for such development activities lies in the inherent difficulties associated with the high surface energy of nanoparticles. Examples of application of such new production techniques include the passivation of metal nanoparticles for safer and easier handling considerations, to the enhancement of dispersion properties and compatibility of nanoparticles with host materials in nanocomposites. Examples of emerging applications are found in biosensors, heat and electrically conducting polymer films, and strengthened polymers. Nanofluids and ferrofluids, which constitute a relatively new class of liquid composite materials, emerge as advanced materials also taking advantage of the unique properties associated with metal nanopowders suspended in an organic medium. The key challenges one faces when processing nanocomposite materials are associated with the compatibility of the nanopowders with the host material, the stability of the suspension, the control of the mutual agglomeration, and the handling of the nanopowders.

Two general processing routes leading to the synthesis of polymer nanocomposites are commonly reported in the literature ([1] and references therein). The *in-situ* approach whereby nanoparticles are synthesized in a solution (wet chemistry) and then the polymer is formed around the nanoparticles. A second, *ex-situ* approach whereby the nanoparticles are first synthesized and stabilized, and then introduced into the polymer matrix through mechanical means. The first approach is based on chemical precipitation and generally involves numerous wet-chemical steps. The second approach involves the use of nanoparticles pre-coated with a thin layer of a material compatible with the host matrix, as precursor materials for nanocomposite fabrication. An interesting aspect of this approach is that the nanoparticle synthesis and nanocomposite formation processes can be isolated and thus, developed and optimized independently. Vollath and Szabó [2] developed a sequential microwave plasma-assisted process whereby nanoparticles coated with ceramic or polymeric materials are synthesized. This process development led to the present work where the synthesis of pre-coated C_{60} nanopowders is considered. Such powders represent potential candidates for nanocomposite and nanofluid applications due the high thermal and electrical conductivities, optical properties as well as physico-chemical stability of C_{60} [3].

2. Experimental details

In this study, pre-coated C_{60} nanopowders are produced from a commercially available C_{60}-rich mixed fullerenes source. The process is sequential and consists in three steps: i) the selective sublimation of C_{60} molecules from the mixed fullerenes extract; ii) the synthesis of nanopowders by gas phase nucleation and growth; iii) the coating of the nanopowders through in-flight plasma polymerization. The rationale that led to the development of this process consists of four aspects: i) Fullerenes C_{60}, have a significant

vapor pressure at modest temperatures [4]. ii) Fullerenes C_{60} are inclined towards polymerization through the formation of covalent bonds between cages but also tend to readily react with functional organic groups [5]. Thus, C_{60} nanopowders of desired size can potentially be synthesized by controlling the residence time of the fullerenes C_{60} in a nanopowder formation zone prior to their exposure to a surface stabilization process. iii) When injected into a weakly-ionized plasma and exposed to the electron gas, nanoparticles develop a negative floating potential due to the build-up of surface charges [6]. The repulsive electrostatic force that develops amongst nanoparticles is expected to play a role in the control of the mutual agglomeration process caused by van der Waal interactions. iv) Plasma polymerization reactions involving a foreign monomer gas and the growing C_{60} nanopowders will terminate their growth by encapsulation. It has been shown recently that the conditions leading to plasma polymerization onto nanoparticles are readily achieved using a monomer gas which produces the methyl radical upon dissociation in the plasma environment [7].

A schematic diagram of the plasma system is shown in Fig. 1A. It consists of three sequential units: (i) the C_{60} sublimation unit, (ii) the nanopowder synthesis tube, and (iii) the tubular plasma polymerization reactor where an optional substrate can be inserted. The C_{60} sublimation unit consists of a quartz piece fabricated to hold mixed fullerenes samples in powder form and to allow inlet for gases (Fig. 1B). Four cartridge heaters uniformly distributed inside a brass furnace are used to bring the powders to the desired temperature (typical range: 500-700 ^{o}C). The sublimed C_{60} molecules and growing nanoparticles are introduced in the plasma reactor along with the carrier/plasma polymerization gas through a narrow quartz tube. The plasma polymerization reactor consists of a 60 cm-long x 4 cm-ID quartz tube with two electrodes mounted externally, whereby a 13.56 MHz RF capacitively-coupled plasma is maintained. The chamber is evacuated with a mechanical pump to a base pressure of approximately 8 mTorr. The pressure during operation with a gas flow is regulated using a manual flow valve. Substrate discs can be placed normal to the flow of gases/nanopowders in order to collect plasma polymerized films and nanopowders.

The raw material used was a refined mixed fullerenes extract purchased from MER Corporation (USA) and having a composition of 75% C_{60}, 22% C_{70} and 3% higher fullerenes. Approximately 10 mg of mixed fullerenes were used every run. Prior to the initiation of the plasma surface treatment, the chamber was evacuated to the base pressure while the temperature of the fullerene extract was brought 50 ^{o}C under the desired process temperature. In order to avoid significant deposition of C_{60} nanoparticles on the substrate before the plasma treatment, the substrate was pushed forward to its desired location just before the treatment started (1 cm to the right of the electrodes' edge). The extract temperature was then ramped to 50 ^{o}C above the desired value over the 10 min plasma treatment time, such that the average temperature during the treatment was near the desired value (550 ^{o}C). The other process conditions were: a 0.025 slm flow of either argon or the monomer gas; a chamber pressure of 133 Pa; and a plasma power of 30 W. Ethane, C_2H_6, a commonly used organic monomer gas was used for the in-flight plasma polymerization onto the growing nanopowders. The same gas was used with success for the in-flight coating of amorphous SiO_2 nanoparticles [7]. The nanopowders were collected from the reactor walls and from Si substrates following treatment in first, an inert argon plasma and then, in the reactive C_2H_6 plasma. The morphology of the nanopowders collected from the reactor walls in the inter-electrode region were analyzed using transmission electron microscopy (TEM) while the morphology of the granular deposits (nanopowders) and organic films formed on the substrate was analyzed using scanning electron microscopy (SEM). A FTIR-ATR analysis of the films obtained in both cases was performed in order to determine their chemical composition.

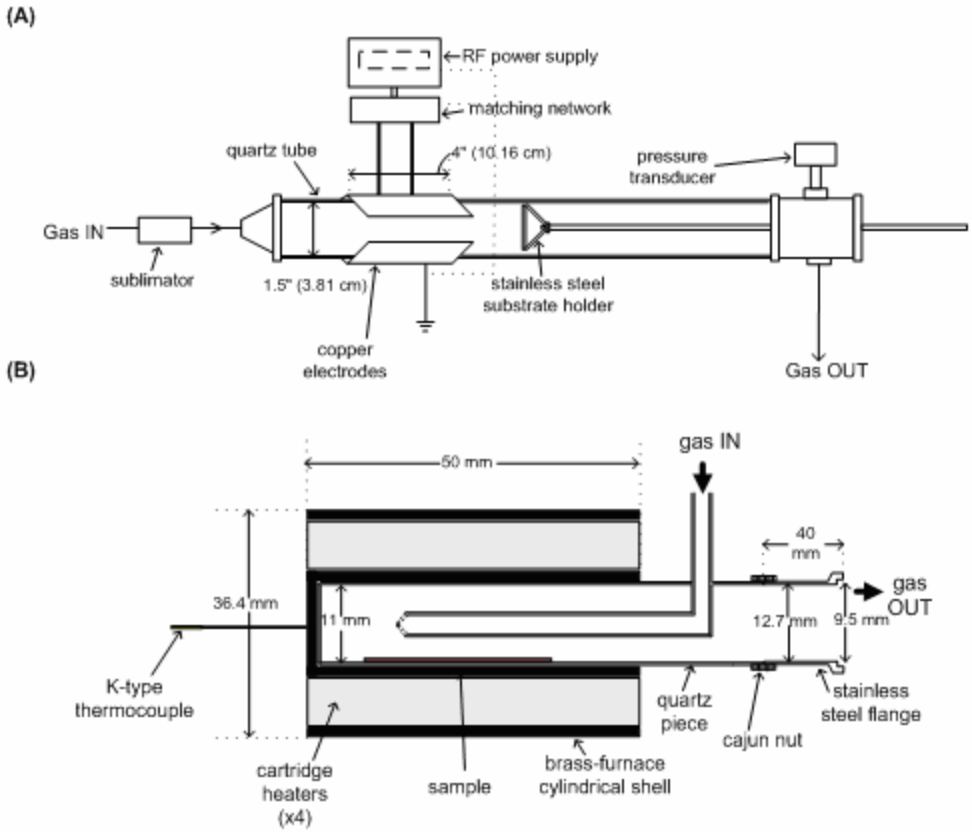

Fig. 1. (A) Schematic diagram of the equipment. (B) Lateral view of particle injector.

3. Results and discussion

Figure 2 shows the contrasting morphological differences between a sample of the as-received mixed fullerenes extract and the nanopowders deposited on the reactor walls during treatment with ethane. The as-received samples (Fig. 2(A-C)) show a significant agglomeration of the particles with no distinct features, resulting in plate-like structures. In contrast, the micrographs of Fig. 2(D-F) reveal fullerene nanopowders of size ranging from 30 to 50 nm and glued together with a translucent coating.

The images on Fig. 3 show the morphology of the deposits obtained on a Si substrate via sublimation and transport of the fullerenes in argon (Fig. 3(A)) and in ethane (Fig. 3(B)), followed by in-flight exposure to the RF plasma of the same gas. In this geometry, the growing nanopowders have a longer residence time in the plasma while the substrate benefits from a higher mass transfer rate due to its perpendicular exposure to the flow. While the treatment of the fullerenes in an inert atmosphere leads to the formation of crystallite-like structures (> 1 μm in size) and several μm-large aggregates, the treatment using ethane gives rise to the formation of 100 to 200 nm-diameter aggregates dispersed over the substrate. The aggregates appear to be made of smaller nanopowders, comparable in size to the ones observed on the reactor walls. A careful look at the nanopowders of Fig. 3(B) reveals that the morphology of the coating on their surface is very similar to the coating on the adjacent Si substrate (Fig. 3(C) & 3(D)). In fact, the individual nanopowders appear to be encapsulated and isolated from each other by a film, and glued altogether into a larger aggregate by the same film. Unfortunately, it was not possible to study the chemical composition of the coating deposited onto the nanopowders.

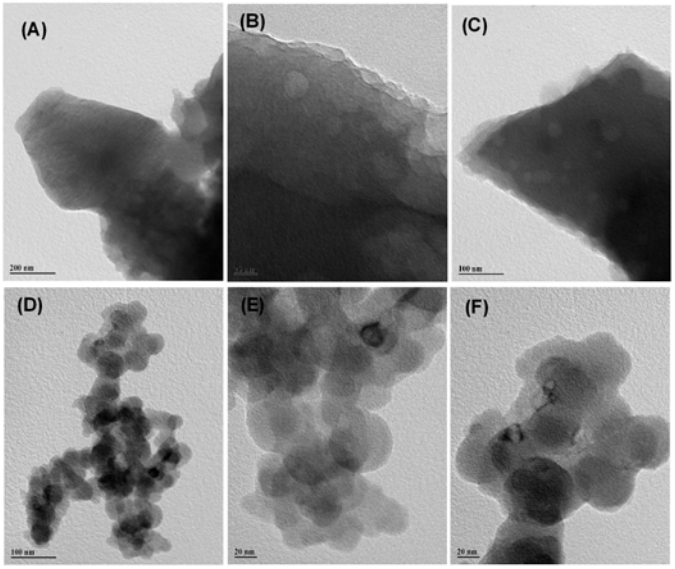

Fig. 2. (A-C) TEM images of untreated fullerene samples. (D-F) TEM images of pre-coated fullerene nanopowders produced with the ethane plasma.

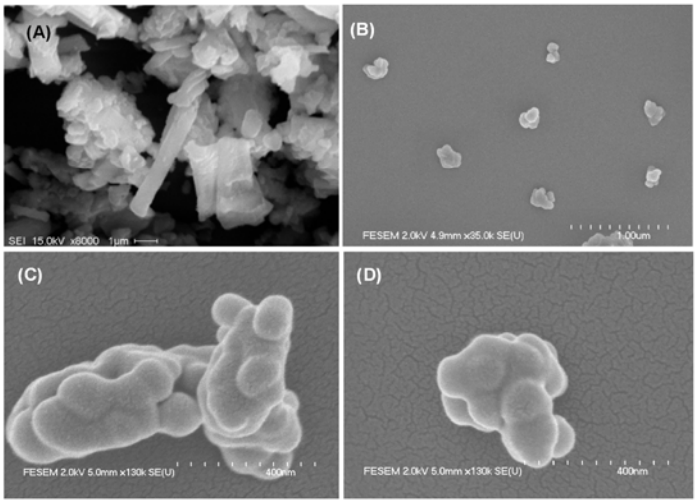

Fig.3. SEM images of the deposits obtained via C_{60} sublimation and transport in argon (A) and ethane (B) followed by exposure to the plasma of the same gas. (C-D) Close-up views of nanopowders obtained in (B).

Figure 4 presents the ATR-FTIR absorbance spectra of the films and granular deposits obtained. Fig. 4(a) shows the spectrum of a pure polyethylene (PE) film manufactured by 3M. Fig. 4(b) shows the spectrum of the polymer film deposited on a substrate under typical experimental conditions but without fullerene sublimation. Peaks of interest that match the pure PE spectrum correspond to the C-H rock and bend excitations around 2900 and 1470 cm^{-1}, respectively, thus confirming the organic nature of the film. The absence of the C-H stretch bands beyond 3000 cm^{-1} indicates lack of unsaturation. Fig. 4(c) shows a spectrum obtained with the granular fullerene films deposited via sublimation and condensation in the inert argon plasma. This spectrum features strong absorbance peaks near 1429 and 1183 cm^{-1}, two characteristic peaks of fullerene C_{60}. It is worth noting that, while monitoring the optical emission from the argon plasma seeded with the fullerenes using a low-resolution spectrometer (Ocean-Optics

USB2000) equipped with an optical fiber, no significant optical emission from the C_2 Swan band around 516 nm was recorded. One would expect to observe C_2 molecular emission from the plasma if fragmentation of the C_{60} occurred.

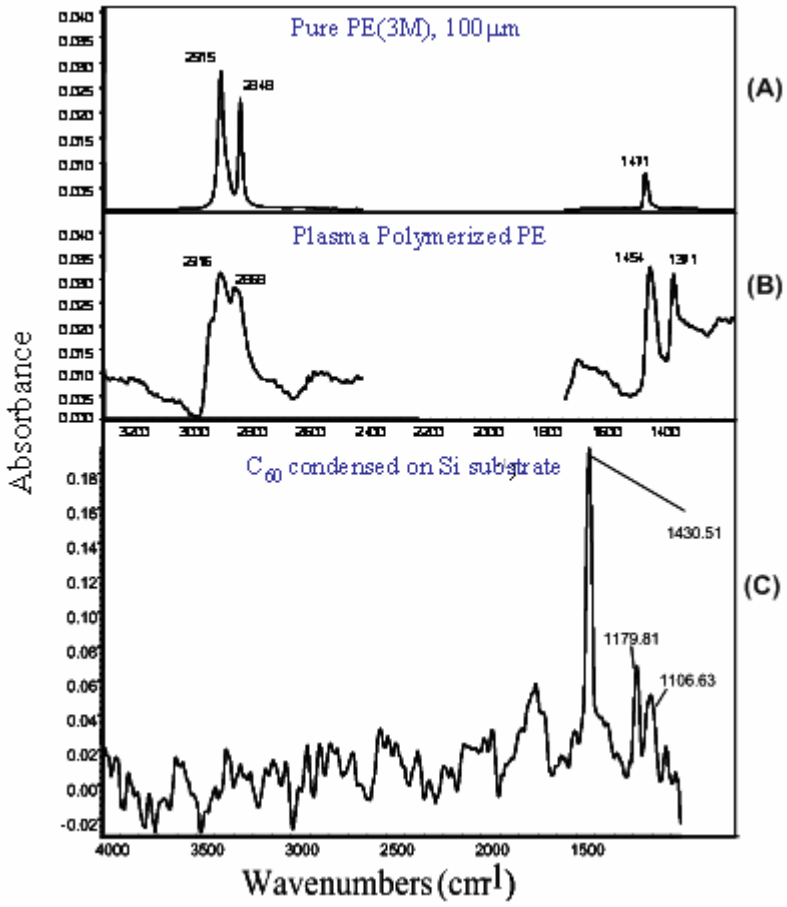

Fig. 4 (A) FTIR-ATR spectrum of a pure polyethylene (PE) film. (B) Spectrum of plasma polymerized PE film (no fullerenes added). (C) Spectrum of fullerene nanopowders film.

4. Conclusions

Under the light of the preliminary observations reported, we propose the following mechanism for the formation of the C_{60} nanopowders from the mixed fullerenes source. During the short duration of the experiments (10 minutes), the fullerenes C_{60} were selectively sublimed from the mixed fullerenes source. Once exposed to a carrier gas, the C_{60} molecules polymerized and agglomerated to form C_{60} nanopowders. With the ethane plasma, a competition between the growth of the C_{60} nanopowders by polymerization and agglomeration, and the encapsulation by the build-up of an organic film set in. Due to the dilution of the fullerenes C_{60} gas by the organic monomer gas, the encapsulation process eventually took over. Otherwise, polymerization of the fullerene C_{60} into large structures, as observed with the inert gas, would have occurred. Much remains to be done after this preliminary investigation. On the other hand, the present process is versatile enough to vary the sublimed fullerene vapor density, the residence time of the fullerene C_{60} in the nanopowder formation zone, and the plasma polymerization conditions (plasma density, pressure and nature of monomer gas).

Development of a Dual-Plasma Process for the Synthesis of Coated Metal Nanoparticles from a Solid Source

C. Qin and S. Coulombe

Department of Chemical Engineering, McGill University, Montreal (QC), Canada

Abstract

A novel process for the synthesis of pre-coated metal nanoparticles is presented. The metal nanoparticles are produced in an inert (Ar) low-pressure pulsed metal vapor arc system which uses the metal of interest as the cathode, and subsequently exposed to a continuous flow C_2H_6 polymerization plasma for in-flight coating. Typical nanoparticle size ranges from 10 to 30 nm while the thickness of the film deposited onto the nanoparticles is ~10 nm. The effect of operating parameters on the nanoparticles' properties and stability of the dual-plasma system are discussed.

Keywords

Coated metal nanoparticles, metal vapor arc, pulsed arc, capacitively-coupled RF plasma, plasma polymerization.

1. Introduction

Due to their unique thermal, electronic, magnetic, and optical properties, metal nanoparticles find numerous applications in various fields either as individual entities (e.g. catalysts, solid additives to propellants [1], raw materials for plasma spraying) or as dispersed phases into host materials (e.g. optoelectronic nanodevices, magnetic ferrofluids [2], nanofluids [3], and polymer nanocomposites). In many of these applications, it is desirable to use metal nanoparticles pre-coated with ultrathin organic layers to reduce their surface energy (i.e. for safe handling and/or to control agglomeration), to enhance their compatibilities with host materials or simply, to avoid contamination (ex. oxidation). Coated metal nanoparticles can be produced by wet chemistry methods, which generally involve numerous chemical steps, or by "dry" plasma-based methods. Vollath and Szabo [4] developed a continuous dual-plasma process whereby finely dispersed coated nanoparticles are produced from gaseous precursors injected into a microwave plasma. Though versatile and applicable to the direct synthesis of metal nanoparticles pre-coated with organic layers, this process involves the use of harmful and unwieldy metal precursors, such as ferrocenes and organometallics. More recently, Kouprine *et al* [5] developed a similar continuous process using a capacitively-coupled RF plasma source. In this report, we present our progress made toward the development of a continuous dual-plasma process whereby metal nanoparticles coated with thin organic layers are produced from a solid source.

2. Overview of the Dual-Plasma Process

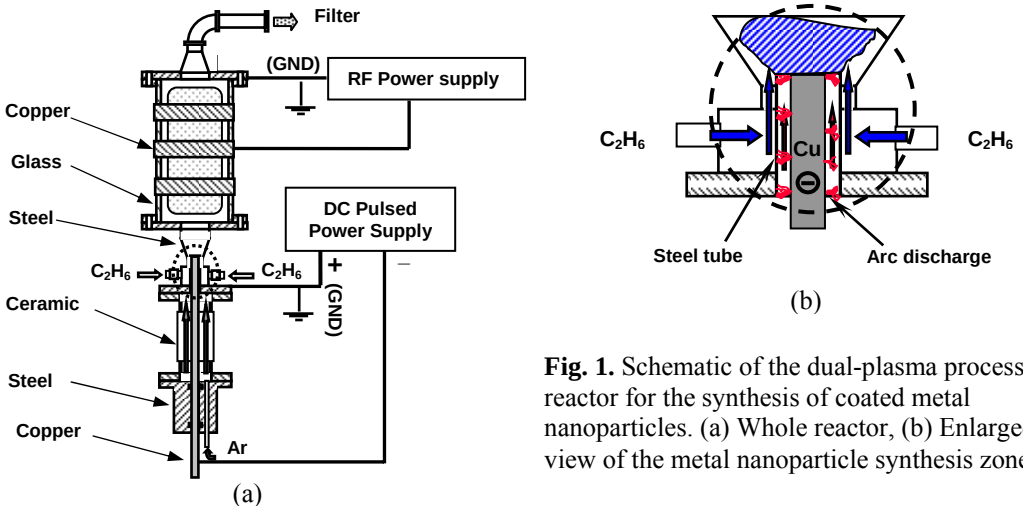

Fig. 1. Schematic of the dual-plasma processing reactor for the synthesis of coated metal nanoparticles. (a) Whole reactor, (b) Enlarged view of the metal nanoparticle synthesis zone.

The process consists of two sub-steps: the metal nanoparticle synthesis followed by the in-flight plasma polymerization onto the nanoparticle surface. A flow-through reactor configuration is used (see Fig. 1 for the detailed schematic of the entire plasma reactor). Both sub-steps have unique requirements and thus, required the development of two different plasma sources within the constraint of a common pressure (1-100 torr). In the synthesis stage, metal vapors are produced from the erosion of the cathode of a low-pressure pulsed metal vapor arc system. The use of pulsed arcs limits the heating of the cathode bulk while maintaining erosion conditions. The cloud of metal vapors released from the cathode surface is transported away and quenched by an inert gas to favor homogeneous nucleation and nanoparticle growth. Further downstream, the nanoparticles are exposed to a capacitively-coupled RF plasma sustained in a mixture of the inert gas and a monomer gas in order to form organic deposits on their surface. The produced nanoparticles are collected over various packings (polymer and paper filters or silica wool) placed inside the vacuum line. The entire reactor is evacuated between each run to a base pressure lower than 10^{-3} torr in order to control the contamination.

Pulsed Metal Vapor Arc Source & Metal Nanoparticle Synthesis

The metal vapor arc system uses as the cathode, a 1/4" rod made of the metal of interest. A stainless steel tube, concentric with the cathode rod, acts as the grounded anode. In the current geometry, the gap between the cathode rod and the inside of the anode is ~1 mm. In order to produce pulsed arcs, we designed and built a self-oscillatory (i.e. not triggered by external means) pulsed DC power supply capable of generating current pulses of amplitude >30 A; A high-voltage capacitor (General Atomics, 336 μF) is charged by a 1.5 kW capacitor charging power supply (Analog Modules, model 5723-1000N) until the voltage across the gap reaches the gas breakdown level. At this point, the capacitor rapidly discharges through the gap, forming a current pulse. A severe erosion of the cathode surface occurs due to the ignition of cathode spots. The process self-regulates itself and a periodic pulsation of arcs is observed. Fig. 2 shows typical arc voltage and current waveforms measured with a digital oscilloscope (Tektronix, TDS2024) equipped with a high-voltage probe (Tektronix, P6015A). A 330 Ω resistor is used to limit the charging current and pulsation rate to ~3 Hz, while the arc discharge current is limited by a ballast resistor (5-20 Ω). The current pulse duration is typically ~3 ms. We recently undertook a systematic study of the effect of the system pressure (1-100 torr), inert gas flow rate (50-2000 sccm Ar), pulse frequency (0.5-10 Hz), and pulsed arc peak current (~30-200 A) on the stability of the self-oscillatory power supply, and the properties of the bare copper powders produced. Preliminary results are presented in section 3.1.

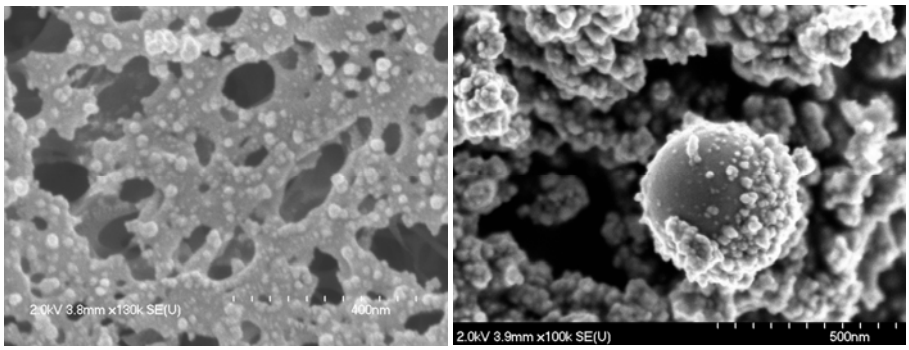

Fig. 3. FE-SEM images of copper powders produced with the pulsed metal vapor arc source (200 sccm Ar, p=50 torr). Left: nanoparticles collected on a polymer filter. Right: particles collected inside the pulsed metal vapor arc reactor.

Plasma Polymerization Reactor

The produced copper particles and inert carrier/quench gas are transported through an expanding nozzle, where a monomer gas is added, and subsequently into a cylindrical reactor made of a Pyrex tube (114 mm I. D. by 305 mm height). The residence time of the gas in this reactor can be adjusted over the 12-120 sec range by varying

the Ar flow rate from 1000 to 100 sccm at 50 torr. Several copper sheets (38 mm-wide), wrapped around the Pyrex tube, are used as RF electrodes: the live and grounded electrodes alternate (starting with a live electrode on the mid-plane of the reactor) to ensure the plasma fills the entire volume available, and to increase the capacitance value of the assembly (better impedance matching with the RF power supply). The current assembly uses three sheets of live electrodes separated by two sheets of grounded electrodes. The spacing between the borders of the live and grounded electrodes is approximately 12 mm. The bottom and top flanges of the reactor are grounded. The electrodes are capacitively-coupled to an amplitude-modulated (square wave) 13.56 MHz RF generator (Dressler, Cesar 1312) through an automatic L-type matching network (Dressler, VM 1000 A). C_2H_6 is used as the source of organic monomers since the methyl radical (CH_3) is regarded as the main precursor in the formation of ultrathin C:H coatings [5]. The effect of the C_2H_6 gas flow rate (5 to 15 sccm) and RF power (40 to 100 W) were considered in this preliminary study (Section 3.2).

3. Results and Discussion

3.1 Synthesis of copper nanoparticles

3.1.1 Pressure

The preliminary experiments revealed that, when the system pressure was lower than 30 torr, the stability of the pulsed arc system was intermittent: the system would sometimes evolve into a stable DC glow discharge where essentially no vapor was produced. At higher pressure, the pulsed arc system was consistently stable and led to the production of a significant amount of powders. Fig. 3 shows FE-SEM (Field Emission Scanning Electron Microscope) images of the copper powders produced under low quench rate conditions (200 sccm Ar) and moderate pressure (50 torr). The powders were collected on a polymer filter located downstream the plasma polymerization reactor (left) and on the anode of the pulsed metal vapor arc system (right). The images clearly reveal two size distributions: nanoparticles whose size ranges from 10 to 30 nm, and much bigger ones whose size can be as large as 1 μm ("macroparticles"). We also observe agglomerates of nanoparticles. The nanoparticles transported downstream to the polymer filter tend to form small agglomerates. In fact, the deposit formed on the anode surface seems to result from the pilling up of several nanoparticles. We suspect that macroparticles are produced as a result of the solidification of liquid droplets ejected from cathode spots upon extinction [6]. In order to control the formation of these macroparticles, the peak current and duration of the pulses can be reduced. The pressure also influences the mean diameter of the produced copper nanoparticles. Fig. 4 shows that the mean diameter of the copper nanoparticles is in the range of 10-30 nm when the pressure is ~60 torr, while this range shifts to 30-50 nm above 100 torr. At higher pressure, the metal vapor cloud produced at the cathode spot does not expand as much [7, 8]. This phenomenon gives rise to a more significant supersaturation of the vapor and to higher rates of collisions, both processes enhancing homogeneous nucleation and particle growth. Larger agglomerates too are observed at higher reactor pressure.

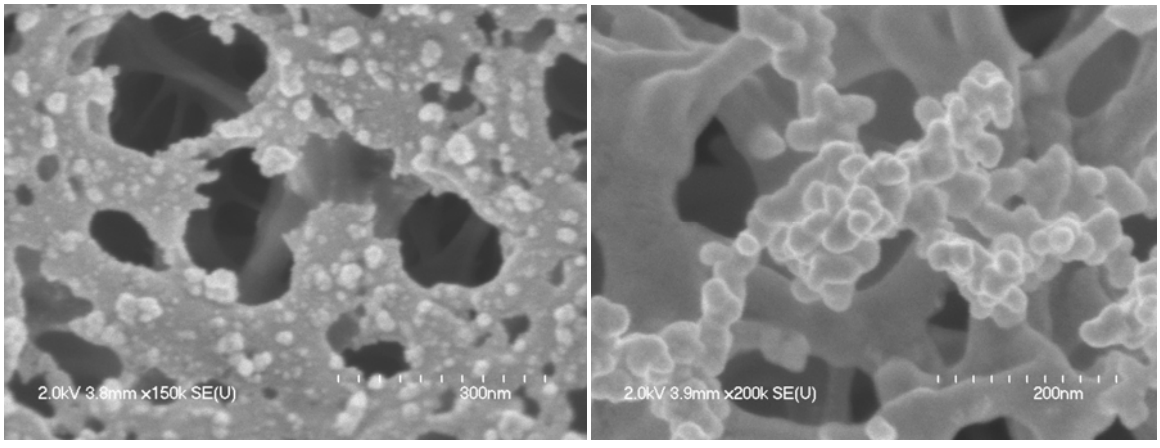

Fig. 4. FE-SEM images of copper nanoparticles produced under different reactor pressures with an argon flow rate of 400 sccm. Left: p = 60 torr; Right: p = 500 torr.

3.1.2 Inert gas flow rate

The FE-SEM images also show that when the gas flow rate is raised above 200 sccm, little effect is seen on the mean diameter of the produced copper nanoparticles. Fig. 5 compares copper nanoparticles produced at a reactor pressure of ~40 torr with 200 (left) and 1000 sccm Ar (right). The nanoparticles in both images are in the range 10~30 nm. The number of nanoparticles collected on the filter is more significant at 200 sccm than at 1000 sccm, since a higher fraction of the nanoparticles are swept through the filter at higher gas flow rate.

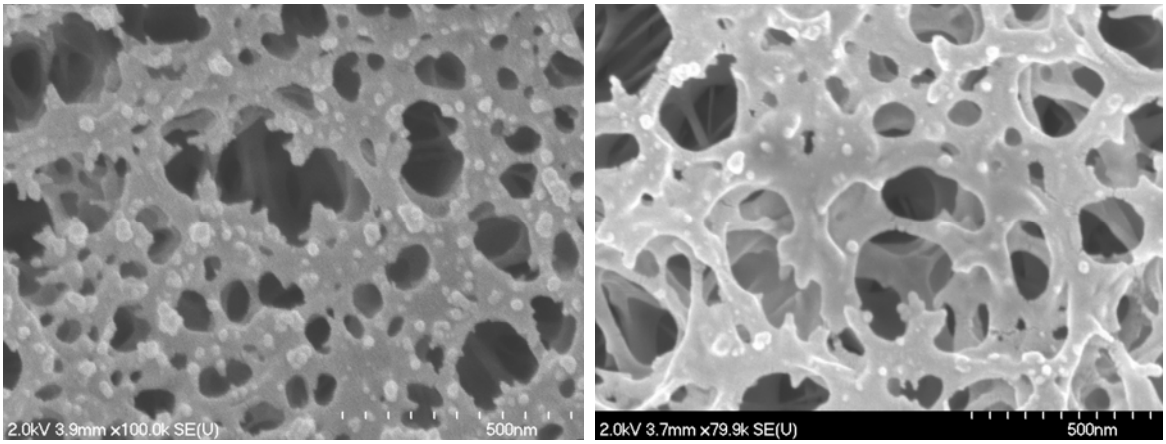

Fig. 5. FE-SEM images of copper nanoparticles produced under different gas flow rates at a reactor pressure of 40 torr. Left: 200 sccm Ar. Right: 1000 sccm Ar.

3.1.3 Frequency and amplitude of current pulses

We found that the arc pulsation frequency and current per pulse both affect the nanoparticle and microparticle production yields, but both seem to have little effect on the mean size of the nanoparticles. When increasing the pulse frequency, more copper vapors are produced per unit of time and consequently, more nanoparticles are produced. On the other hand, a higher pulse frequency increases the heat load on the copper rod to the point of bulk melting. Operation at higher current enhances the cathode erosion rate but at the same time, leads to an increase of the macroparticle yield; the increased erosion rate is mainly caused by the ejection of more liquid droplets from the cathode spots. Our preliminary process optimization study revealed that the use of a pulsation frequency of 3-5 Hz, and a current per pulse of 40-60 A, leads to the best compromise. Additional metal vapor source development efforts are currently under progress. An interesting avenue is to use magnetic confinement of the cathode spots in order to increase the metal vapor pressure within the cathode spots and in turn, reduce the fraction of the heat load dissipated by heat conduction to the cathode [9] (i.e. control the formation of macroscale liquid volumes).

3.2 Plasma polymerization

Fig. 6 shows FE-SEM images of coated copper nanoparticles collected on the polymer filter. Due to limitations of the working conditions of the FE-SEM, the images of coated particles are not as clear as the ones with bare metal particles. Nevertheless, one can distinguish a thin film (~10 nm) covering the individual copper nanoparticle. It is also interesting to notice the small-size nanoparticle agglomerates (~100 nm): most of these agglomerates show Cu nanoparticles isolated from each other by the coating and some others, showing small agglomerates of Cu nanoparticles that formed before the surface coating took place. We infer from these images that the current reactor configuration and operating conditions favor the formation of the coating before the metal nanoparticles get a change to agglomerate. Furthermore, despite the size distribution of the nanoparticles, the thickness of the deposited film seems to be relatively uniform. This result seems to indicate a uniform distribution of active radicals in the plasma polymerization chamber [10] and a narrow distribution of residence

times. The images also show that the individual coated copper nanoparticles tend to scatter more on the polymer filter, suggesting that the surface energy of the nanoparticles is reduced due to the presence of the film.

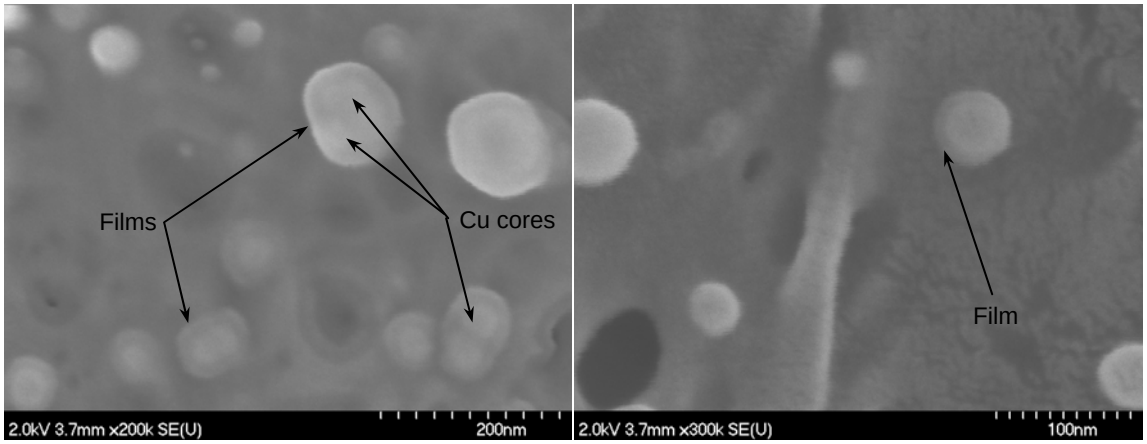

Fig. 6. FE-SEM images of coated copper nanoparticles (CW rf plasma power: 40 W; Ar flow rate: 300 sccm; C_2H_6: 10 sccm; Pressure: 65 torr)

4. Preliminary conclusions

We demonstrated that copper nanoparticles, ranging in size from 10 to 30 nm and coated with a ~10 nm-thin film, can be synthesized in a single-step by combining a cathodic arc evaporation/condensation process, with an in-flight plasma polymerization process. It has been demonstrated that the reactor pressure, the peak current and frequency of the pulsed arcs, and the flow rate of the carrier/quench gas, play important roles in the control of the nanoparticles' properties and yield, and in the stability of the pulsed arcs. Our preliminary optimization study led to the adoption of the following conditions for the nanoparticle synthesis stage: chamber pressure: 30 - 60 torr; inert carrier/quench gas flow rate: 400 - 800 sccm; arc pulsation frequency: 3 - 5 Hz; and peak arc discharge current: 40 - 60 A. Further research activities aimed at mitigating the formation of macroparticles and optimizing the in-flight plasma polymerization process are currently under progress.

Collection of Nano-powders Generated by Radio Frequency (RF) Plasma Spray Synthesis (PSS) Processing, Using a Sampling Probe

L. Jia, F. Gitzhofer

Energy, Plasma and Electrochemistry Research Centre (CREPE)
Université de Sherbrooke, Canada

Abstract
A particle-sampling probe has been designed and constructed for the continuous collection of nano-powders produced by the plasma spray synthesis (PSS) process. The probe comprises a powder sampling line (inner tube), a quench gas line (outer tube) and a water-cooling jacket surrounding the outer tube. The results obtained to date indicate that the sampling probe location in the plasma reactor and the quenching gas flow rate employed are the most important parameters involved in the satisfactory operation of the sampling probe.

1. Introduction

Recently, the Radiofrequency (RF) Plasma Spray Synthesis (PSS), based on using solution precursors as the process feedstock, has become a mature and advanced materials processing technique for nano-particles synthesis. In this process, the liquid phase precursor is atomized and injected into the high temperature plasma flame, the plasma synthesized particles being collected by a series of filters downstream. As the atomized droplets enter the high temperature flame and are accelerated towards the collecting surface, various step-wise occur [1-4]. As shown in Fig.1 [5], the first step is the evaporation of the solvent, which is followed by "condensation" of the solid precursor materials. Chemical reactions are initiated next, followed by grains nucleation and growth, resulting in the formation of dense solid particles. Interactions among these highly reactive particles lead to the formation of either larger particles/crystals, agglomerates or aggregates.

In order to characterize the freshly synthesized powders, the conventional method is to scrape the powders from the chamber walls and the filters, prepare the specimen for transmission electron microscopy (TEM) or field emission scanning electron microscopy (FESEM), obtain and analyze the images. There are several drawbacks in this method, for example, it is necessary to clean the chambers and the filters perfectly after completing the experiment. During the plasma synthesizing process, the nano-powders adhere to internal walls of the plasma chamber and the filters. If the clean-up is not performed well, undesirable particle contamination would be caused to future process products, resulting in inaccurate powders characterization. However, in practice, this cleaning work takes more than two hours according to the previous experiences.

The conventional product recovery methods do not recover the plasma produced powders at the desired chamber positions. This may cause uncertainty in the experimental results. Furthermore, the conventional method is vulnerable to contamination, because it is necessary to separate the activities of powder collecting and specimen preparation.

Accordingly, there exists a strong need for a sampling probe that has a quick but complete clean–up characteristic, a reduced risk of cross-contamination, yet be capable of withdrawing powder samples from all desired chamber positions.

2. Experimental

2.1. Experimental setup and procedure

The experimental setup, as used in this study, is illustrated by the schematic diagram of Fig.2, and consisted of three major parts: (1) an induction plasma torch (model PL – 50, from Tekna Plasma System Inc. Canada) connected to a radio frequency (RF) power supply; (2) a water cooled cylindrical reactor attached to a filter assembly; and (3) a sampling probe system connected to a vacuum pump. A water cooled atomization probe penetrates the plasma along the torch axis, thereby permitting the injection of the cerium nitrate solution into the plasma. The probe tip is "axially" located in the centre of the torch [6].

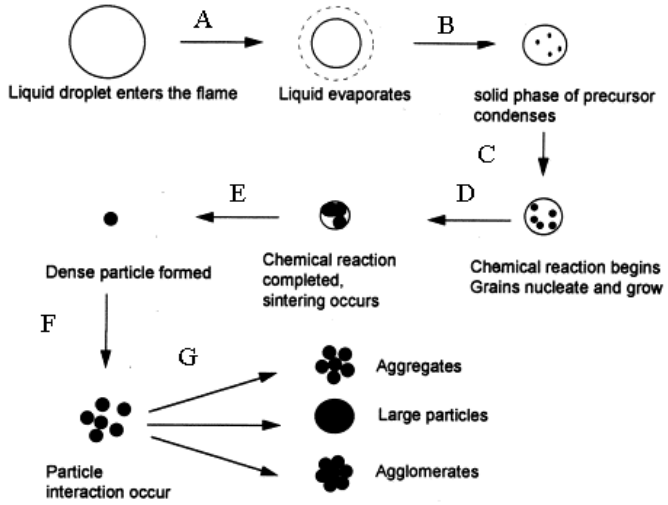

Fig.1. Schematic of the Plasma Spray Synthesis process

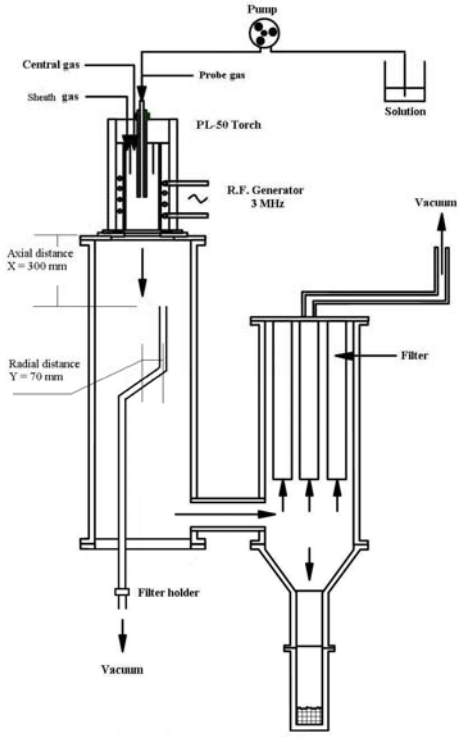

Fig.2. RF plasma installation for PSS

The plasma spray synthesis of nano-powders with consistent properties requires control of both the size and the size distribution of atomized feed liquid droplet droplets and optimization of the spray parameters. Hence, a series of experiments were carried out by varying the gap size of the atomization probe, the pressure and flow rate of the atomizing gas and the flow rate of the liquid feedstock, and recording the variations in the droplet size distribution of the aerosols using a Malvern RTsizer. Based on the results of these experiments, atomization and spray parameters were optimized to obtain droplets with 12 μm mean size [7].
In this work, the pressure in the plasma reactor chamber and the torch plate power were considered as the variable parameters in order to obtain more experimental data towards the end of the sampling probe evaluation. The experimental conditions for these tests are summarized in Table 1.

2.2. Sampling probe system

The sampling probe is described in detail by reference to Fig. 3 which shows a schematic view of the sampling probe. It comprises a perforated cup that is made from molybdenum because of its very high melting point (2896 K), a powder sampling line (inner tube), a cleaning liquid and drying gas line (outer tube) and a water-cooled jacket surrounding the outer tube. The sampling probe has an outer diameter of 13 mm, a median diameter of 10 mm and an inner diameter of 5 mm. It is constructed from four concentric thin wall stainless steel tubes. The median tube (inside water – cooling jacket) guides the cooling water to and from the perforated cup. A pump is connected to the outlet of the inner tube and draws a flow of gas into the inner tube through the perforated cup. A standard 3.08 mm TEM copper grid is disposed within the sample holder, and used to withdraw the sample powders. Quench gas is introduced to the probe, via the outer tube, to quench and entrain the as-synthesised powder clusters. After each sample collection, the inner tube is cleaned by the injection of the cleanser liquid (water) and then dried using a compressed gas flow. In our application, helium (He) is used as the quench gas because of its higher thermal conductivity compared to that of other inert gases [8].
In order to evaluate the utility of the sampling probe, it was located at various positions within the reactor chamber and performance comparison experiments were carried out. Initially, the sampling probe was located on the axis of the reactor chamber, the axial distance between the torch exit and the probe perforated cup (denoted

as X) was 500 mm (X = 500 mm). In a second position, by rotating the sampling probe symmetrically, the probe perforated cup was able to traverse the reactor chamber cross-section circularly. The radial distances between the axis of the reactor chamber and the perforated probe cup of the sampling probe (denoted as Y) were 70 mm (Y = 70 mm). Finally, the sampling probe was relocated at X = 300 and 400 mm and Y = 0 and 70 mm, respectively, and the sampling evaluation experiments repeated. In order to compare the two sampling methods, synthesized powders were also collected from the wall of the reactor chamber at the same sampling probe collecting position after each experiment.

The powder samples so collected were examined by TEM or FESEM to observe their surface morphology and subsequently, to measure their size by using a software which was developed specially to address agglomerated powders diameter measurement based on fractal dimensions, to be published soon by the same authors.

Table.1. PSS experimental parameters

Plasma torch	PL - 50
Central plasma gas [slpm]	27 (Ar)
Sheath plasma gases [slpm]	90 (Ar) 80 (O_2)
Power [kW]	35 and 50
Chamber pressure [kPa]	8 and 12
Atomization gas pressure [kPa]	345
Atomization gas [slpm]	21 (Ar)
Solution concentration [mol/L]	1
Solution injection flow rate [mL/min]	10

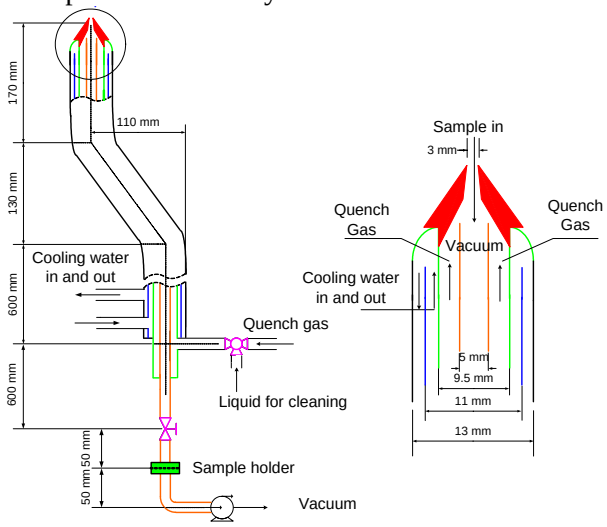

Fig.3. Schematic of the sampling probe

3. Results and Discussions

3.1. Determination of quench gas flow rate

The quench gas introduced into the sampling probe is used to quench and entrain the freshly "as-synthesized" nano-powders. Fig.4 (a) is a graphical presentation of the quench gas flow rate's influence of the synthesized powders' average particle size. It can be observed that smaller helium flow rates, up to 21.5 slpm, do not greatly affect the synthesized powder particle size. A major difference is observed when the helium flow rate is raised to 29 slpm, the powder particle size then is falling to below 20 nm. However, this does not mean that the quench gas flow rate can be increased without limit to continually reduce the size of the synthesized powder particles. Fig.4 (b**)** shows that, if the helium flow rate is raised to 36.5 slpm, not all of the helium flow can be extracted by the vacuum pump, part of the helium input would by-pass the sampling probe, and it may cause the plasma characteristics to be affected.

Additionally, in order to determine the optimum quench gas flow rate Q_1, the sampling gas flow rate Q_2 is calculated. The sampling gas, which should contain all of the quench gas, passes through the inner tube of the sampling probe, due to the imposed pressure difference (vacuum). According to the Hagen-Poiseuille equation, the sampling gas flow rate Q_2 through the inner tube is the product of its cross section area and the average gas velocity. The average velocity is calculated by summing all of the gas velocities over the suction probe section and then dividing the result by the probe cross section area [9]:

$$\langle v_z \rangle = \frac{\int_0^{2\pi}\int_{kR}^{R} v_z r dr d\theta}{\int_0^{2\pi}\int_{kR}^{R} r dr d\theta} = \frac{(p_0 - p_L)R^2}{8\mu L} \qquad (1)$$

Thus, the total volume flow rate through the inner tube can be calculated by (2),

$$Q_2 = \pi R^2 \langle v_z \rangle = \frac{\pi (p_0 - p_L) R^4}{8 \mu L} \qquad (2)$$

where $p_0 - p_L$ is the pressure difference between the sampling probe inlet and exit (Pa); R is radius of the inner tube (m); L is length of the tube (m); and μ is the viscosity of the gas ($Pa \cdot s$).

The calculated value of Q_2 (from (2)) for our experimental conditions is 41.2 slpm, which is much higher than the experimental result (between 29 and 36.5 slpm). The difference between the calculated and the measured sampling gas flow rate can be explained as follows:

- The actual flow rate difference may be attributed to the value of the fluid parameter (viscosity), used in (2), were developed for gases only, whereas our input materials is biphasic (i.e. as nano-dispersed solids and gases).
- In the previous calculation (2), no bending of the sampling probe is considered. However, the resistance caused by probe bending is unavoidable during the sampling process.

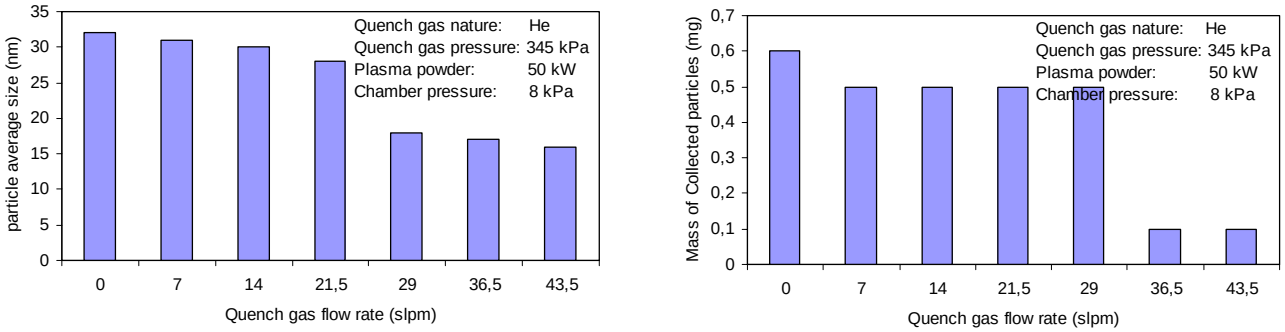

Fig.4. Influence of quench gas flow rate on (a) the synthesized particle average size and (b) the mass of synthesized powder at axial position 300 mm

Consequently, in considering the provision of the highest possible cooling rate to the suspended particles within the sampling probe, the quench gas flow rate of 29 slpm is fixed as the optimum value in the following experimental tests.

3.2. Effects of sampling method and position

Fig.5 illustrates the effect of the sampling methods on the synthesized powder size. It is observed that when the sampling probe is located at an axial position of 300 and 400 mm from the torch exit plane (X = 300 and 400 mm, Y = 0 mm), the sizes of powders that are collected by the sampling probe are reduced by about 30% and 20%, respectively, compared to those powders collected using the conventional method. This finding was expected since, as illustrated in Fig.1, it is supposed that the "grains" are nucleated and then "grown" in the plasma flame between the axial locations of X = 300 and 400 mm. The "grains" are drawn into the sampling probe at the point where the quench gas is introduced. These grains are rapidly cooled to cause the production of smaller sized grains. Furthermore, the micrographs shown in Fig.6**,** produced by TEM for the revelation of powder morphology, indicate that the high cooling rate also reduces the rate of particle aggregation and leads to decreased agglomeration levels in the powder [10]. Fig.5 also shows that the average particles size, collected within the sampling probe, is almost same as that collected from the reactor wall at the 500 mm axial location (X = 500 mm), because particle interaction has occurred (step G) and aggregated powders are formed at this region. Thus, the quench gas has no influence on the powder grain size.

Fig.7 shows the effect of sampling position on the synthesized powder size. The presence of the large powder size at the radial location of 70 mm can be explained by incomplete evaporation of the injected evaporation. The plasma flame is characterized by a certain temperature distribution in the radial and axial directions. When the radial location is 70 mm, the gas temperature is now too low for complete evaporation of the solvent and

condensation of the precursor materials at the outer layer of the plasma flame and the product particle size is consequently increased.

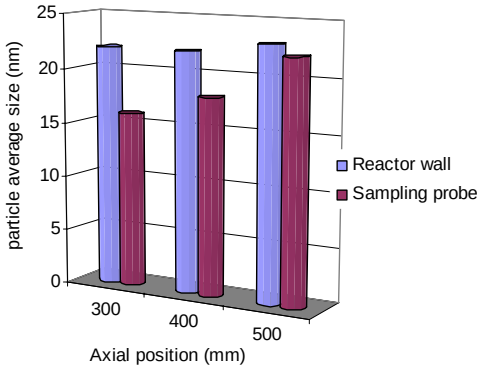

Fig.5. Effect of the sampling method on the synthesized

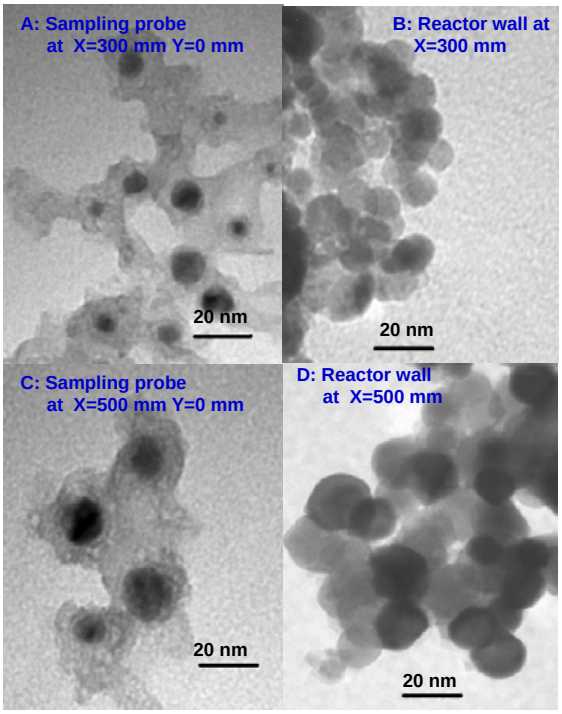

Fig.6. TEM micrographs illustrating the effect of sampling method on the degree of powder agglomeration.

3.3. Effects of chamber pressure and plasma power

The influence of the chamber pressure as well as that of the plate power on the size of powder (collected by the sampling probe) can be clearly recognized by reference to Fig.8. Fig. 8 shows the influence of plasma power and chamber pressure on the synthesized powder size that was collected using the sampling probe.

For a given plasma power, decreased powder size is observed when the chamber pressure decreases. Powders follow the “free molecular regime” in the condensation zone. Consequently, “Brownian coagulation mechanism” can occur and powders grow by the process of collisions and fusions. Thus, as the chamber pressure increases, the rate of collisions increases, providing for the particle size continuing growth.

On the other hand, for a given pressure, large variations in the powder size are noticed when the plasma power level (Fig.8) is changed. Initially, as the plate power is raised, the plasma to particles heat transfers increases. Evaporation is thereby favoured, and particle velocities are increased. This results in diminished residence times in the plasma for the particles and leads to shorter growth times and decreased particle diameters.

All the experimental results on the influence of plasma power and chamber pressure on the synthesized powder size, collected using sampling probe, are in good agreement with the previous published results [8], obtained using a conventional powder collecting method. This agreement also validates the successful application of the sampling probe.

3.4. Sampling probe clean–up

As mentioned before, during the sampling process, nano-powders adhere to the internal wall of the sampling probe, leading to contamination of future processing products. This is unacceptable for the proper operation of the sampling probe. Thus, the probe should be cleaned by water and dried by compressed gas after completion of every experimental use. In order to identify satisfactory completion of the clean-up process, experimental tests were conducted to evaluate the clean-up achieved. All previous plasma operating parameters were employed,

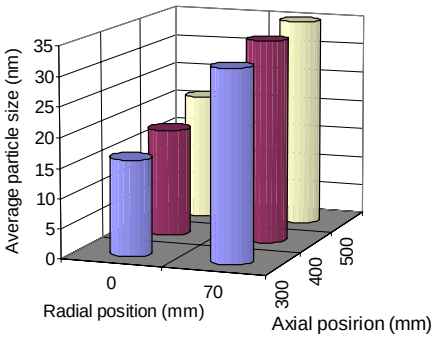

Fig.7. Effect of sampling position on the synthesized

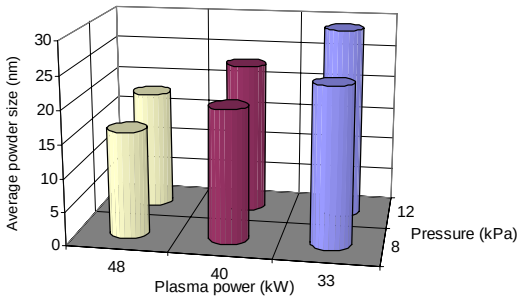

Fig. 8. Influence of plasma power and chamber pressure on the synthesized powder size collected using sampling probe

with the exception of the solution injection. Observation of the now empty TEM grid confirms that the clean-up task is successful.

4. Conclusions

A particle-sampling probe has been demonstrated to successfully collect nano-powders that are produced by plasma spray synthesis (PSS) processing. Compared to the conventional sample collection method, this technique has more advantages, i.e. quick clean-up, reduction in the risk of contamination and withdrawal of powders at the desired internal plasma chamber position. The quench gas is introduced into the sampling probe at a flow rate of 29 slpm. This benefits the reduction of grain size and the degree of agglomeration of the synthesized powder. The optimum sampling position has been found at the axial position X = 300 mm inside the reactor chamber, which also coincides with the position for optimum product particle size generation. This approach is compatible with the combinatorial approach which will be used extensively in the Energy Plasma and Electrochemistry Research Centre.

Abstract

The multi-layer system of alternated inorganic and organic layers is considered to be the winning technology for ultra-barrier permeation layers for flexible electronics. Here we present our first studies concerning the moisture permeation barrier properties of inorganic films achieved by means of the expanding thermal plasma. Moreover, we report on the interphase development between the polymer and the barrier layer, as investigated by means of *in situ* and real time diagnostics, i.e., spectroscopic ellipsometry.

Keywords

Plasma Enhanced-CVD; permeation barrier coatings; in situ real time diagnostics.

1. Introduction

In the last three-four decades polymers have rapidly spread in several and diverse technological fields due to their benefits, i.e., lightweight, transparency, printability, sealability, safety, flexibility, mouldability. Next to the "allure" of plastics, polymer- based technologies started to face also their major and inherent deficiencies, i.e., their low surface energy/ poor reactivity and high gas/vapor permeation. Consequently, plasmas became widely acknowledged in modifying and tailoring the polymer surface chemistry (e.g., for improving polymer/metal adhesion), as well as in providing thin (≈ 100 nm) gas/vapor permeation barrier film deposition on the polymer substrates [1,2]. Literature on plasma deposition of inorganic barrier layers (mostly SiO_2, Si_3N_4) flourished: plasma- deposited films performed better than evaporated and sputtered counterparts in terms of barrier properties and adhesion to the polymer substrates; the ultimate barrier layer performance (O_2 transmission rates in the range of 0.1-0.5 $cm^3/m^2 \cdot day \cdot atm$) was found to be governed by defects density in the deposited layer [3].
Nowadays, the interest in polymeric substrates grows in fields where long- term stability devices are required, such as flexible solar cells and OLEDs (electronics integrated into textile, rollable displays). Here, the film barrier technology needs to achieve moisture permeation as low as 10^{-6} $g/m^2 \cdot day$, in order to guarantee, for example, a 10 years- lifetime for a flexible OLED device. Due to the limits reached by single plasma-deposited barrier layers, a few μm-thick multi-layer system consisting of alternated inorganic and organic layers appears to be the winning technology in flexible electronics, reaching moisture permeation values as low as 10^{-5} $g/m^2 \cdot day$ [4]. Plasma technology, however, has not been yet explored (with a few exceptions, [5]) in the deposition of multi-layer barrier systems, since sputtering/ evaporation (of the inorganic barrier layer) and vacuum deposition + UV curing (of the organic interlayer) are mostly preferred. Though successful results in terms of moisture permeation barrier are achieved, the role of the organic interlayer is still under debate and not fully developed: smoothening of the inorganic surface roughness [4], decoupling of the defects present in the inorganic layer [6], infiltration of the organic (liquid) precursor in the defects of the underlying inorganic films [7], are the most plausible hypotheses. The presence of the interlayer, therefore, can affect the growth of the inorganic layer (and vice versa), as well as the final mechanical performance of the multi-layer system (e.g., adhesion between the polymer and the inorganic layer and between the inorganic layer and organic interlayer). In this framework, plasma deposition can certainly contribute to the improvement of a multi-layer system design: the development (and, ultimately, the control) of an interphase between the polymer and the inorganic layer (as well as between the inorganic and the organic interlayer), due to the synergic effects of radicals, ions

and UV light [8], may affect the barrier and mechanical properties of the system. Moreover, the possibility of an entirely plasma-deposited multi-layer system may simplify the roll-to-roll or batch production line because a single chamber for barrier deposition would be required. This contribution aims:

- to describe our recent results on SiN_x and SiO_2-like barrier layers deposited by means of the expanding thermal plasma (ETP), a remote plasma where ion bombardment towards the substrate is negligible (E_i< 2V);
- to report on the development of an interphase region between the inorganic layer and the polymeric substrate, as followed by means of in situ and real time diagnostics, i.e. spectroscopic ellipsometry.

2. Experimental

The ETP set-up, already described in detail in [9], is depicted in Figure 1. Briefly, the ETP is a remote plasma where an Ar (Φ_{Ar}) plasma is ignited at a variable arc current (I_{arc}) in a wall-stabilized dc cascaded arc in a pressure (P_{arc}) range of 0.1-0.4 bar. The arc consists of three cathodes, four cascade plates and an anode in which a nozzle is present. The thermal plasma expands supersonically through the nozzle into the deposition chamber kept in the pressure ($P_{chamber}$) range of 0.1-0.3 mbar. The Ar ion and electron fluence (Ar^+, e^-) expanding from the arc are fully controlled by the plasma parameters, i.e., Φ_{Ar} and I_{arc}, and measured by means of Langmuir Probe [10]. Co-precursors for SiO_2-like film deposition are O_2 and hexamethyldisiloxane ($(CH_3)_3SiOSi(CH_3)_3$, HMDSO), injected via the nozzle and via a ring placed at 5 cm from the nozzle, respectively. Co-precursors for SiN_x film deposition are NH_3 (via the nozzle) and SiH_4 (via the ring). Table 1 summarizes the deposition parameters. The depositions were carried out on (100) Si substrates and 100 μm-thick poly(ethylene 2,6 naphtalate) substrates placed on a substrate holder 60 cm (in the case of SiO_2-like films) and 40 cm (in the case of SiN_x films) distant from the nozzle. The deposition temperature was fixed at 100°C (the glass transition temperature of PEN is 128°C) and a He backflow was used for thermal contact between the polymer and the substrate holder. An active $N_{2(l)}$/ water cooling system guaranteed a constant substrate temperature (± 10°C) during plasma processing (determined to be ± 10°C in the case of deposition on c-Si).

Table 1. ETP deposition parameters for SiO_2-like and SiN_x films.

Parameters	**SiO_2-like**	**SiN_x**
Φ_{Ar}	30 sccs	40 sccs
I_{arc}	75 A	40 A
Φ_{O2}; Φ_{NH3}	16.6 sccs	16.6 sccs
Φ_{hMDSO}; Φ_{SiH4}	0.4 sccs	0.4 sccs
$P_{chamber}$	0.11 mbar	0.14 mbar

As already commented in the previous section, in the ETP the growth of films occurs in the absence of ion bombardment: this is due to the low electron temperature (≈ 0.3 eV) in the downstream region, which, consequently, allows developing a very low bias voltage at the substrate (E_i < 2 V). Therefore, dedicated studies on the effects of ion bombardment on the film growth were performed by means of an external rf substrate bias: the substrate holder was connected to a 13.56 MHz RF power supply; the substrate voltage and peak-to-peak voltage were monitored using a high voltage probe and an oscilloscope operating in DC mode.

The deposited layers were characterized by means of IR spectroscopy and in situ spectroscopic ellipsometry in the 245-1000 nm range at an angle of 68°. In situ real time ellipsometric studies, with a time resolution of 2 s, were performed on the PEN substrates during the SiO_2-like film growth. The optical properties of the PEN substrate were obtained by fitting the ψ and Δ angles in the range of 300-1000 nm with the Cauchy model, a dispersion relationship often used for transparent films. Below λ= 300 nm, the optical properties of the polymer were obtained by a point-by-point fit. The SiO_2-like and SiN_x film bulk were also modeled by means of the Cauchy formula.

The water vapor barrier properties of the SiO_2-like (data not reported here) and SiN_x films on PEN were evaluated by means of the Ca test; the SiN_x layers were also tested in a multi-stack system consisting of PEN/SiN_x(130 nm)/P(400 nm)/SiN_x(130 nm), where P is a sprayed/UV cured acrylate-based interlayer.

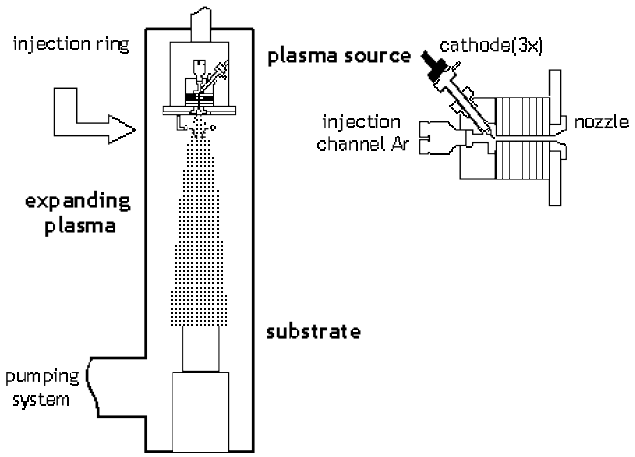

Figure 1. Expanding thermal plasma setup.

3. Results and Discussion

3.1 ETP deposition of inorganic moisture barrier layers

Figure 2a shows the SiN_x film refractive index (λ = 633 nm) increase (corresponding to an increase in film density and/or N-to-Si ratio) as a function of the rf power delivered to the substrate, confirming the results already presented on ETP- deposited SiN_x densification by means of ion bombardment [11].

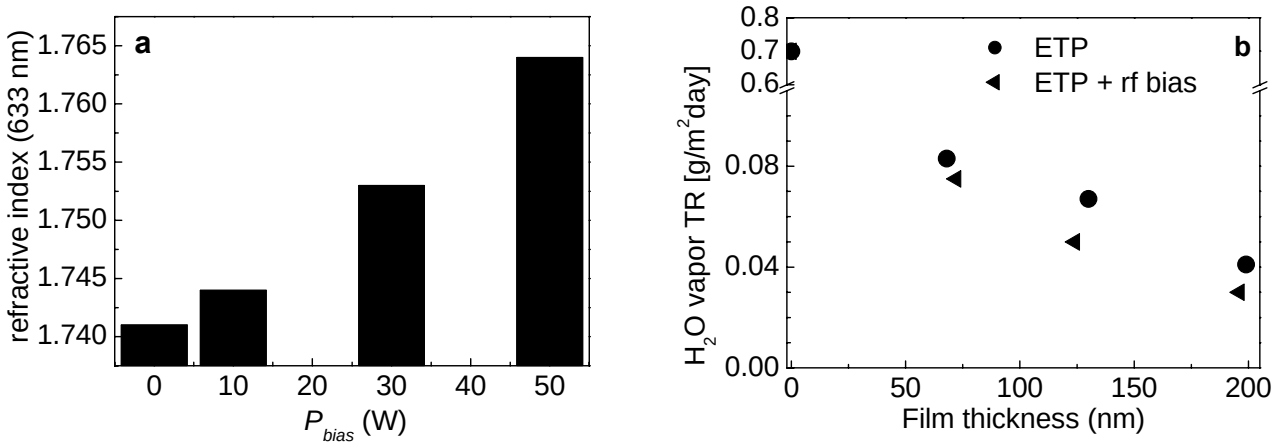

Figure 2. a) Refractive index (=633 nm) as a function of the biasing power externally applied to the substrate. b) Water vapor permeation of PEN/SiN_x, the SiN_x layer being deposited in the presence and absence of subtrate bias (P_{bias}= 50 W; V_{bias}= -160 V).

The moisture barrier permeation of SiN_x layers grown in the presence and absence of ion bombardment was tested and reported in Figure 2b: it appears that the substrate biasing allows to deposit efficient single SiN_x barrier films ≈ 50 nm thinner than SiN_x layers obtained in the absence of ion bombardment. These results agree with what reported in literature: a critical barrier layer thickness in the 50-100 nm range [12], when the films are deposited by means of rf plasmas (i.e., ion bombardment is present). Evidently, the ion bombardment- induced film matrix densification does not contribute to an improvement in the film barrier properties (the water vapor transmission rate of a 200 nm- thick layer hardly decreases); instead, the data in Figure 2b are indicative of conductance-limited permeant transport (e.g., via defects) across the barrier layer. The SiN_x layer deposited in the presence of an external substrate bias (P_{bias}= 50 W) has been tested in a two dyads barrier system, as described in the Experimental section. Figure 3 highlights the beneficial effect of an interlayer between two

SiN_x layers: the water permeation decreases of a factor 100 compared to the pristine PEN. At this rate, three additional dyads (P/SiN_x) could be sufficient to meet the requirements for OLEDs encapsulation.

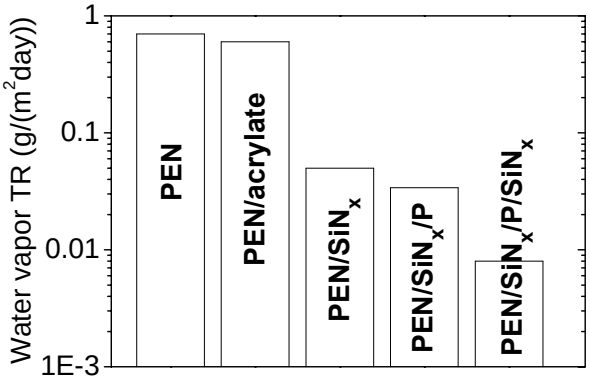

Figure 3. Water vapor transmission rate of a two dyads system, PEN/PEN/SiN_x(130nm)/P(400 m)/SiN_x(130nm).

3.2 Interphase development during the deposition of an inorganic layer on a polymer substrate

Literature studies on plasma deposition of inorganic layers on polymer substrate have shown the presence of an interphase region between the polymer bulk and the deposited layer bulk [8]. This region has been only investigated by means of ex situ diagnostic tools, such as x-ray photoelectron spectroscopy (coupled to Ar^+ sputtering), IR spectroscopy and Rutherford backscattering spectroscopy [8, 13]. On the contrary, in situ real time studies during the interphase evolution and inorganic film growth have not been reported; moreover, the optical (e.g., via spectroscopic ellipsometry) detection of an interphase developed between a polymer substrate (polycarbonate) and SiO_2 was reported to be difficult to attain [14]. The formation of this interphase region is hypothesized to develop during the early stage of interaction between the plasma and the polymer surface: UV light, non-depositing radicals (e.g., O, OH, N, NH_x), ion bombardment may, in fact, affect the polymer surface before appreciable deposition occurs. The presence of the interphase can strongly influence the adhesion of a barrier layer/polymer system, as well as the inorganic layer critical thickness.

Here, initial studies devoted to the detection of the interphase have been carried out first on plasma- deposited SiN_x layers on PEN substrates by means of *ex situ* spectroscopic ellipsometry. Figure 4a shows the experimental ψ data of a SiN_x layer deposited on PEN fitted with two models. It can be observed that a *homogeneous layer* model, which assumes constant optical properties for the deposited SiN_x layer, does not properly fit the experimental data. On the contrary, including an interphase region before the bulk growth occurs, improves the fitting. Figure 4b shows the evolution of the refractive index *n* (at 633 nm) as a function of the film depth: a graded interphase of ≈ 25 nm appears to be present before the SiN_x bulk layer develops. Also a surface roughness modeled according to the Bruggeman effective medium approximation was included. Thin SiN_x film depositions (up to 50 nm) have been also carried out: Figure 4b shows that their refractive index values align with the evolution of the refractive index observed for the thick SiN_x layer, therefore, confirming the adopted optical model. The thin film *n* values are, however, lower compared to those describing the interphase region: this can be explained by post-deposition oxidation due to the porosity of the layers. Although the interphase region is optically modeled by linearly mixing the dielectric function of the SiN_x bulk layer with different percentages of voids, the interphase region may be differently interpreted. A (sub)-surface polymer modification by means of NH_x radicals and UV light, resulting in a decrease of the polymer refractive index (*n*= 1.77 at 633 nm) could occur before appreciable deposition takes place.

These initial *ex situ* studies have been followed up by an *in situ* real time investigation on the growth of SiO_2-like films on PEN in order to monitor the development, if present, of the interphase region. The SiO_2-like films were deposited at a deposition rate of 3.5 nm/s (as derived from the growth of a 150 nm thick film on Si).

Figure 5a shows the refractive index development (at 633 nm) as obtained by modeling the deposited layer on PEN (*static measurement*) and by modeling the same layer during its growth (*dynamic measurement*).

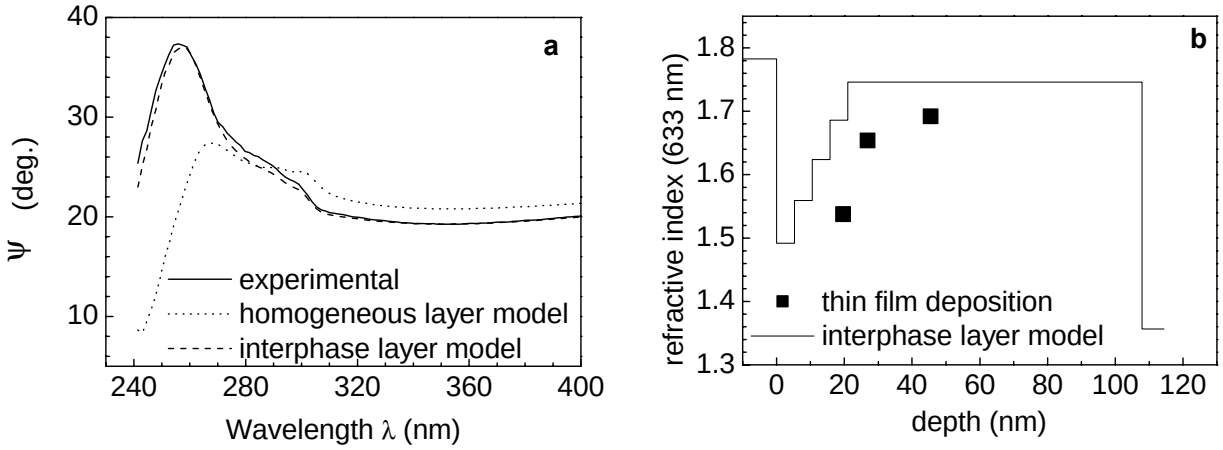

Figure 4. a) Experimental ψ data for a SiN_x film deposited on PEN, fitted with two different models. b) Refractive index evolution as a function of the SiN_x film depth for the interphase layer model. The refractive index and thickness of three thin SiN_x layers deposited on PEN are also shown.

The optical model built up for the SiO_2-like layer grown on PEN includes a graded composition- interphase region, interpreted as a linear combination of the (complex) dielectric functions of the polymer substrate and the SiO_2-like film bulk. The *in situ* real time ellipsometric data confirms the presence of an interphase characterized by optical properties, which are intermediate between the polymer and the inorganic layer bulk. This interphase region, which extends for ≈ 30 nm, can be interpreted as it follows. During the initial growth of the SiO_2-like layer a polymer (sub-) surface modification via atomic oxygen (and UV light) occurs, most certainly, increasing its porosity. More in detail, the refractive index values in the 10-30 nm-depth region are too high to be attributed to SiO_2-like layers; instead, they suggest the presence of carbon. Literature studies [8] document the presence of a carbon-rich interphase which formation is attributed to the initial interaction of ions and photons with the polymer surface. Its partial ablation would generate volatile hydrocarbon fragments which, mixed with the plasma chemistry typical of a SiO_2 deposition, lead to the formation of an "organosilicon"-like interphase. In the expanding thermal plasma, however, the ion bombardment effect can be definitely neglected and, although Ar metastables could play a role in surface processes, their density is about a factor 10 lower than the ion density [15]. Also, if the considerably high deposition rate is taken into account (3.5 nm/s), a high radical flux towards the substrate can be estimated around $2\text{-}5\cdot10^{19}/m^2\cdot s$. In conclusion, the observed interphase region developed during the expanding thermal plasma deposition of SiO_2-like films can be attributed to a polymer modification due to a non- depositing radical (O, OH) flux competitive with the depositing radical (Si, SiO) flux. In this framework, initial growth of the SiO_2-like layer via island formation cannot be excluded. Moreover, when short depositions (≤ 10 s) are performed on both Si and PEN substrates, different deposition rates are observed, as shown in Figure 5b. The higher deposition rate in the case of PEN appears to point out towards an initial growth of a porous layer; moreover, the presence of an intercept ≠ 0 in the case of PEN, seems to suggest the physical contribution of the (modified) polymer sub-surface to the interphase region observed in Figure 5a.

4. Conclusion

We have addressed the deposition of inorganic permeation barrier layers on PEN substrates by means of the expanding thermal plasma with and without an external substrate bias. The ion bombardment does hardly affect the water vapor permeation rate; however, it allows depositing efficient (barrier improvement factor of 23) single SiN_x barrier films ≈ 50 nm thinner than SiN_x layers obtained in the absence of ion bombardment. The SiN_x layer was tested in a two dyads barrier system, with a water permeation decrease of a factor 100 compared to the pristine PEN. In the absence of ion bombardment towards the substrate, an interphase development between the polymer bulk and the inorganic film bulk is observed. At this moment it is hypothesized that non-depositing radicals (O, OH in the case of SiO_2 deposition) may be responsible for polymer sub-surface modification during the initial layer growth.

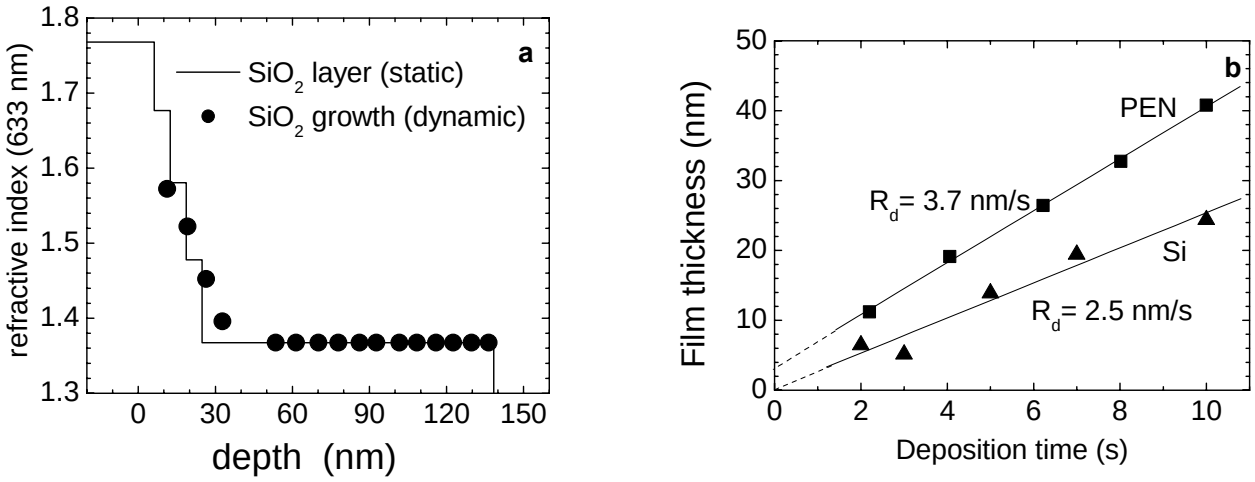

Figure 5. a) Refractive index evolution as a function of the SiO_2–like film depth, as obtained by modelling the deposited layer on PEN (static measurement) and the same layer during its growth (dynamic measurement). b) Growth rate of SiO_2-like films on Si and PEN substrates for short deposition times.

Abstract

Decontamination of a phytopathogenic strain of agricultural interest *Erwinia carotovora atroseptica* (Eca) is achieved by means of gliding arc discharges in humid air in specially adapted devices. Cultures of Eca exposed to the plasma in two different gliding arc reactors prototypes were inactivated by ten logarithm units. The destruction kinetics of the bacteria with the two prototypes are compared and the involved mechanisms discussed.

Keywords

Gliding arc discharges, decontamination, viability, sterilisation

Introduction

Among the emerging decontamination techniques, the electrical discharges are probably the most promising methods for getting efficient plasma techniques. The gliding arc discharges (or glidarc) draw industrial attention because of their low cost in equipment and working conditions, since they are operated at atmospheric pressure and low temperature. Moreover their efficiency for the destruction of micro-organisms have been already established on *Escherichia coli* [1], *Erwinia* spp. [2] and *Staphylococcus epidermidis* [3] .

Several techniques give rise to non-thermal plasmas at atmospheric pressure and low temperature, i.e., pulse and/or dielectric barrier discharges, glow, microwave and gliding arc discharges. Most of them were recently tested for pollution abatement of liquid effluents. The literature also reports attempts to use non-thermal plasmas for bio-decontamination [4]. However, the mechanisms responsible for bacterial destruction are poorly known and the effect of this technique on pathogen bacteria has never been investigated.

We have selected a strain of Erwinia which is a major potato pathogens [5]: *Erwinia carotovora atroseptica* (Eca), Indeed, many countries encounter serious problems with pectinolic Erwinia which cause the loss of entire crops and financial damages estimated to 100 billions dollars a year for potatoes producers. In temperate regions, *Erwinia carotovora atroseptica* is frequently responsible for potato diseases and the producers are seeking for rapid and efficient decontamination techniques that could be applied for the treatment of both water and solid surfaces. This bacteria was selected to test the efficiency and the reproducibility of the glidarc quenched plasma treatment.

Two generations of glidarc reactor prototypes were used for this study, and the relevant destruction kinetics of Eca are compared. These results are discussed in regard of the mechanisms potentially involved in the decontamination process.

Materiel and method

Gliding arc reactors

Two prototype reactors were used for this study: both derive from the gliding arc device previously described by Lesueur *et al.* [6]. The simplest reactor (Reactor I) is sketched in figure 1.

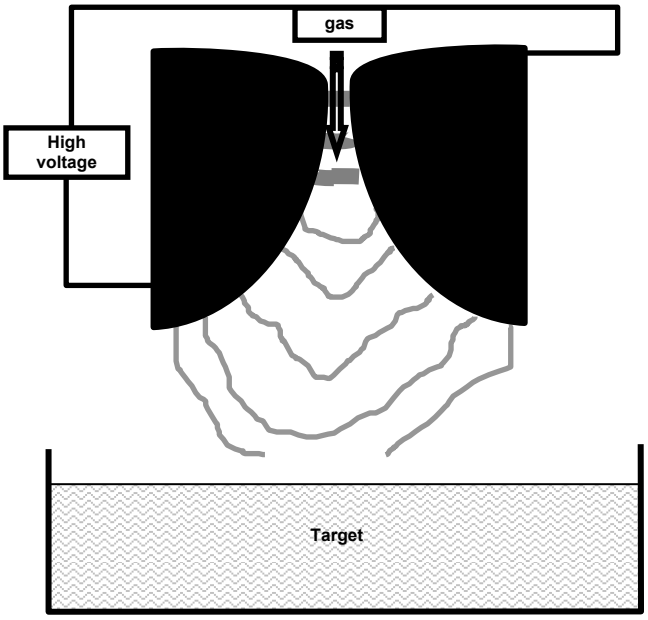

Figure 1: Scheme of the gliding arc reactor I.

It consists in two metallic diverging electrodes raised to a high voltage fall (9kV, 100mA in open conditions) fitted with a feeding gas nozzle disposed along the axis of the reactor. An arc forms at the electrode minimum gap and moves along the electrodes as it is pushed by the gas flow, until it breaks in a plasma plume and a new arc forms. The plasma plume then makes contact with the target and the plasma activated species react at the liquid-gas interface.

The plasma is a mixture of N_2 and O_2 supplied by an air compressor. The feeding gas gets water saturated by passing through a bubbling flask filled with distilled water in order to create more reactive species. The working parameters of the reactor, such as the gas flow rate ($L.min^{-1}$), the electrode gap and the distance between the electrode tips and the target are controlled.

The reactor of the second generation (Reactor II) is a development of the former one. The general scheme of the reactors is similar but the improved reactor II involves electronic improvements that provide a more energetic plasma which occupies a larger volume and allows to treat a more important liquid surface.

Bacterial strain and culture conditions

Erwinia carotovora atroseptica 1526 was provided by the French Collection of Phytopathogenic Bacteria (CFBP, Angers).

The bacteria were maintained as glycerol stocks and stored at – 80°C for further use. 5ml precultures were grown on LB medium at 28°C for 24 hours. An aliquot of them were used to inoculate 100ml of sterile LB medium, grown in the same conditions, to allow bacteria to be in statinary growth phase. 25 ml of these cultures were used as samples and exposed to the plasma.

Before and after each plasma treatment, counts of surviving cells were determined by the standard platting technique. The CFU (Colonies Forming Units) were counted after 48h at 28°C.

Viability of bacteria

The viability, i.e, the growing faculty for of the bacteria, was assessed with the LIVE/DEAD *backlight* viability kit (Molecular Probes, Eugen, OR) based on the use of SYTO 9® and propidium iodide nucleic acid probes. Whereas SYTO 9® can easily enter a bacteria and labels all the living population, propidium iodide only penetrates cells with damaged membranes. The SYTO 9® green labelled bacteria are thus considered as living cells while the red stained bacteria obtained with propidium iodide are actually dead cells.

Untreated and gliding arc treated cultures of Eca were observed by Scanning Electron Microscopy. Photomicrographs were realised with a S4500, Hitachi camera.

Results and discussion

The effect of the gliding arc technique was studied over a 15 minutes period, which is long enough to inactivate the whole bacterial population. The plots reported in figure 2 illustrate the kinetics of the treatment on the growth potential of *Erwinia caratovora atroseptica* relevant to the two reactor prototypes.

The kinetics evolutions of the bacterial population (Log N) with the treatment time (min) presents three steps: *i)* the initial plateau accounting for a lag phase, during which the number of growing cells remains almost steady, *ii)* a rapid decrease in the bacterial population accounting for an overall first order kinetic law with the inactivation rate $k \approx 3.33\ s^{-1}$ (the relevant rate of which reaches 10 logarithm units of the bacterial population within 30 seconds) and *iii)* a steady state characterised by a number close to zero number of bacteria able to generate colonies on Petri dishes at the end of this second phase.

As evidenced in figure 2, the gliding arc reactor II is more efficient for bacterial destruction than reactor I in our working conditions since the total destruction of the bacterial culture is obtained for 8 min with reactor I and for less than 5 min with the matching reactor II. This difference is assigned to a more energetic discharge available in reactor II than in reactor I, which thus induces a faster reaction due to an increased production of activated species.

During the plasma treatments, no variation of the suspension temperature is observed: the target temperature never gets higher than 25°C (reactor I) or 35°C (rector II) and prevents from considering any direct thermal effect [2].

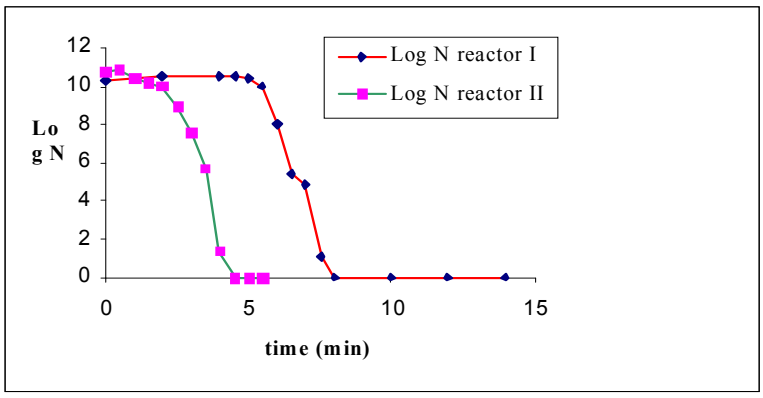

Figure 2: Destruction plots of *Erwinia carotovora atroseptica 1526* (Eca) vs. exposure time t(min) relevant to the couple of two gliding arc reactors.

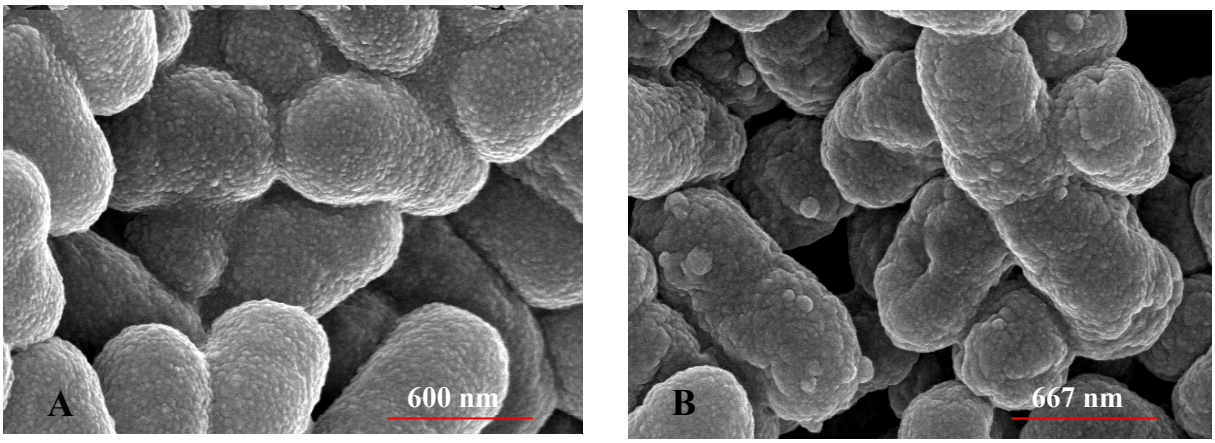
The effects of the electric discharges and those of the plasma species on bacteria are still poorly known and specially those concerning the gliding arc.

Different degradation mechanisms are proposed in the literature to explain the bacteria death:
* Pelletier [7] and Lerouge *et al.* [8] suggest that the alteration of the integrity of the membranes is followed by irreparable damages of DNA and RNAs.

* The UV light was proposed as the main component of the plasma responsible for the lethal effect. Moisan *et al*. [4] demonstrated that the UV energy transferred by the discharge to the surrounding gas in low pressure discharges corresponds to the absorption band of nucleic acids. However, the number of UV photons emitted by a gliding arc discharge is limited [9], so the effect observed for such treatments probably involves other determining factors.
* We have thus to develop the main valuable assumption to account for the action of the glidarc discharges on bacteria which is based on the chemical processes induced by the discharges in humid air. Benstaali *et al.* [10] evidenced oxidising and acid effects in aqueous solutions of organic compounds exposed to the discharge. These changes are respectively attributed to the occurrence of the $HO^{\bullet}$ and $NO^{\bullet}$ radicals formed in the humid air plasma [11]. Our measurements confirm that $NO^{\bullet}$ is responsible for acid effects and for a steep pH lowering of the medium by means of the formation of HNO_2/HNO_3 derivatives in solution. The relevant rapid pH fall from 6.87 to 3.55 [2] can provoke a stress so violent that the bacteria have no time to adapt and die.
The matching radical involved in the discharge, $OH^{\bullet}$, is a strong oxidising agent which is probably associated with the rapid degradation of organic matter [12]. In addition, it combines to yield H_2O_2, in aqueous medium, and hydrogen peroxide is well known for its very high sterilisation activity. Indeed, this reactive species can induce alterations of enzymatic activities, hyperoxydation of lipids, protein degradation and DNA alterations.

The results of bacterial destruction obtained by direct counting are consistent with those obtained by epifluorescence observations [2]. The bacteria exposed to glidarc plasma were not stained by the matching fluorescent probes and the untreated bacteria were effectively green-fluorescent. Since the SYTO 9 ® and propidium iodide dyes bind to the nucleic acids, the lack of fluorescence of the treated bacteria can be explained by the denaturation and/or fragmentation of DNA and RNAs. The total absence of green labelled bacteria after the exposure to glidarc indicates that this technique do not generate viable but non cultivable forms of *Erwinia.* This result reinforces the interest of the glidarc decontamination process for industrial applications.



Figures 3 A and B: SEM photomicrographs of *Erwinia carotovora atroseptica* 1526. A) Eca untreated, x 50 000, B) Eca treated for t = 2.5 min, x 45000

The epifluorescence technique demonstrates that exposure to the plasma for a few minutes causes very important damages to the bacteria and suggests a loss of integrity of the bacterial membranes. This assumption is confirmed by SEM observations that show ruptures and/or disorganisation of the membrane (figures 3 A and B).

Conclusion

The presented study reports the effects of a new decontamination technique, i.e., the use of the gliding arc discharge at atmospheric pressure, on closely related bacterial pathogens of industrial interest. Simple improvements in the reactor prototype first qualitatively confirms the former results on bacterial inactivation and additionally shorten the treatment time by a ratio close to 2. The absence of formation of resistant forms of *Erwinia* after exposure to the discharge is also demonstrated. These features strongly suggest that the decontamination process is related to the occurrence of the plasma formed reactive species and is affected by changes in the composition of the culture medium and very important impact on the bacterial structure.
Work in progress is intended to precise the impacts of the gliding arc discharges on the bacterial structure.

Abstract

The influence of weak electric fields on burner-stabilized, premixed CH_4-air flames was investigated at a flat flame burner at pressures down to 60 mbar. From temperature profiles evaluated from the CH $A^2\Delta$-$X^2\Pi$ (0,0) emission band at 431.42 nm and from chemo-luminescence intensity profiles a shift of the reaction zone of the flame in direction of the E-field increasing with the applied voltage was obtained. At high reduced electric fields E/n ionization and the excitation of N_2-emission bands were observed.

Keywords: premix combustion; reaction zone; electro-hydrodynamics; ionic wind; temperature profile; ionization; glow discharge

1. Introduction

The influence of electric fields on flames has often been investigated in the past. Calcote and Pease e.g. attributed the increase of the stability limit of an n-butane air flame on a Bunsen burner to an ionic wind induced by the interaction of the electric field with chemi-ions present in the flame [1]. Noorani and Holmes [2] obtained an extension of 83 % of the blow-off limit of a laminar premixed methane-air flame. A systematic experimental study of electric-field effects on flame stability was presented by Calcote and Berman [3] who found effects on flame stability for laminar as well as turbulent flow. A comprehensive treatment of theoretical aspects of the interaction of electric fields with flames was given in [4] and [5] by Lawton, Weinberg and Mayo. They showed that the body force transferred is proportional to the current density induced by the electric field and that the attainable ion wind velocity is limited by the current density corresponding to the breakdown field strength of the electrode-flame system. However, corona discharges can also be utilized for combustion control [6, 7]. Presently a growing number of publications are devoted to plasma-chemical control of combustion processes [8]. Nevertheless, a clear picture of electric field combustion control under conditions where plasma-chemical effects are unlikely to occur is still missing.

Thus the objective of the investigations reported here is to give experimental evidence of ionic wind effects on the reaction zone of a CH_4-air premix flame at reduced electric fields E/n lower than those required for electrical gas breakdown and in a transitional region of E/n values, were combustion-assisted gas discharge effects can be observed. All experiments were performed on a McKenna flat flame burner [9] because in this case the burner-stabilized, laminar flow, premix combustion can be described by 1-dimensional simulation using e.g. Chemkin. At atmospheric pressure a spatial resolution of around 10 μm would be required in order to observe electric field effects on position and thickness of the reaction zone. Since with decreasing pressure both the gap between burner surface and reaction zone and the thickness of the reaction zone increase [10], the investigations were performed at pressures between 60 mbar and 200 mbar.

2. One-Dimensional Model of Electro-Hydrodynamic Effects on Premix Combustion

Since a simple 1-dimensional model of electro-hydrodynamic effects on premix combustion has been published in [4] only a short review will be given here. Electrons and ions are generated by chemo-ionization

$$CH + O \rightarrow HCO^+ + e^- \qquad (1)$$

in the reaction zone of the flame. They are removed from the reaction zone by the convective flow of the flame, undergo charge exchange reactions, and finally recombine. Because negative oxygen ions are not

very stable at high temperature electrons are the dominating negative charge carriers. When an electric field is applied, charge separation occurs on scales larger than the Debye length. The following assumptions are made: (i) Generation of charge carriers outside the reaction zone can be neglected. (ii) Due to charge separation the only charge carriers are electrons between anode and reaction zone, and positive ions between cathode and reaction zone. Therefore outside the reaction zone recombination does not take place. (iii) The ion current density between cathode and reaction zone equals the electron current density between anode and reaction zone. This is a consequence of the continuity of current density at the reaction zone.

Because of the small electron mass only the ions are able to transfer momentum to the gas flow, which results in an ionic wind directed towards the cathode. Neglecting viscous losses, the stationary, one-dimensional momentum balance equation reads

$$\rho \cdot u \cdot \frac{\mathrm{d}\,u}{\mathrm{d}\,z} + \frac{\mathrm{d}\,p}{\mathrm{d}\,z} = f_{es} \tag{2}$$

where u, ρ, and p are the flow velocity, mass density, and pressure, respectively, and z gives the height above the burner surface. If other external forces can be neglected the force density f_{es} is determined by the electric field acting on the ions

$$f_{es} = e_0 \cdot n_i \cdot E \tag{3}$$

where e_0 denotes the elementary charge. Using the approximation

$$v_{di} = \mu_i n \cdot E / n \tag{4}$$

for the ion drift velocity with the reduced mobility $\mu_i n$ being independent of the gas density n, and the definition of the ion current density

$$j = e_0 \cdot n_i \cdot v_{di}, \tag{5}$$

the force density is found to be proportional to the current density:

$$f_{es} = j \cdot n / \mu_i n \tag{6}$$

Two extreme cases can be considered in solving (2): If the pressure gradient dp/dz is neglected an ionic wind velocity

$$u = \sqrt{f_{es} \cdot d_{cr} / \rho} = \sqrt{j \cdot d_{cr} / \mu_i n \cdot n / \rho} \tag{7}$$

results at the cathode, where d_{cr} is the distance between reaction zone and cathode. In the other case a pressure gradient proportional to the force density is generated.

If electron collision ionization occurs, which due to the high temperature (and low gas density) is more likely between reaction zone and anode, assumption (ii) is no longer valid, and ions may contribute to the current density thus inducing electro-hydrodynamic effects in this region, too. At sufficiently high electric field strength even gas discharge breakdown can take place. Then electrons contribute to the current density between reaction zone and cathode, such that (6) and (7) are no longer valid. As a consequence a reduced ionic wind velocity results.

3. Experimental Set-up and Procedure

A McKenna flat flame burner was mounted inside the lower vertical arm of a CF six-way cross with a nominal inner diameter of 150 mm (Figure 1). It consisted of a water cooled porous bronze plate with a diameter of 60 mm, through which the methane–air mixture was passed. A water-cooled exhaust gas pipe connected the upper vertical arm of the six-way cross to a water ring pump via a throttle valve by which pressures down to 60 mbar could be controlled. Three view ports equipped with fused silica windows provided optical access to the flame.

A ring electrode 90 mm in diameter made of stainless steel wire (∅ 4 mm) was placed 60 mm above the burner plate and connected to a DC high voltage power supply. The burner plate was connected to ground. To measure the current a 2 MOhm resistor was inserted between the HV supply and the ring electrode. Short rise time square wave pulses were generated by means of a fast high-voltage transistor switch HTS controlled by a wave generator. Voltages were measured using two HV-probes; the current was

evaluated from the voltage drop at the 2 MOhm resistor.

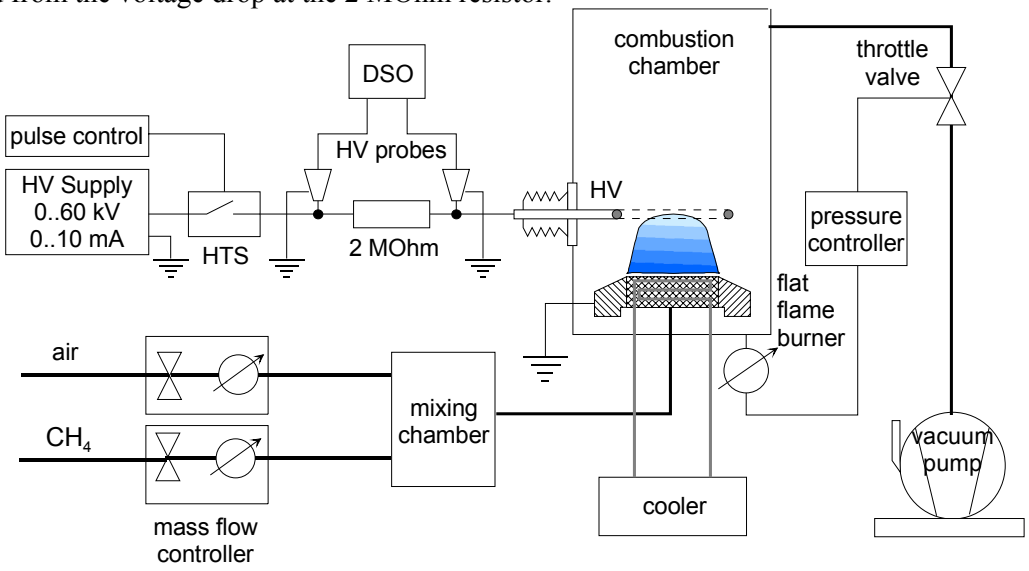

Figure 1. Set-up of the low pressure combustor

For spectroscopic investigations an image of the flame (magnified by a factor 1.43) was focused on the entrance slit of an imaging spectrometer of 500 mm focal length, equipped with a 1200 lines/mm grating blazed at 300 nm using two quartz lenses. Spectra were recorded by an intensified CCD camera with 1024 x 1024 pixels on a square of 13.3 x 13.3 mm^2. 10 (and in some cases 20) rows of the CCD-chip were „binned" to obtain a sufficient signal-to-noise ratio. Thus the spatial resolution of 90 (or 180 μm) was lower by a factor of 10 (or 20) than the theoretical limit.

For temperature measurements emission spectra were appropriately corrected for sensitivity variations and background and normalized to their peak intensity. The normalized spectra were fitted to spectra simulated with the temperature as a parameter [11,12] using a least-square-fit algorithm. Without an electric field this procedure can be applied to the CH $A^2\Delta$-$X^2\Pi$ (0,0) emission band at 431.42 nm and to the OH-band at 308 nm. For the CH-band good agreement between the maximum temperature obtained this way and the adiabatic flame temperature was achieved. From the OH-band, however, unreasonably high temperatures were derived. When sufficiently strong electric fields were applied, the N_2-bands of the second positive system $C^3\Pi_u$-$B^3\Pi_g$(0,0) at 337.13 nm, and $C^3\Pi_u$-$B^3\Pi_g$(0,1) at 357.69 nm could also be observed.

4. Experimental results

Temperature profiles

Temperature profiles with and without electric field were taken at pressures of 60, 80, and 200 mbar (Figure 2). The operating conditions of the flat flame burner are shown in Table 1. For a quantitative assessment of the temperature profiles a representation of the temperature data as a function of z similar to that of Berg et al. [16] was chosen:

$$T(z) = A + B\left\{1 - \exp\left[C(z - z_0)^D\right]\right\} + F(z - z_0)^2 \qquad (8)$$

From these profiles minimum and maximum temperature, maximum temperature gradient $(dT/dz)_{max}$, thermal thickness δ_L^T, (defined as $(T_{max}\text{-}T_{min})/(dT/dz)_{max}$), and displacement of the flame-front (defined as $z(T_{1/2},0)$-$z(T_{1/2},U)$ where $T_{1/2}$ is the average of minimum and maximum temperature) due to the applied voltage U were evaluated (Table 2).

As expected the thermal thickness of the flame increased with decreasing pressure. At 200 mbar it amounted to 0.2 mm and rose to 1.7 mm at 60 mbar. While at 200 mbar the application of an electric field did not result in effects on the temperature profile observable with the available spatial resolution, conspicuous changes occurred at 60 mbar. The CH temperature profile was displaced towards the burner by

1.3 mm. At the same time the flame front was flattened while the maximum temperature of about 2200 K did practically not change. The thermal thickness increased and reached values from 2.3 to 2.5 mm. These effects were measured both with DC and pulsed electric fields.

The displacement of the flame front as a function of applied voltage was evaluated from axial intensity profiles of the total visible emission, which peaked near the maximum of the temperature profiles. For 60 mbar and a DC voltage of 2.5 kV good agreement between the displacement of the temperature profile (Table 2) and that of the intensity profile was achieved. Up to this value the displacement increased linearly with the applied voltage.

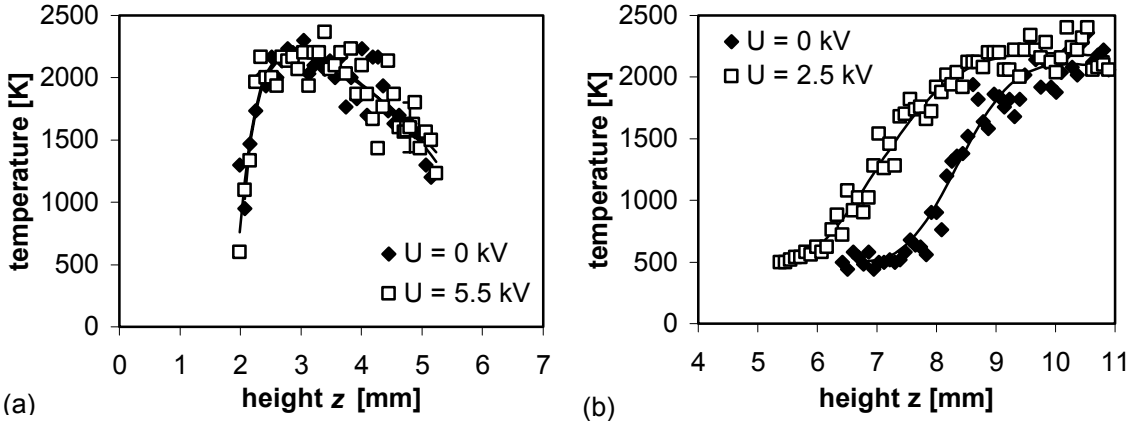

Figure 2. Influence of the electric field on the temperature profile evaluated from the CH $A^2\Delta$-$X^2\Pi$ (0,0) emission band (a) at a pressure of 200 mbar; (b) at a pressure of 60 mbar.

a) Unipolar square wave excitation; pulse rise time 100 µs, duration 1 ms, repetition frequency 500 Hz.
b) Rough estimates only. Minimum temperature could not be determined exactly.

Electrical characteristics

From the voltage-current characteristics of the flame taken at p = 60 mbar (Figure 3) several conclusions can be drawn: At low voltage electrons and ions generated due to chemo-ionization are partly separated and drawn to the electrodes before they can recombine. Thus the current increases with increasing voltage. Application of the model described above using a reduced ion mobility of $2.7 \cdot 10^{21}$/Vms results in an

ionic wind velocity at the cathode of about 1.8 m/s for a voltage of 2.5 kV (Figure 2b), which exceeds the feed flow velocity of 0.52 m/s substantially. Thus it appears likely that near the cathode a pressure gradient is generated due to the applied electric field.
At a DC-voltage of 800 V, when all charge carriers are extracted from the reaction zone before they can recombine, the current saturates. The increase of current at voltages larger than 1.7 kV can be attributed to ionization by electron collisions. The presence of the flame is considered to be essential for this effect. However, from the present experiment no conclusion about the transition from a non-self-sustained to a self-sustained glow discharge can be drawn. The different slope of the characteristics at negative electrode polarity can be attributed to the ratio of the electron mobility in the cold feed gas to that in the product gas of the combustion process being roughly equal to the inverse ratio of the respective temperatures 500 K/2200 K ~ 0.15.
Under pulsed excitation the current increases substantially slower as a function of the applied voltage amplitude. As will be seen more clearly below this indicates, that the relaxation of the space charge distribution between the reaction zone and the electrodes takes much more than 1 ms.

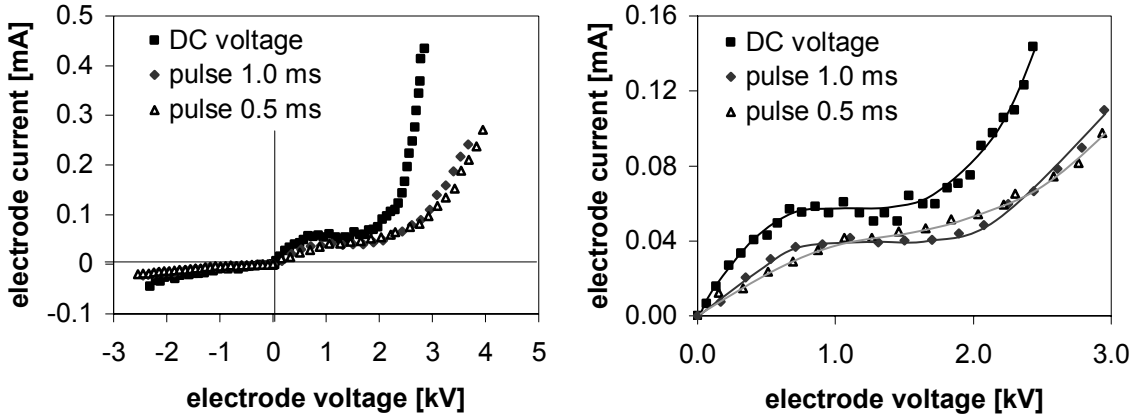

Figure 3. Voltage-current characteristics of the flame for DC and pulsed voltage (rhs shows a magnified view)

Relaxation of the reaction zone on application of electric fields
The temporal behaviour of the reaction zone was investigated by applying voltage pulses with an amplitude of U = 2.6 kV, rise time less than 0.1 ms and duration exceeding 100 ms. Photographs of the luminous zone of the flame were taken with an intensified CCD camera at preset times after the beginning of the high-voltage pulses. The displacement of the reaction zone required about 36 ms, which can only partly be understood in terms of the ionic wind propagating towards the cathode. However, according to [14] the time required to transfer momentum to the unburned gas by collisions between ions and neutral molecules may be several 10 ms.

N_2-emission bands
The appearance of N_2 bands is attributed to the onset of gas discharge effects that are responsible for the population of the high-lying upper level $C^3\Pi_u$. Thus it indicates the presence of electrons and of sufficiently strong reduced electric fields. Because of the inhomogeneous electric field due to the electron space charge near the ring electrode an increase of the N_2 band emission both in axial and in radial direction can be observed (Figure 4a). Therefore the conclusion can be drawn that the highest ionization rates occur near the ring electrodes. A few mm upstream of the ring electrode the profile measured at the axis shows substantially higher intensity values than that measured outside of the combustion zone having a radius of 30 mm, only. This indicates that due to the higher temperature and the ensuing lower density in the axial region higher reduced electric fields predominate.
Finally the temperature profiles evaluated from the N_2 spectra deviate from the CH temperature profiles (Figure 4b): Evaluation of the CH band results in a temperature of 500 K near the burner surface increas-

ing to its maximum value of 2200 K in a 3 mm wide zone. Evaluation of the N_2 $C^3\Pi u$-$B^3\Pi g$ (0,0) band resulted in the same maximum temperature, but even 6 mm upstream of the maximum a temperature of 1400 K is observed. This indicates that excitation and quenching mechanisms must be different for both species.

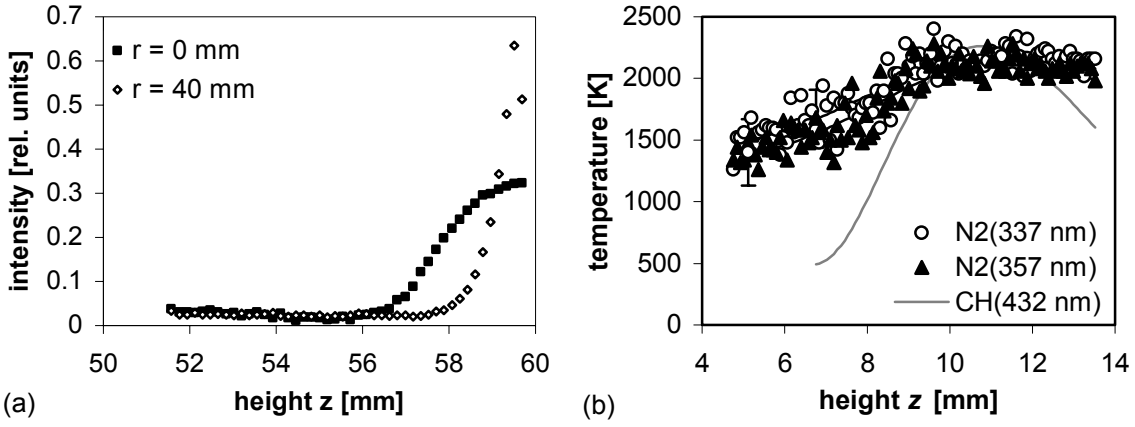

Figure 4. Intensity profiles of the N_2 $C^3\Pi_u$-$B^3\Pi_g$(0,0) band emission (a) and temperature profiles evaluated from N_2-emission bands (b) (pulsed excitation; temperature profile evaluated from CH emission shown for reference).

5. Conclusions

The displacement of the reaction zone of a low pressure burner stabilized flat flame is roughly proportional to the applied electric field in a wide range covering charge separation, current saturation and onset of gas discharge effects. The peak temperature is not influenced by application of an E-field. On application of square wave pulses the relaxation of the reaction zone takes several 10 ms. From the N_2 $C^3\Pi u$-$B^3\Pi g$ (0,0) band emission intensity profiles information about the reduced electric field can be obtained. High intensities are found in regions around electrode structures with small radius of curvature or in regions of high temperature. The temperatures upstream the reaction zone of the flame evaluated from the N_2-bands of the second positive system are unrealistically high indicating a non-thermal excitation mechanism of the upper molecular levels.

Abstract
TiO_2 coatings doped with varying amounts of V, Nb or Ta oxides were deposited by suspension plasma spraying (SPS). The dopants were incorporated *in situ* by plasma spraying of aqueous suspensions of fine oxide powders. Microstructural properties were studied by X-ray diffraction (XRD) and micro-Raman spectroscopy. The photocatalytic activities of coatings doped with 4 at.% of either Nb or Ta exceeded those of standard Degussa P-25 sol-gel coatings.

Keywords
Titania coatings, anatase, rutile, group V elements, photocatalytic activity, suspension plasma spraying

1. Introduction

The 4th International Symposium on Group Five Compounds has proclaimed these compounds key elements in solid-state chemistry, material science, catalysis, and engineering of functional materials [1]. In particular, V, Nb and Ta demonstrate great potential for various research and industrial applications, both as a main component or a dopant. Doping is a very effective way to improve the electronic performance of different semiconductor systems including titanium dioxide. TiO_2 is of particular interest as an outstanding photocatalyst for environmental applications such as water or air purification by degradation of organic pollutants [2]. Also, in recent years a rapid increase occurred of research interest into TiO_2 in the field of gas sensors [3-6]. Its high sensitivity, improved selectivity and fast response make it particularly suitable for automotive applications.
Improvement of photocatalytic and sensory properties of TiO_2 can be achieved by doping with different elements [7,8]. Among them, V, Nb and Ta show unique features: they are pentavalent, have ionic radii close to Ti^{4+}(61 pm) and thus demonstrate higher solubility of their oxides in the TiO_2 lattice. It has been found that (i) small amounts of Nb_2O_5 added to TiO_2 powder significantly increase surface acidity and photocatalytic activity [9], (ii) TiO_2–Nb_2O_5 sensors show higher sensitivity and shorter response time than pure TiO_2 [3-6, 10, 11], and (iii) low doping levels of Nb and Ta efficiently suppress the anatase-to-rutile phase transition below 1000°C [12, 13]. Addition of vanadium oxide can reduce the band gap of TiO_2, by a downward shift of the conduction band [14, 15] suggesting effective utilization of the visible part of the spectrum of the sun in photocatalysis.
Research into and development of mechanically stable TiO_2 coatings without reduction of their photocatalytic activity is being pursued worldwide. A variety of deposition techniques have been applied to achieve well-adhering, porous coatings with high photocatalytic activity. They include, among others, sol-gel processing [16], chemical vapor deposition [14] and rf sputtering [5]. However, thermal spraying also appears to be an appropriate process to produce coatings demonstrating such improved properties with additional promising economic prospects for industrial scale-up.

2. Experimental

2.1. Suspension plasma spraying

Thermally sprayed TiO_2 powder frequently decomposes at elevated temperature to form oxygen-deficient, non-stoichiometric Magnèli phases Ti_nO_{2n-1}. To counteract this effect and to deposit coatings with stoichiometric composition the oxygen containing atmosphere of an induction plasma torch was selected.

The suspension plasma spraying (SPS) process was introduced about 10 years ago and has been applied to the deposition of a variety of metallic and ceramic materials [17-20]. Also, *in situ* synthesis of ceramic coatings by reactive SPS was successfully achieved [21].

In the present work, (V, Nb, Ta)-doped TiO_2 coatings were deposited by reactive suspension plasma spraying with a wide range of dopant concentrations (0–16 at.%). The dopants were incorporated *in situ* by plasma spraying of aqueous suspensions of fine oxide powder mixtures in given proportions. Figure 1 shows the plasma reactor used for the experiments. The plasma source is a PL50 induction plasma torch from Tekna Plasma System Inc., Sherbrooke, Québec, Canada. The rf power is supplied by a 500 kHz rf generator from Himmelwerk GmbH, Tübingen, Germany, delivering a maximum power of 60 kW. The plasma expands into a water-cooled vacuum reactor. The substrate can be scanned in two orthogonal horizontal directions to coat larger surface areas.

Although in previous experiments it was found that oxygen must be added to the plasma gas to maintain the TiO_2 stoichiometry, the amount of oxygen had no significant influence on the stoichiometry of the titania coatings obtained. Therefore, all experiments were performed with low oxygen content (85 slpm Ar, 3 slpm O_2). The reactor pressure was kept constant at 20 kPa. The rf power was 24 kW. The precursor was fed with a rate of 3 ml/min and atomized with 5 slpm Ar using an air-blast atomizer, shown enlarged in Fig. 1, left bottom corner.

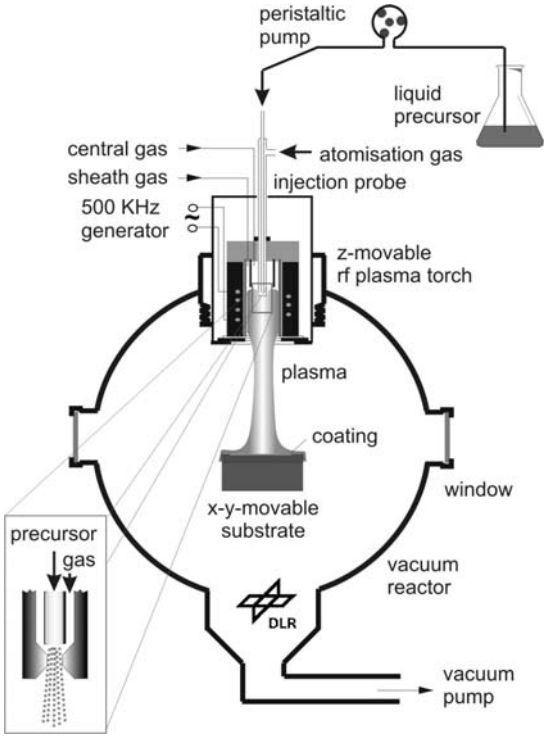

Fig. 1. Induction plasma reaction chamber.

2.2. Materials

Suspensions were prepared from 67 mass% deionised water and 33 mass% anatase powder with a crystallite size <10 nm and an average agglomerated particle size of 0.2 μm. The specific surface area (BET) was >250 m^2/g. Nb and Ta doping was performed by adding appropriate amounts of V_2O_5, Nb_2O_5 or Ta_2O_5 powder of identical particle size to the suspension. The precursor suspensions applied contained the following doping concentrations (in at. % of TiO_2): 0.5, 1.0, 2.0, and 4.0 % V, Nb and Ta, respectively. Furthermore, suspensions containing 8, 12, and 16 % of Nb resp. Ta were applied.

Titanium (cp-Ti) metal sheets and vitreous silica plates with dimensions of 8.5 x 12.5 x 1 mm^3 were used as substrates. Prior to spraying the Ti substrates were grit-blasted with fine alumina powder (-120+60μm) and ultrasonically cleaned in alcohol for 15 min. The vitreous silica plates were sized to fit a mini-photoreactor designed at the J. Heyrovský Institute of Physical Chemistry, Academy of Sciences, Prague, Czech Republic.

2.3. Coating characterization

The microstructure of the as-sprayed TiO_2 coatings was characterized by Raman spectroscopy using a Dilor XY double spectrometer equipped with a liquid nitrogen cooled CCD detector. The Spectra-Physics 2016 Ar+ ion laser line at 514.5 nm wavelength with an output power of 5 mW was used for excitation. Raman spectra were collected at 5, 10 and 50 times magnifications in backscatter geometry at room temperature. The spot size of the laser probe was between 1 and 10 μm. The spectral resolution was 1 cm^{-1}.

Information on the crystalline structure of coatings was obtained on an X-ray $\vartheta/2\vartheta$ Bragg-Brentano diffractometer (40kV/25mA) with CoK_α radiation at a scan rate of 0.04° 2Θ s^{-1}.

Coating surface roughness was measured using a Hommel Tester T8000 profilometer according to DIN EN ISO 4287. The parameters Ra, Rz and Rmax were found to be 3.6, 24.0 and 29.2 μm, respectively. Typical coating thickness was between 10 and 12 μm.

The photocatalytic activity of doped TiO_2 plasma-sprayed coatings was tested in a special mini-photoreactor designed from a standard spectroscopic cell using the decomposition of 0.01M 4-chlorophenol in aqueous solution with 0.01M $NaClO_4$. The sample was irradiated by polychromatic UV light (> 320 nm) from an Hg-lamp (Narva HBO 200, 26 V, 2 A). The UV radiation was filtered with an IR liquid filter and with a solid WG-3 UV cut-off filter. The pH change following a release of hydrochloric acid was continuously monitored by a glass electrode positioned above the sample coating. The initial reaction rate of the HCl formation is supposed to be proportional to the photocatalytic activity of the coating. The pH changes of the solutions were measured in both, in the dark and under UV irradiation. The kinetic parameter was determined from a slope of dependence (pH vs. time). The rates of pH changes obtained were compared with those of standard Degussa P-25 coatings under the same test conditions.

3. Results and Discussion

3.1. Phase content of the coatings

Figure 2 shows XRD patterns of the precursor anatase powder (top) as well as of a typical SP-sprayed coating (bottom). Anatase and rutile contents were estimated from the ratio of the intensities of anatase (101) ($2\theta = 29.4^o$), I_A and rutile (110) ($2\theta = 31.9^o$), I_R by the equation [22]

$$Rutile(\%) = 0{,}679 \cdot \frac{I_R}{I_R + I_A} + 0{,}312 \cdot \left(\frac{I_R}{I_R + I_A} \right)^2 \qquad (1)$$

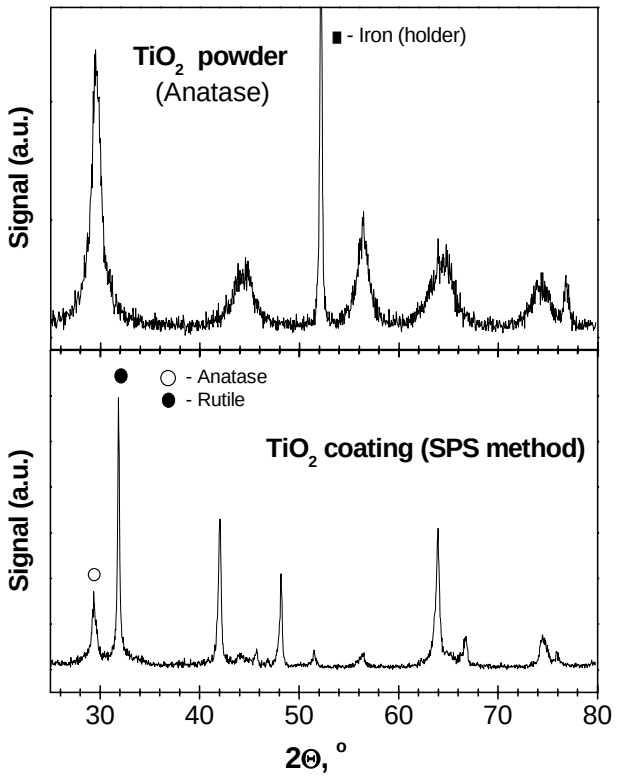

Fig. 2. XRD pattern of precursor anatase powder (top) and a typical SP-sprayed titania coating (bottom). The circles indicate, respectively the most intense interplanar spacings of rutile (110) and anatase (101).

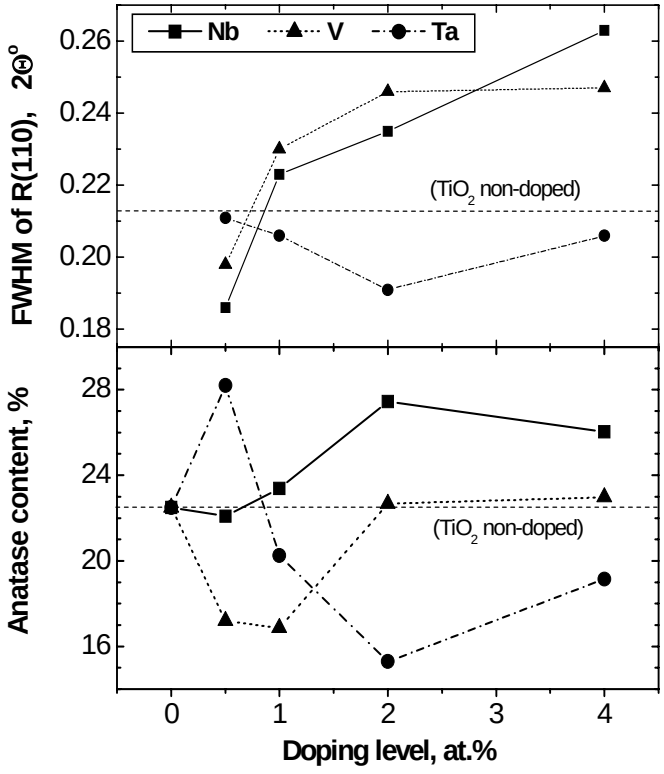

Fig: 3. FWHM of rutile (110) (top) and calculated anatase contents (bottom) of SPS titania coatings as functions of the doping concentration. The dotted lines refer to non-doped SPS titania coatings.

Undoped SPS titania coatings show anatase contents around 22% (Fig. 3, dotted line). Doping with 2 to 4at% Nb increases the anatase content to about 28%. Evidently Nb_2O_5 and V_2O_5 dissolve well in the TiO_2 structure as confirmed by a shift of the (110) spacing of rutile towards lower diffraction angles as well as by an increase in FWHM of the (110) spacing of rutile (Fig. 3, top).
Photoelectron spectroscopic (XPS) measurements of the $Nb3d_{5/2}$ line showed Nb^{5+} atomic concentrations in TiO_2 coatings ranging from 1 to 3 at%, approximately corresponding to the Nb contents in the precursor powders. Contrariwise, doping with Ta beyond a concentration of 1at% showed reduced anatase contents, presumably owing to only limited solubility of the Ta ion in the structure of anatase (Fig. 3, top).

3.2. Raman micro-probe analysis

Anatase is known to undergo irreversible transformation to the thermodynamically stable rutile structure during thermal spraying. Furthermore, the photocatalytic efficiency of titania coatings depends not only on their anatase content but also on their surface microstructure*, e.g.*, the distribution of spatial and structural inhomogeneities. Since Raman scattering is a useful tool to characterize thin films and coatings, in particular to detect and quantify spatially inhomogeneous surface states, micro-Raman spectroscopy was used to analyse and classify the phase structure and surface quality of SPS coatings.
Compared to XRD data, Raman spectroscopy provides information on the structure of submicron surface regions, *i.e*. regions essential to UV light penetration and hence the photocatalytic process. The micro-probe Raman method associated with the scanning mode of the laser beam allows collecting a huge amount of statistical information (10^3-10^4 points/cm^2 coating surface) on the TiO_2 phase content through so-called phase mapping. Intensities, peak positions, and widths of Raman bands of both anatase and rutile phases provide unique information on the crystalline quality of the coatings. The micron-scale spatial resolution of the Raman method coupled with the visual monitoring technique gives a more realistic and relevant picture than conventional x-ray diffraction.

Optical microscopy of the coating surfaces shows three different surface features tentatively denoted as (i) "bulk" coating as main background matrix, (ii) "exploded" splats, and (iii) glassy splats. The contrast image analyses of the coating surfaces showed about 80% of the surface area belonging to type (i) with the remainder approximately equally represented by types (ii) and (iii).The microstructure of these typical objects was analysed by the Raman micro-probe technique to yield the spectra shown in Fig. 4.

(i) The microstructure of the "bulk" coatings consists of a porous skeleton-like matrix of rutile filled with fine anatase particles. Consequently, the vibrational spectra of this phase (Figs. 4b to d) show additional Raman bands at 238(comb), 447(E_g) and 611(A_{1g}) cm^{-1}, suggesting the coexistence of rutile and anatase.
(ii) The "exploded" splats consist of agglomerates of anatase particles that have reached the coating surface without thermal transformation. Their origin is probably related to the formation of bigger suspension droplets that did not disintegrate in the plasma but were spray-dried to form hollow spheres that exploded upon impact. The Raman spectrum (Fig. 4a) is composed of five from six characteristic Raman bands at 147(E_g), 197(E_g), 396(A_{1g}), 515(B_{1g}) and 638(E_g) cm^{-1}, corresponding to different vibrational modes

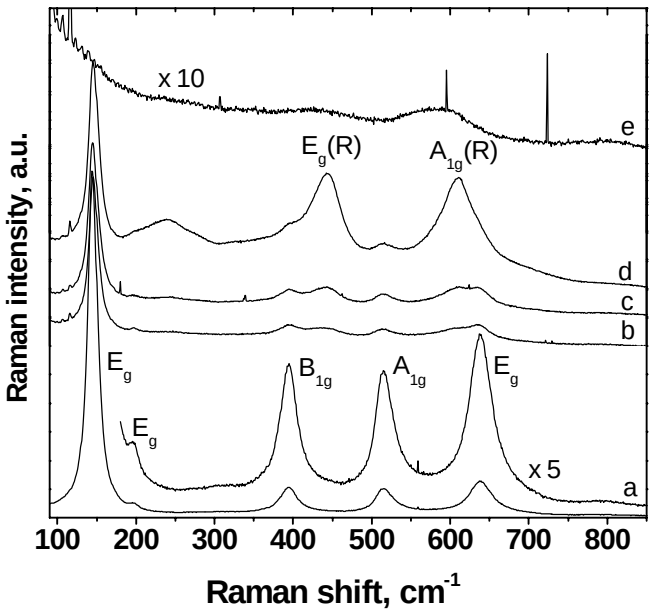

Fig. 4. Raman spectra of (a) "exploded" splats (type (ii)), (b to d) "bulk" coating (type (i)), and (e) glassy splats (type (iii)) of SPS titania coatings. For details see text.

of the anatase structure. The first one is the most intensive band, serving as a "finger-print" for the anatase structure during phase mapping.
(iii) The Raman spectra of the glassy splats (Fig. 4e) show the more or less amorphous structure of titania particles also originating from single bigger suspension droplets that did, in comparison to type (ii), completely melt after spray drying, either due to their limited size or due to their residence closer to the hot central axis of the plasma jet. The spatial distribution of these molten particles at the coating surface is comparable to that of the spray-dried agglomerates of anatase particles of type (ii). No additional Raman modes were found in the doped samples. For a more precise estimation of the anatase-rutile ratio the Raman micro-probe method is insufficient. Hence, a calibration with quantitative XRD of the near-surface coating layer is required. Nevertheless, from the intensity ratios of the two characteristic Raman bands of anatase (147 cm^{-1}) and rutile (447 cm^{-1}) a rough estimate could be obtained, yielding average values around 40-50% anatase in the "bulk" coating of type (i).

3.3. Photocatalytic performance

The rates of pH changes (d(pH)/dt) during photocatalytic degradation of 4-chlorophenol in aqueous solution in contact with doped titania coatings irradiated with UV light are shown in Figure 5. The Nb resp. Ta doped coatings demonstrate quite similar degradation rates with the maximum activity at 4at.% of doping, which exceeds that of standard Degussa P-25 sol-gel coatings. Doping with V appears to quench the photocatalytic performance of the coatings (low values not shown in Fig. 5). A compelling reason for this unexpected behaviour is still missing.

As pointed out by Sobczynski and White [23] the solubility of Ta in TiO_2 is very low. While it increases with temperature, at 1400°C it is still three times lower than that of Nb. The fact that in the present study the photocatalytic activities of Ta- and Nb-doped TiO_2 coatings are comparable suggests that additional electronic effects pertaining to Ta must be considered. Such effects could, for example, be related to a more strongly reduced coating surface in the presence of Ta ions, forming oxygen vacancies and leaving OH groups connected to the resulting Ti^{3+} ions [24].

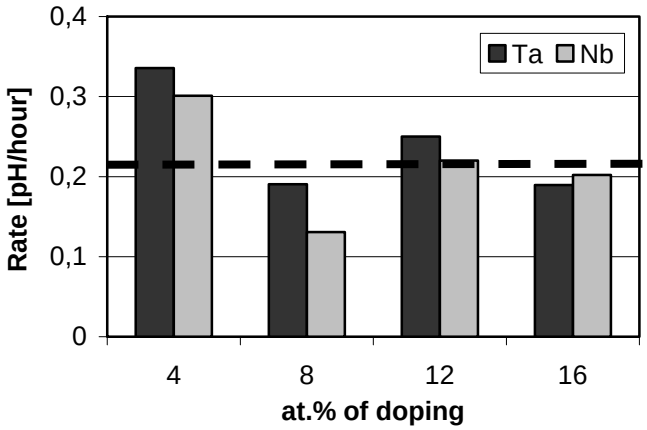

Fig. 5. Rates of pH changes during degradation of 4-chlorophenol on contact with doped TiO_2 coatings under UV radiation. The dashed line indicates the rate of a standard Degussa P25 sol-gel coatings.

4. Conclusions

(V, Nb, Ta)-doped TiO_2 coatings were deposited by suspension plasma spraying. The dopants were incorporated *in situ* by plasma spraying of aqueous suspensions of fine oxide powders. Microstructural properties were studied by X-ray diffraction (XRD) and micro-Raman spectroscopy. Special attention has been paid to the inhibition of the thermally induced anatase-to-rutile transformation by the dopants and the associated improvement of the photocatalytic activity of the sprayed coatings.

The plasma-sprayed coatings were about 10-12 μm thick with a deep blue-grey colour, indicating (i) the introduction of new electronic states into the band gap of the TiO_2 host, and (ii) an oxygen loss of the original TiO_2 powder due to the thermal treatment in the plasma. The surface morphology of the coated samples was rough and inhomogeneous due to the different size of droplets formed in the suspension spray. Larger "spray-dried" particles adhering to the surface of the samples contained higher amounts of anatase and were thought to constitute unmelted remnants of larger anatase precursor particles. By micro-Raman technique it was possible to identify the phase content and the crystalline quality of these microscopic objects. The XRD results obtained revealed a high solubility of V_2O_5 and Nb_2O_5 in TiO_2 and a more limited one for Ta_2O_5. The incorporation of dopant atoms into the TiO_2 lattice leads to broadening and shifting to lower diffraction angles of the TiO_2 XRD

peaks. The estimated anatase content of the coatings reached the maximum value of 28% for moderate doping levels, substantially higher than for non-doped TiO_2 coating.
Coatings doped with 4 at% of either Ta or Nb demonstrate a photocatalytic activity of about 0.33 pH/h and 0.30 pH/h, respectively, 40 to 50% better than that of a standard Degussa P25 sol-gel coating (0.22 pH/h).In spite of the quite low anatase content in the coatings the results of the photocatalytic performance of the coatings are quite encouraging for large-scale applications of group V element-doped TiO_2 SPS coatings.

Au nano-wiring process by plasma processes

Mikinori Suzuki and Shinzo Morita

Department of Electronic Information System, Nagoya University, Nagoya, 464-8603, Japan

Abstract

Au nano-wiring process with using plasma processes was proposed because metal wiring circuit fabrication is almost impossible to process by a conventional lithography. The processes are nano-insulation bed fabrication, C-Au-S semi-conductive layer formation and electroplating of Au. Au plating was confirmed by ESCA measurement, which was formed on n-type Si wafer in $NaAuCl_4$ solved ethanol at 0.5 atom%. Au nano-wiring circuit was processed on the n-type Si with a resist trench pattern of 100 nm L&S, but circuit wiring pattern was broken lines. In order to form continuing wire line, Au plating is trying to performed with using C-Au-S semi-conductive layer which is formed by co-operation process of plasma CVD and sputtering, because the C-Au-S layer with Au content more than 10 atom% has sub-nanometer conductive grain. Au nano-wiring process will be completed forming the circuit on nano-insulation bed.

Keywords: nano-wiring, electroplating, $NaAuCl_4$ solved ethanol, C-Au-S semi-conductive layer, nano-insulation bed

1. Introduction

Nano-lithography for a single electron transistor (SET) working at a room temperature is the most interesting target in the study of lithography after Likharev and others [1]. However there are many problems to be solved. We expected quantum dots in C-Au-S film formed by cooperation process of plasma CVD and sputtering by several experimental results of refractive index [2], ESCA [3], X-ray diffraction [3], AFM/STM [4] and spectroscopic ellipsometry [5]. In order to evaluated the quantum properties, nano-wiring circuit must be fabricated. Au nano-wiring process was proposed to realize the nano-wiring circuit because nano-metal wiring fabrication by a conventional lithography process is almost impossible to realize. The proposed nano-wiring process is performed by an electro-plating method. The processes are composed by nano-insulation bed fabrication, C-Au-S semi-conductive layer formation and electroplating of Au

The nano-insulation bed fabrication process is performed as following, nanometer size polls or walls are formed on n-type Si wafer by a lithography, the polls and walls on Si wafer are oxidized, then the polls and walls are etched off to flat the surface. Therefore the Si wafer surface is composed with insulating and semi-conducting area [6].

The C-Au-S semi-conductive layer formation is realized by cooperation process of plasma CVD and sputtering [2].

The electro-plating of Au wires is realized by using $NaAuCl_4$ because $NaAuCl_4$ can be solved in ethanol. The Au atom can be electro plated under the electric field in the liquid.

In this work, the Au nano-wiring circuit is aimed to fabricate by using plasma processes.

2. Experiments

In order to confirm the electro-plating on n-type Si wafer, the two parrel Si wafers with 1 cm distance were immersed in $NaAuCl_4$ solved ethanol at 0.5 atom% as shown in Fig. 1 and the 9V battery was connected

to them. Then the surface of n type Si wafer was served to ESCA measurement to confirm the plated materials. The ESCA measurement was performed with using ESCALAB 210 (VG. SCIENTIFIC LIMITED).

The nano-wires were tried to form on the n-type Si by the electroplating after a resist pattern fabrication using the $NaAuCl_4$ solved ethanol. The resist pattern was fabricated by an electron-beam patterning system (JEOL, JBX-6000SG). The fabricated pattern was observed by SEM.

Where the n-type Si wafer doped by Sb shows a resistance less than 0.02 Ωcm. The pattern delineation was performed by an electron-beam patterning system (JEOL, JBX-6000SG) at an acceleration voltage of 50 KV and electron-beam current of 100 pA.

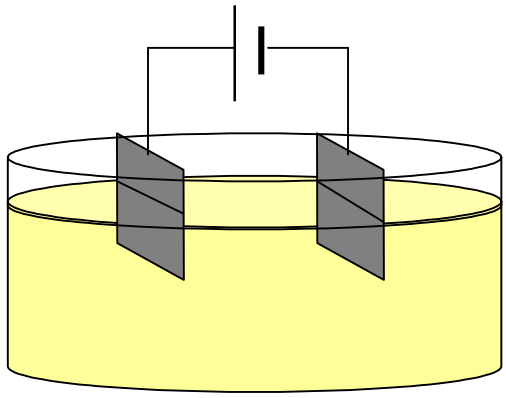

Fig.1. Reactor for an electroplating with $NaAuCl_4$ solved ethanol

3. Experiment Results and Discussion

Au plated Si wafer was examined by ESCA measurement. The Au atom layer was detected, but there are no Au atom peak at the anode electrode. Whereas the Au was plated only on the cathode electrode.

Resist pattern was formed on Si wafer by an electron-beam delineation. The 100 nm L&S resist pattern was filled by Au on n type Si wafer as shown in Fig. 2. Au wiring pattern was not continuous. The reason why the dots pattern was formed on linear trench structure in the resist film was formed. There are two reason, one is that the resist was not developed completely and other is that oxidized part inhibited the Au plating. Presently the most possible one is oxidized area in the trench bottom.

Therefore some additional process was proposed to realize uniform plating of Au film on the n-type Si wafer. Then the C-Au-S semi-conductive layer formation was proposed here, because the film will contain sub nm C-Au-S dots and the Au continuous wire will be realized by the electro plating of Au film at about 1nm thickness.

About 100 nm width Au electroplated lines on the C-Au-S film in the trench array was observed by SEM as shown in Fig. 2. Au plated line was not continuous. Possible reason will be referred to the C-Au-S film because the Au content was not large as expected.

4. Future work

The cross section model pattern of nano-insulation bed and electro-plated nanometer size wire are shown in Fig. 3. The nano-insulation bed will be formed as following; nanometer size polls or walls are formed on n-type Si wafer by a lithography. At the next step, the polls and the walls on the Si wafer are oxidized, then the polls and walls are etched off to realize uniform flat surface but the positions of polls and walls are remained without oxidize. On the un-oxidized area which is n-type Si, semi-conductive C-Au-S

layer is coated by cooperation process of plasma CVD and sputtering, then Au layer will be electro plated on the C-Au-S layer on the area the polls and the walls had been fabricated.

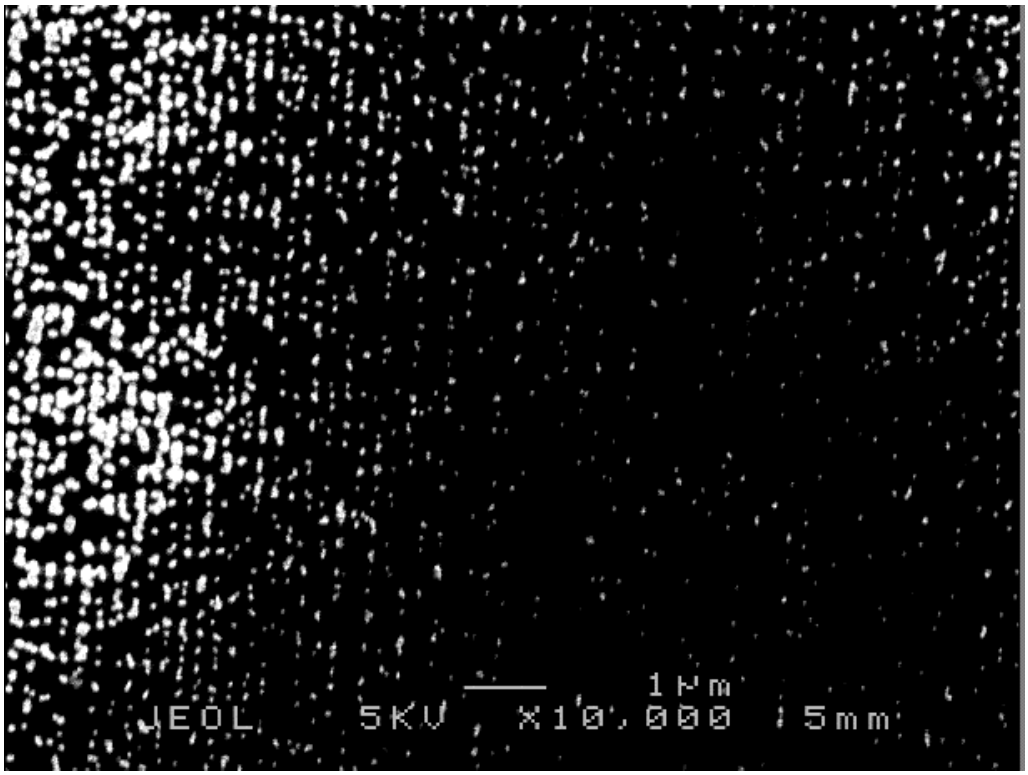

Fig.2. Electroplated Au nano-wires through resist pattern at 100 nm L&S after O_2 plasma ashing of resist.

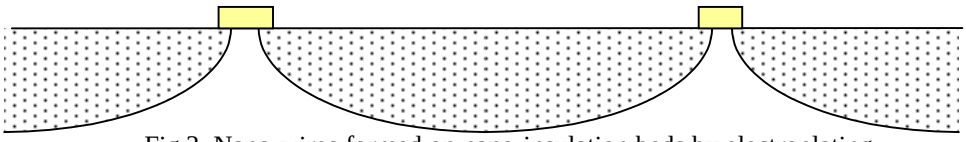

Fig.3. Nano-wires formed on nano-insulation beds by electroplating using $AuNaCl_4$ solved in ethanol.

5. Conclusion

The nano-wiring process was proposed by an electroplating with using $NaAuCl_4$ solved ethanol on the C-Au-S film formed by cooperation process of plasma CVD and sputtering. However continuous line pattern was not formed. The electro-plating process must be optimized.

Acknoweledgement

A part of this experiments were carried out at the Center for Co-operation Research in Advanced Science and Technology, Nagoya University. We express our gratitude to all who contributed to this study.

Abstract
Deposition of plasma polymer thin films on poly(ethylene terephthalate) track membranes was realized in a direct current parallel plate discharge generated in dimethylaniline vapors, leading to formation of composite porous structures. The change induced by the plasma polymerization deposition on the basic characteristics of the composite membranes (pore size, wettability, surface charge, water permeability) is presented. The study of the water permeability through the composite structure formed revels that it depends nonlinearly on pressure at different PH values of the filtrate. This is interpreted in the frame of a model in which the molecular interactions in aqueous media change the conformational state of the molecules deposited by plasma polymerization inside the pores.

Keywords: Plasma polymerization, Poly(ethylene terephthalate) track membrane, Conformational changes, Controlled permeability;

1. Introduction

The development of responsive functional devices, in which the basic properties can be controlled by changing external parameter values are of high applicative interest and gained considerable attention in the last period. Among them the design and preparation of filtration membranes with controllable transport properties, whose permeability can be regulated by changing environmental conditions such as temperature [1], solution pH [2, 3], electrical [4] and magnetic [5] fields, solvent composition [6], pressure [7] were recently discussed. A way to create membranes with controlled transport properties is to exploit the ability of macromolecules at the surface layer of pores to perform reversible conformational transitions. The research in this direction is related to approaching methods leading to formation of polymeric layers with predefined chemical structure at the surface of membranes. To this aim various techniques are employed: chemical [1], radiation-induced graft polymerization of monomers [2], preliminary activation of the surface by plasma with a subsequent grafting of polymers from the solution [3], deposition on the surface of membrane thin polymeric layers obtained with the help of plasma polymerization [7]. These investigations are of major practical and scientific importance as they allow not only gaining of a wide spectrum of membranes with unique properties, but also to discover opportunities of synthesis of membranes with new functionalities, as example imitating the biological ones.

In this paper the water permeability of composite membranes obtained by deposition of a polymeric layer formed by plasma polymerization of the dimethylaniline vapours (DMA) onto a porous substrate consisting of poly(ethylene terephthalate) track membranes (PET TM is studied. A direct-current (DC) discharge was selected for polymer deposition because it is very effective in creating high concentration of functional groups; it is known that such groups play a key role in the processes of mass transfer. Dimethylaniline was chosen as monomer, since nitrogen-containing polymers are capable of forming cationic units in an acidic medium, which can influence the conformational state of macromolecules. In addition, experiments of doping the composite membranes with iodine were performed because it is also known that iodine has a high electron affinity and doping with iodine increases the concentration of positively charged units in a polymeric layer. The dependencies of water permeability on pressure at various pH values of the filtrate solution, obtained for the membranes prepared in the above conditions, are presented and discussed.

2. Experimental

The technique of producing track membranes consisted of two steps. First the irradiation of PET thin foils with

positively ionized atoms of krypton accelerated up to an energy of ~ 3 Mev/nucleon was realized at the cyclotron U-400 (Flerov Laboratory of Nuclear Reactions, Dubna). Subsequently, the irradiated foils were subjected to physico-chemical treatments in a caustic solution [8], leading to the removal of the material along the ions trajectory. Poly(ethylene terephthalate) (PET) track membranes of thickness of 10.0 μm with pore density of $2 \cdot 10^8$ cm^{-2}), and effective pore diameters of 0.215 μm were obtained in this way.

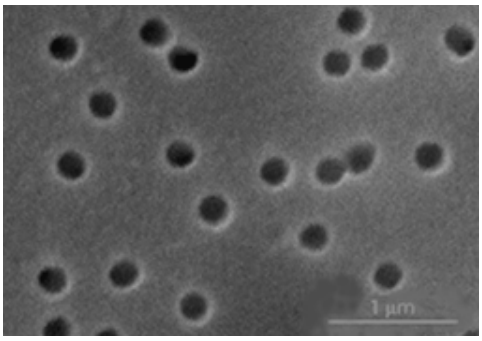
As substance for membrane modification by plasma polymerization, *N*,*N*-dimethylaniline (Fisher Scientific Co, USA) with T_{boil} = 193 °C was used. No additional purification has been applied. Deposition of the plasma polymer was realized at a pressure of DMA vapours 26.6 Pa and a discharge current density 0.1 mA/cm^2 . The deposition time was varied in the range of 20-180 s. Only one side of the membranes was subjected to the plasma treatment. Details on the treatment procedure and the schematic of the plasma reactor set-up can be found in reference [9].

The doping with iodine was realized by introduction of the plasma deposited track membrane in a desiccator containing saturated iodine vapour at 20 C for 30 minutes.

The characteristics (pore size, thickness, contact angle, chemical composition, morphology) of the initial and modified membranes were determined through a series of complementary procedures and techniques, as described in detail in [10].

The thickness of the membranes was measured by using an electronic meter of thickness (Unit Tesa, Austria). The effective pore size was calculated from the air flow rate, taking into account the gas flow regime in the pores. The surface morphology and the pore structure of the initial PET TM and that modified by plasma were investigated with a scanning electron microscope JSM-840 (JEOL). The water contact angle was determined by the goniometrical method. Fresh distilled water was used for the measurements. The permeability of membranes to water solutions with various pH values was measured with a standard filtration installation (FMO-2). The effective membrane area subjected to permeability investigations was 254 mm^2. Solutions of hydrochloric acid of various concentrations were used as working solutions.

a)



b)

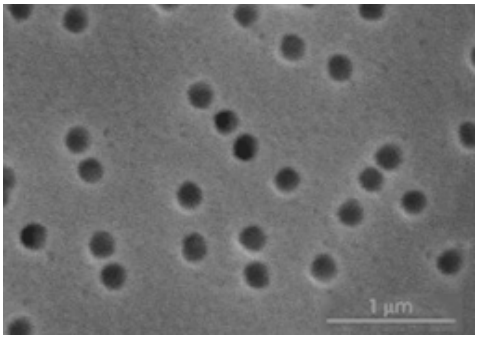


Fig. 1. SEM photographs of the initial PET TM (a) and PET TM treated by plasma for 180 s (b).

The chemical composition of the membranes modified by plasma and the DMA polymer was studied by ESCA and FTIR spectroscopy. The ESCA spectra were recorded with a Riber SIA-100 spectrometer (MgK_α, 100 W, 15 kV, 20 A) provided with a MAC-2 electron energy analyzer. The position of peaks (the binding energy values) was calibrated against the C_{1S} standard peak (284.6 eV). FTIR-spectra were recorded with a Bruker Equinox 50S spectrometer in the range of 400-4000 cm^{-1}, working with 500-fold accumulation of data and a scanning step of 2 cm^{-1}.

3. Results and discussion

Scanning Electron Microscopy images of membranes surface, before and after the plasma deposition are shown in Figure 1. As it is seen, the plasma does not have destroying effects on the surface and the pore contours are not changed. This is different as comparing with the treatment of PET TM membranes in oxygen containing radiofrequency plasmas. Moreover, at a closer look, a slighter decrease of the pore diameters can be observed, which suggest that the deposition inside the pores occurred.

The results concerning the modification of the mass, thickness, effective pore diameters, and contact angles of membranes subjected to treatment with various duration in the DC plasma generated in DMA vapours are presented in Table 1. An increase of the mass of membranes is observed, which can be explained by the deposition of the polymeric layer on its surface. As expected, the thickness of the mem-

branes increases too, while the effective diameter of pores decreases. These results strongly confirm that the deposition of the polymer took place both on the surface of the membrane and on the walls of its pores.

Table I. Change of the membrane characteristics during plasma treatment

Plasma treatment time, s	Relative increase in the mass, %	Thickness, μm	Effective pore diameter, μm	Water contact angle, deg
Control	–	10.0	0.215	65
20	9.5	10.3	0.210	45
60	11.5	10.5	0.205	45
180	13.5	10.7	0.200	45

The PPDMA deposition in pores is sustained by the ESCA data as well. According to the ESCA data, nitrogen atoms were detected both on the treated and on the untreated sides of the membrane. This is the proof that plasma species responsible for deposition penetrate inside the pores and the polymer layer reaches the reverse side of the sample. The analysis of PPDMA ESCA spectrum shows the presence of peaks related to carbon and nitrogen atoms, and notifies on small content of oxygen. The ratio of nitrogen atoms to carbon atoms in the plasma polymer and the initial DMA is practically the same. These results indicate that the chemical structure of the deposited polymer is much closed to the chemical structure of the initial DMA. These results are confirmed by the FTIR spectroscopy. In the FTIR spectra of the deposited membranes the vibration of bonds specific to the structural units of the DMA, like that of the aromatic rings is prominent. A small amount of oxygen in PPDMA can be explained by the presence of residual oxygen in the plasma-forming gas and also by subsequent oxidizing of PPDMA in the ambient air, after plasma treatment, which is characteristic for polymers synthesized by plasma polymerization technique.

Plasma treatments lead to the modification of the contact angle, and the wettability of the surface increases. After deposition the contact angle values (Θ) were not more than 45°, irrespective of the plasma treatment time, which can be compared with the initial contact angle value of 65°. The wettability improving can be connected with the formation of additional hydrophilic groups on the surface; as example PPDMA absorption spectrum contains the absorption bands connected with stretching vibrations of CN groups in tertiary amines.

The above mentioned results prove that in all cases, irrespective to the treatment duration, there is a complete coating of the membrane surface by a layer of the deposited polymer. SEM observations say about the absence of erosion of the membrane surface under plasma treatment, mass and pore size measurements proves the deposition of a layer on membrane and inside the pores, the ESCA and FTIR analyses testify that the composition of the deposited film is closed to that of the initial DMA monomer.

The dependence of water permeability, in acidic medium corresponding to pH=1.2, upon the applied pressure is presented in Figure 2. The curve 1, corresponding to the initial PET TM, reveals a linear dependence that is typical for membranes with a hard structure at a viscous character of the filtrate flow (when the pore diameter is much larger than the size of water molecules [11]). For the plasma modified membranes with DMA the dependence of water permeability upon pressure, with the same filtrate, is not linear (Figure 2, curves 2 and 3). Apparently, this effect is caused by the decreasing of the pore diameters which may be explained by the changing of PPDMA macromolecules conformation state. Indeed, at low pH values the protonation of the nitrogen atoms will occur, due to the high concentration of the H^+ ions in solution. The segments of the macromolecules of the plasma deposited polymer acquire a positive charge, as is pictured in Figure 4. This causes the swelling of the molecular chains and formation of a gel [12], which lead to a decrease of the pore size (pore contraction). The PPDMA macromolecules in this case are disposed like a loose "glomus". Such a conformational state of macromolecules results from the electrostatic interaction of charged segments with water molecules and is steady. One may observe that the curves behaviour depends on the relative mass increase during the plasma treatment. Higher is the mass increase, lower is the permeability and higher is the departure from the linear dependence exhibited by the untreated membrane. This correlates with the thickness of PPDMA layer. The departure from

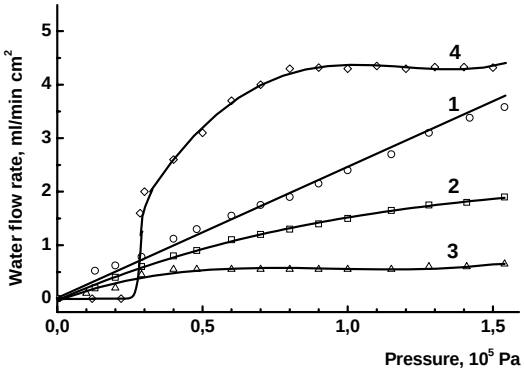

Fig. 2.

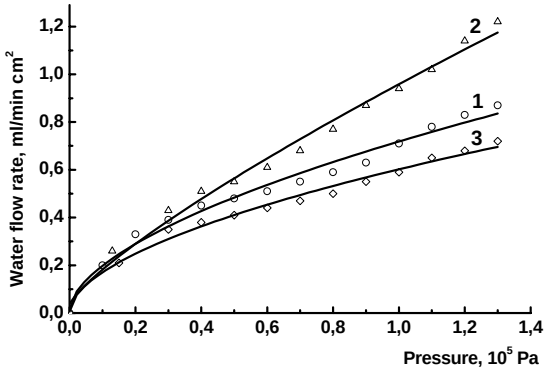

Fig. 3.

Fig. 2. Dependence of water flow rate on the value of applied pressure if filtering a solution with pH = 1.2 for initial PET TM (1), PET TM treated by plasma during 20 s (2), PET TM treated by plasma during 60 s (3), and PET TM treated by plasma during 60 s and doped by iodine (4).

Fig. 3. Dependence of water flow rate on the value of applied pressure when filtrating a solution with pH = 4.6 for initial PET TM (1), PET TM treated by plasma during 60 s (2), and PET TM treated by plasma during 60 s and doped by iodine (3).

the linear behaviour of the treated membranes indicates that the degree of swelling of plasma deposited polymer is significant in comparison with the swelling of the initial polymeric matrix.

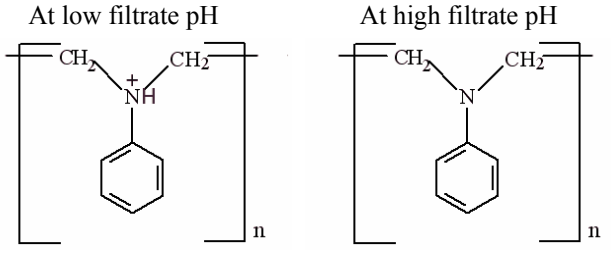

Fig. 4. Chemical structures PPDMA in various mediums.

The dependence of water permeability, in a medium corresponding to pH=4.6, upon the applied pressure is presented in Figure 3. For the initial membrane (curve 1) the increase of the filtrate pH (the reduction of ion concentration H^+ in the solution) changes in non-linear, as comparing with curve 1 in Figure 2, the dependence of water permeability on the applied pressure. At pH = 4.6 the dissociation of carboxylic groups increases – pK_{COOH} in PET TM is abut 3.6-3.7 [10]. This leads to formation of a negative charge on PET TM macromolecules which changes, due to the coulombian repulsion, the conformational state. The lower values of the permeability and the nonlinear character of the dependence, as comparing with Figure 2, curve 1 points out at the decrease of the pore diameters. Moreover, for the modified PPDMA membrane (Fig. 3, curve 2) an increase of the water permeability is observed which relates to the reduction of the protons concentration in the filtrate. In the medium with higher pH the content of positively charged atoms nitrogen in PPDMA decreases, therefore the electrostatic interaction gets weaker. With decreasing Coulomb's interaction, the nonelectrostatic interaction of hydrophobic groups, in this case, of non-polar CH_2-groups increases [12]. That results in a collapse of the gel and to the transition of macromolecules in a compact conformational state of "globule" type. This state does not cause appreciable decreasing of the pore diameters. Consequently for modified membranes used at this pH values one can still observe a viscous character of the filtrate flow: the dependence of the water permeability upon the the applied pressure has an almost linear character (Fig. 3, curve 2). It is interesting to mark that despite a lower effective diameter, the values of the flow for the modified membrane are higher than for the initial PET TM. Probably, this aspect is related to the changing of the structure and chemical composition of the surface layer of the membrane.

The treatment of the DMA plasma modified membranes in iodine vapours leads to diffusion of the latter into the surface layers of the membrane and of the pores, as proved by ESCA and FTIR investigations. From Fig. 2 (curve 4) it is seen that in an aqueous medium with low value pH = 1.2 such a membrane is not permeable up to $2.8 \cdot 10^4$ Pa. This is caused by a large swelling of the plasma deposited polymer and the gel formation, whose volume closes completely the pores (Fig. 5a). The increase of pressure over $2.8 \cdot 10^4$ Pa causes a collapse of the gel, and the membrane pores pass into an "open" state (Fig. 5b). The membrane in such state is characterized by high water permeability values. This phenomenon is related to the conformational transformation of PPDMA macromolecules from the loose "glomus" to the compact "globule", which is characteristic for polymers containing charged monomeric segments [12]. The pressure growth results in the decrease of the distance between the

fragments of macromolecules that, in turn, change the balance of hydrophobic and electrostatic forces, the forces of intermolecular attraction becoming dominant resulting in pores opening. A similar effect can occur not only at the pressure and pH solution increase, but also at the change of the solution temperature or quality of the solvent. Increase of pH value (at 4.6) causes partial loss of the charge fixed on nitrogen atoms; therefore, sharp weakening of intramolecular electrostatic interaction is observed and formation of a gel does not occur in this case. Thus, the macromolecules of the deposited polymer, having compact conformation, do not block the penetration of solution into pores. As a result the dependence of the flow through the membrane upon the value of applied pressure is of viscous character, similar to the case of modified TM not containing iodine (Figure 3, curve 3).

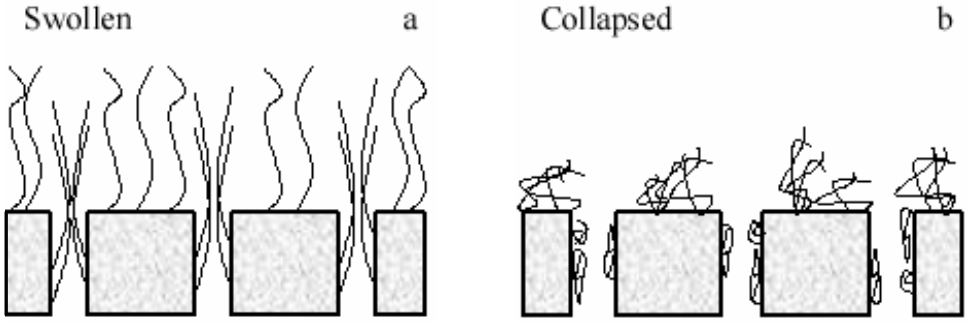

Fig. 5. Schematic illustration of the change in permeability of the track membrane with PPDMA layer: a – medium with low pH value; b – medium with high pH value.

4. Conclusion

The results presented in the paper prove that the plasma polymerization in a discharge configuration with the membrane at anode leads to deposition both at the surface and inside the pores. The polymer obtained from DMA plasma has swelling capabilities when introduced in water solutions with low pH values. The swelling of the PPDMA layer deposited onto the pore surface causes the decrease of the pores diameters, accompanied by a decrease of the water permeability. The introduction of iodine in the PPDMA layer results in formation of a polyelectrolyte, whose swelling in media with low pH value causes a complete contraction of pores in a specific range of pressure. Consequently, the PET track membranes, modified by DMA plasma, are capable of a reversibly change of water permeability depending on the pH of solution and the applied pressure.

Abstract

A compact quantum cascade laser measurement and control system (Q-MACS) based on infrared absorption spectroscopy has been developed for time-resolved plasma diagnostics, process control and trace gas monitoring. The Q-MAC system contains a tuneable quantum cascade laser which can be directed through a plasma or into a multipass cell for exhaust or trace gas detection. Rapid scan software with real-time line shape fitting provides a time resolution up to 1 μs to study kinetic processes of infrared active compounds in plasmas or gases. The capabilities of the Q-MAC system have been demonstrated for trace gas detection and in plasmas.

Keywords:

Plasma diagnostics. Process monitoring, Absorption spectroscopy, Quantum Cascade Laser

1. Introduction

Plasmas containing molecular precursors are used in a variety of plasma enhanced chemical vapour deposition and etching systems to deposit or remove thin films. For reasons of enhanced efficiency, increased stability and product quality the direct control of such plasma applications is a challenging subject for plasma technology. The key to an improved understanding and control of chemical active discharges is the analysis of the fragmentation of the precursor and the monitoring of transient or stable plasma reaction products, in particular the measurement of their ground state concentrations. Therefore appropriate diagnostic tools are necessary allowing an on-line process monitoring in such applications.

Tuneable infrared diode laser absorption spectroscopy (TDLAS) in the mid infrared spectral region between 3 and 20 μm, using lead salt lasers, is a well known non-invasive technique for the detection and the measurement of stable and radical molecular species not only in the gas phase but in gas discharges as well [1,2]. It can also be used to determine neutral gas temperatures and to investigate dissociation processes in a wide range of molecular discharge plasmas. The TDLAS method also allows time resolved measurements.

The main disadvantage of TDLAS systems, based upon lead salt diode lasers, is the necessary cryogenic cooling of the lasers and even of the detectors, because they operate at temperatures below 100 K. Systems based upon lead salt diode lasers are typically large in size and require closed cycle refrigerators and/or consumables like liquid nitrogen.

The recent development and commercial availability of quantum cascade lasers with distributed feedback (DFB-QCL) based on sophisticated band structure engineering offers an attractive new option for infrared absorption spectroscopy. Pulsed DFB-QCL are able to emit mid-IR radiation near to room temperature. Compared to lead salt lasers, QCLs allow the realization of very compact mid-infrared sources characterized by narrow line width combining single-frequency operation and considerably higher power values of tens of mW. The output power is sufficient to combine them with thermoelectrically cooled infrared detectors, which permits a decrease of the apparatus size and gives a unique opportunity to design compact liquid nitrogen-free mid-IR spectroscopic systems. Such a quantum cascade laser absorption spectroscopic (QCLAS) system of decreased instrument size and weight would lead to a reduced transport logistics. “Turn-Key” operation and unattended remote monitoring and control at an improved safety level and at a low level of maintenance could be ensured. These positive features of QCLAS systems can open up new fields of application in research and industry, including studies of gases in atmospheric, environmental and plasma chemistry but also for in-situ control of industrial plasma processes.

This article describes a compact quantum cascade laser measurement and control system (Q-MACS) which has been developed for time-resolved plasma diagnostics, process control and trace gas monitoring [3]. The Q-MAC system contains a tuneable quantum cascade laser which can be directed through a plasma or into a multi-pass cell for exhaust gas detection. With examples of trace gas detection and of phenomena in plasmas the capabilities of the Q-MAC system is demonstrated.

2. The Q-Macs-Basic

As platform for various applications of QCLAS the Q-MACS-Basic, has been designed. It consists

1. of a laser head, which serves as the mount for commercially available QCL-chips and has the complete associated electronics to drive the laser in,
2. of a supply unit, which delivers the supply voltages needed in the laser head of Q-MACS and where the user can read and set the working parameters of the QCL, and
3. of a connection cable between the two parts.

Figure 1 shows a photograph of the three parts of this system, the Q-MACS-Basic. In Table 1 the main technical features of the Q-MACS-Basic are given. The supply unit allows in addition the remote controlling

Figure 1. Q-MACS-Basic system with laser head, supply unit and connection cable.

of the Q-MACS via a commercial PC and the software "TDLWintel". TDLWintel is a Windows based software package of Aerodyne Research Inc., which is used to tune the QCL, to remote control the operating parameters of the Q-MACS as well as to analyse and display the measurement results [4,5]. TDLWintel allows an easy integration of the system into experiments. The software sweeps the laser frequency over the full infrared transition or group of transitions using a small bias dc ramp and returns absolute species concentrations from non-linear least squares fits of the transitions. For time resolved measurements the stream mode of data acquisition can be applied. Fig. 2 shows the block diagram of the electronics of the laser head of Q-MACS-Basic capable of operating at high power, voltage up to 30 V and current up to 15 A, and high duty cycle. An efficient, highly stable peltier cooling enables temperatures in the range between – 35°C and 40 °C to be attained. Variable pulse length from 8 ns to 255 ns allow the laser to be operated in true pulsed or near to CW regimes, the "Intrapulse Mode". In addition the laser can be tuned via a bias current ramp of up to 1 A, the "Interpulse Mode".

Width of single pulses:	8 … 255ns
Pulse frequency:	up to 1 MHz
Working modes:	Intrapulse (Single pulse) Interpulse (Bias DC-Ramp)
Temperature range for the QCL:	-35 … + 40 °C
QCL Provider	Alpes Lasers Laser Components

Table 1: Technical features of the Q-MACS-Basic.

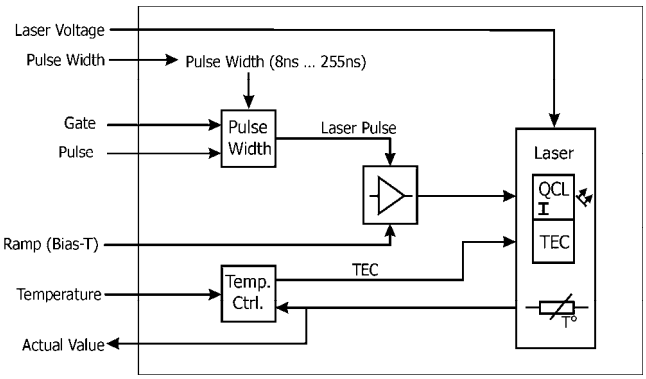

Figure 2: Block diagram of the electronics of Q-MACS-Basic

3. Examples of Applications

Measurements with the Q-MACS-Basic were performed in an industrial pulsed dc plasma reactor to deposit borone based hard coatings. Figure 3 shows an absorption spectrum of diborane near 1613 cm^{-1} recorded with 5 % admixture of this molecular precursor gas in hydrogen and argon. Using TDLWintel it was possible to monitor permanently the concentration change of diborane while driving a process plasma. The measurement results are not only displayed but can be transferred via hardware interfaces to other systems, e.g. for the use in automated process monitoring and controlling. These measurements proof that QCLAS can be useful to improve the reliability and effectiveness of industrial plasma processes.

The scan through an infrared spectrum can not only be done by a bias dc ramp, in the interpulse mode. Another option is the scanning in single, longer pulses, the intrapulse mode. Recently new routines were developed to control the Q-MACS in this mode via TDLWintel. An example of a 1.7 cm^{-1} long scan in this mode is shown in figure 4. Since the duty cycle of QCL is about 1 percent the temporal resolution can be in this mode as good as some µs. Therefore it fits very well measurements of rapidly changing chemical processes.

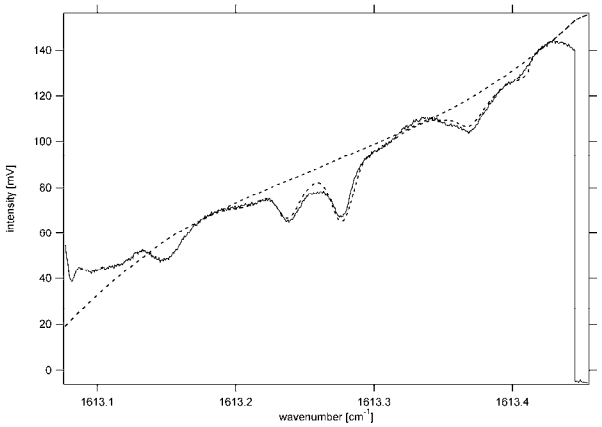

Figure 3: Absorption spectrum and fit of diborane at 1613 cm^{-1} measured in an industrial pulsed DC reactor with 5 % diborane in the gas inlet (p= 200 Pa).

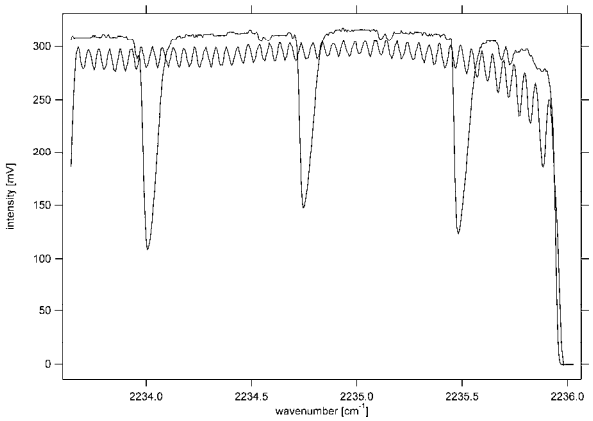

Figure 4: Absorption spectrum of a N_2O reference gas cell (l= 15 cm, p= 6.6 mbar) at 2235 cm^{-1} and the etalon pattern of known fringe spacing (fsr = 0.049 cm^{-1}) in a single QCL pulse (t= 100 ns).

4. Q-MACS-Trace

For high sensitive trace gas measurements a compact and transportable measurement system, the Q-MACS-Trace was developed. It combines the Q-MACS-Basic with an 50 m astigmatic multi-pass absorption cell of the Herriot type [6], a compact optical system and a computer system. The sensitivity of the Q-MACS-Trace was as high as a few ppb (parts per billion – $1/10^9$). Fig. 5 shows a photograph of the Q-MACS-Trace with optical arrangement and laptop for analysis. The Q-MACS-Trace optical system is designed around the QCL laser head.

Figure 5: Photograph of the Q-MACS-Trace with optical arrangement and laptop for analysis.

5. Summary

The Q-MAC-System was used to study dissociation processes of several precursor gases, as e.g. hydrocarbons or boron containing species, in industrial reactors. The applicability of Q-MACS and of QCLAS for high sensitive trace gas analysis and for on-line process monitoring under industrial-near conditions has been proofed.

Numerical Simulation and Experimental Evaluation of Solidification Behavior of Vacuum Plasma Sprayed Ti-6Al-4V Alloy

H.R. Salimijazi, M. Raessi, T.W. Coyle, and J. Mostaghimi
Centre for Advanced Coating Technologies, University of Toronto, Canada

Abstract
In the present study, the solidification behavior and morphology of a single splat of Ti-6Al-4V alloy deposited under Vacuum Plasma Spray (VPS) conditions were investigated using both numerical simulation and experimental observations. A three-dimensional model of droplet impact has been employed to investigate the solidification behavior of a single particle of Ti-6Al-4V alloy under vacuum plasma spray conditions. The numerical results were compared to the experimental observations of the behavior of droplets with the same in-flight droplet characteristics such as droplet temperature, velocity, and size. The behavior of a 50 μm diameter Ti-6Al-4V alloy droplet at an initial temperature of 1600°*C* impinging with an impact velocity of 500 *m/s* onto the surface of a Ti-6Al-4V alloy substrate at 800°*C* was simulated numerically. The average cooling rate and solidification front velocity were estimated to be 6×10^8 °*C/sec* and 63 *cm/sec*, respectively. Numerical results showed that approximately 30% of the droplet material is lost due to splashing. The thickness of the simulated splat, calculated from the cross-section of the solidified droplet, was approximately 4 μm in the central region of the splat. The splat thickness and diameter found by numerical simulation was in good agreement with the experimental results.

Vacuum plasma spray, Numerical simulation, Droplet impact, Solidification behavior, Ti-6Al-4V alloy

Introduction

Ti-6Al-4V alloys have been widely used in the aerospace industry for more than three decades due to their superior properties. These properties have also increased demand for the alloy in other applications such as biomedical, automotive, and power generation industries. Due to the high reactivity with oxygen, poor weldability and low thermal conductivity, these alloys are difficult to process and form using conventional techniques, especially for complex shaped components. Near-net-shape forming of the alloy by Vacuum Plasma Spraying (VPS) is a promising new alternative to conventional manufacturing processes. In a VPS process, Ti-6Al-4V powders are fed into the high gas velocity and temperature environment generated by a dc arc in a plasma torch inside an evacuated chamber. The powders are melted and accelerated toward the substrate which is located approximately 20 cm from the torch. The powder particles impact the substrate or prior deposit, spread out and finally solidify to form splats. Thus, the as-sprayed microstructure consists of individual splats connected to each other by mechanical inter-locking and chemical bonding across the splat boundaries. A significant density of microcracks and pores are found at the inter-lamellae boundaries. Therefore, the properties of thermal spray deposits depend on the solidification history and morphology of individual splats and the strength of the inter-lamellae contacts [1-4].

Computational Modeling of a Single Ti-6Al-4V Molten Metal Droplet

Thermal spray deposit properties mainly depend on the solidification and morphology of individual splats after solidification on the substance or prior deposit. The form of splats after solidification is a function of droplet characteristics, such as in-flight particle size, velocity, and temperature distributions and also substrate temperature, surface roughness, and material. A three-dimensional model of free-surface fluid flow of droplet impact and solidification developed by Bussmann *et al.* [5] and Pasandideh-Fard *et al.* [6] has been employed. The model has been discussed in detail in previous publications [5-9].

Only a quarter segment of the droplet was simulated and the entire droplet reconstructed by reflecting the results about planes of symmetry. The contact resistance was assumed to be zero which means maximum heat transfer of the droplet to the substrate. Thermophysical properties of the molten Ti-6Al-4V alloy and substrate used in calculations are given in Table 1.

Table 1: Data used for the numerical simulation of a Ti-6Al-4V molten droplet.

Physical property	Value	Reference
Initial splat temperature (K)	1873[a]	
Substrate temperature (K)	1073[a]	
Melting point temperature (K)	1873	[10]
Latent heat of fusion ($kJkg^{-1}$)	440[b]	[10]

Diameter of particle (μm)	50[a]	

[a] Measured values from experiments were used.
[b] Values for commercially pure titanium were used.

Figure 1 shows a sequence of the numerical simulation of a 50 μm diameter Ti-6Al-4V alloy droplet, initially at 1600°C, impinging with an impact velocity of 500 m/s onto a smooth surface of Ti-6Al-4V alloy substrate at 800°C. Column (a) shows the droplet during successive stages of impact on the surface. Column (b) illustrates half of the A-A cross section of the spreading of the droplet at the corresponding times.

Immediately after impact, the droplet flattens and spreads in the radial direction. Since melts always wet their own solids, a small contact angle would be expected between the droplet and the substrate or prior deposit layer. Thermal contact resistance between the substrate and droplet is neglected in the numerical simulation. The temperature of the flattened splat is uniform and there is a large temperature gradient between liquid and substrate. With such a high cooling rate, the liquid layer quickly cools down to below the melting point, T_m=1600°C, solidification starts, and further spreading is arrested. The points of contact between the substrate and flattened droplet act as heterogeneous nucleation sites. Crystals nucleated by both homogenous and heterogeneous mechanisms grow into the melt at a growth rate which is not controlled by the heat transfer rate. A small portion of the drop which is in contact with the substrate solidifies during spreading (see Fig. 1(b) at 0.1 μs). The residual liquid jets out over the periphery of the solidified bottom layer. This radial flow of liquid becomes unstable and disintegrates into fingers at the edge of the drop (see Fig. 1(a) at 0.1 and 0.22 μs). Some of these fingers finally detach to form satellite droplets; called “splashing”. These small droplets solidify during splashing and/or after impacting on the substrate or prior deposit. The low heat content, velocity, and temperature of the satellite droplets during impact result in formation of weakly adherent solidified fine droplets around the bulk of the splat. The splashed particles reduce adhesion of splats and can be seen in the fracture surface of the as-sprayed structure. Figure 2 shows SEM micrographs of (a) a fracture surface of the as-sprayed Ti-6Al-4V alloy

showing splashed particles, and (b) the morphology of a single splat of Ti-6Al-4V which impacted onto the ground surface of the titanium alloy substrate initially at 800°*C*.]

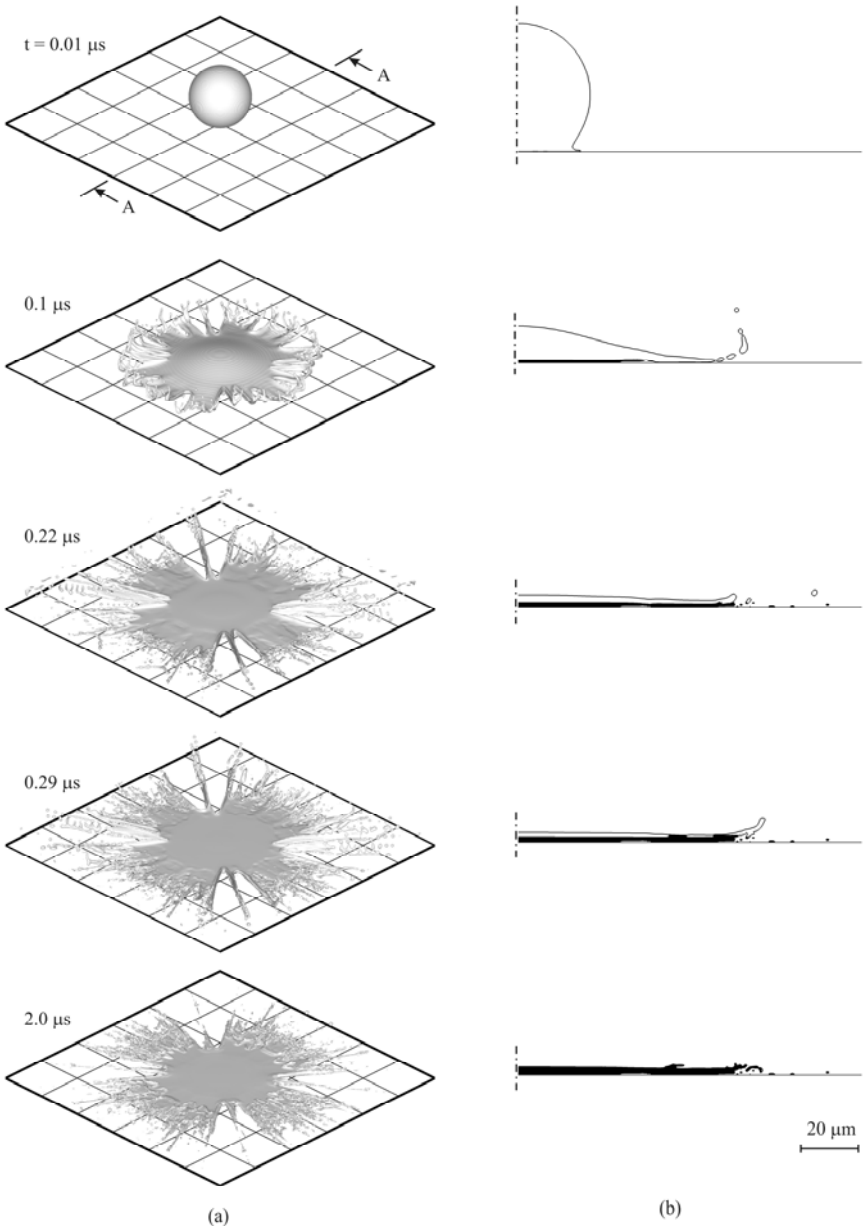

Figure 1: (a) Computer generated images of a 50 *μm* diameter Ti-6Al-4V alloy droplet at 1600°*C* impacting with a velocity of 500 *m/s* onto a titanium substrate at 800°*C*. (b) A-A cross section of the droplet at the corresponding times. Solid phase is shown in black.

The heat of fusion released from solidification increases the temperature of the residual liquid. When the growth rate becomes limited by heat transfer, further nucleation would be suppressed, and columnar crystal growth from the interface into the droplet would occur with a planar front morphology. After solidification, the splat cools down through the β phase region ands enters the α plus β region (at the beta transus temperature) of the phase diagram at a very high cooling rate; see Figure 3. Because of the high cooling rate, the β transus temperature would be shifted down towards the α + β region compared to

equilibrium cooling conditions. Hence, the martensitic formation of α' within the columnar β gains is expected.

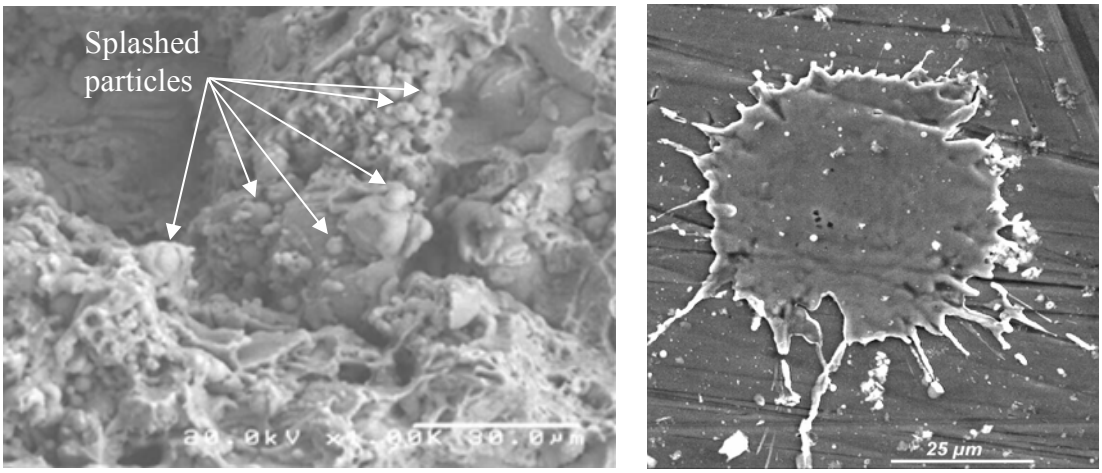

Figure 2: SEM images of (a) fracture surface of the as-sprayed Ti-6Al-4V alloy showing splashed particles and (b) morphology of a single splat of Ti-6Al-4V alloy.

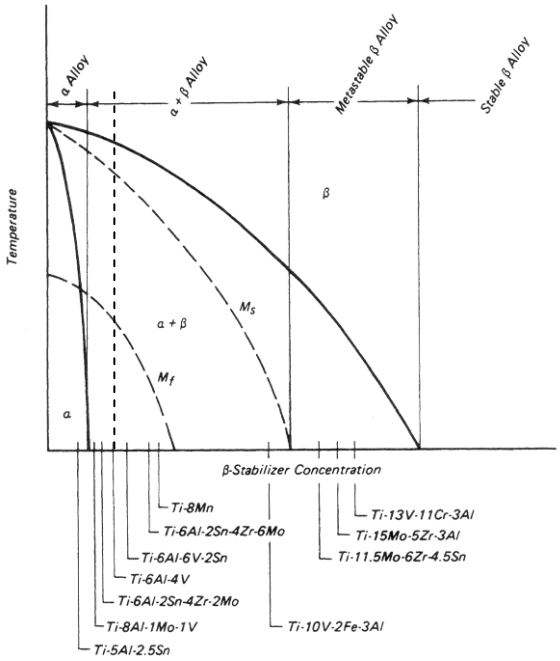

Figure 3: Pseudo titanium phase diagram.

Figure 4 illustrates the normalized volume of the droplet and the volumes of liquid and solid phases as a function of time. About 30% of the droplet material is lost due to splashing starting approximately 0.18 μs after the impact. The solidification rate reduces at approximately 0.08 μs after the impact because of the latent heat released by the thin solid formed at the interface. The thickness of the simulated splat is estimated from the cross section of the solidified droplet after impact (see Fig. 1b at 2 μs) to be approximately 4 μm in the central region of the splat.

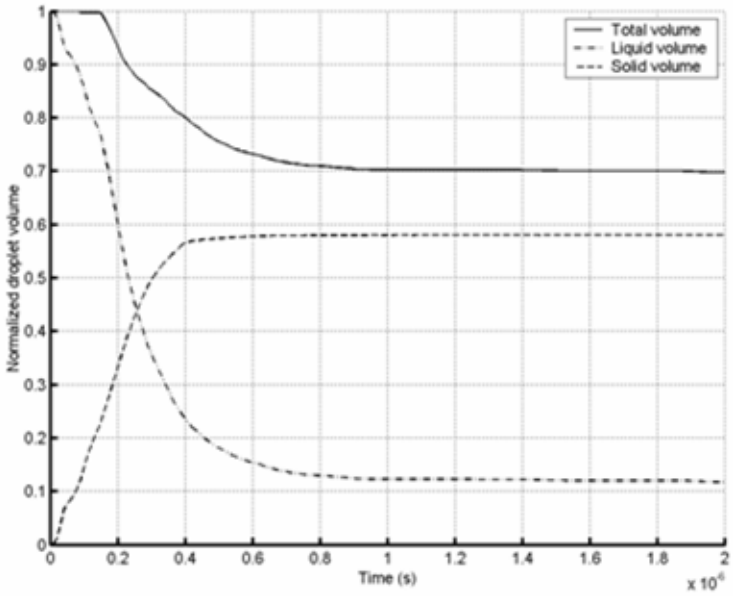

Figure 4: Calculated total volume of the droplet and the volumes of liquid and solid phases, all normalized by the initial droplet volume, versus time.

Figure 5 presents the calculated droplet temperature as a function of time at various positions within the splat, such as the centre of impact near the splat-substrate interface (point 1), middle of splat thickness (point 2), and close to the top surface of splat (point 3). The average temperature of the splat is also depicted in this figure. As expected, point 1 experiences a sharp temperature decrease immediately after impact. The cooling rate can be derived from the curves. Since the solid-liquid interface acts as a planar heat source while moving through the splat, the cooling rates change discontinuously at the solidification point. The inversion which occurs at 0.08 μs on the near substrate-splat interface curve is due to formation of a thin layer of solid on the substrate. Because of the latent heat released by solidification, the cooling rate of point 1 after 0.08 μs decreased. The solid-liquid interface has passed through the region near the mid point of the splat at around 0.23 μs and finally it has reached the outer surface of the splat at 0.4 μs and solidification is complete. At this time, the solidified splat cools down to the substrate temperature, which it reaches at 2 μs. The calculated average cooling rate is approximately 6×10^8 $^\circ C/sec$.

Discussion and Conclusion

The solidification behavior and morphology of a single droplet of Ti-6Al-4V alloy under vacuum plasma spray conditions were successfully simulated. The average cooling rate was estimated to be 6×10^8 $^\circ C/sec$ under interface-controlled heat transfer circumstances. The contact resistance at the droplet/substrate interface was assumed to be zero. Under real conditions, because of the existence of inclusions and roughness and the formation of micro-gaps within the splat/substrate interface, there is a contact resistance at the interface and therefore, actual the cooling rate is lower than the estimated value. The experimentally measured cooling rate under vacuum plasma spray conditions for nickel was reported [4] to be of the order of 10^7 $^\circ C/sec$, which is slightly lower than that obtained from the numerical results. Simulated results showed that solidification of a single splat was complete after 0.4 μs and approximately 30% of the initial droplet was splashed after solidification. While the solidification front morphology was assumed to be planar in this study, both planar and dendrite front morphology under vacuum plasma spray conditions have been reported in the literature [4]. Thus, the three-dimensional numerical model has to be developed to predict the solidification morphology and the transition conditions from dendrite to planar growth. The cooling rate and solidification behavior may change using dendrite front morphology

growth. Despite differences in the assumed substrate roughness and contact resistance between the numerical model and experiments, the estimated splat thickness and diameter by numerical simulation exhibited good agreement with the experiments.

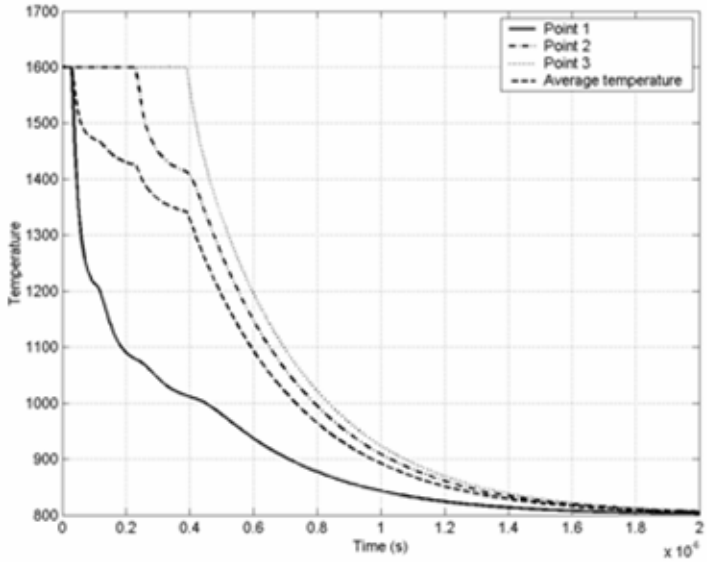

Figure 6: Calculated droplet temperature at the centre of impact (point 1), mid-point of the splat (point 2), top surface of the splat (point 3), and the average temperature of the splat.

ABSTRACT

HID lamps (High-Intensity Discharge) are gaining ground in the lighting industry because of their very high energy efficiency (up to 40%). In these lamps, which are operated in the arc regime and which are contained in a ceramic balloon, filled with argon or xenon, mercury, and salts of various rare earth metals and iodine), de-mixing occurs. This de-mixing is driven by differences in diffusion velocities of molecules and atoms. Furthermore, helical instabilities might occur in the lamp. Both phenomena are severely modified under 1 G conditions: convection will bend a horizontally burning arc channel upwards, and a vertically burning arc channel will exhibit convective cells. This makes it impossible to study these phenomena on the ground. If a proper understanding of these phenomena is to be gained, experiments under microgravity are necessary.

The main objectives of the experiment are: (1) determination of the critical factors for the onset of helical instabilities in HID lamps and (2) characterisation of the radial de-mixing processes by radially resolved high-resolution emission spectroscopy.

To this end, special hardware has been designed and built which houses a very compact high-resolution spectrometer, a video camera and a caroussel with 20 lamps in it. The lamps are measured consecutively.

The experiments have been performed successfully by the Dutch astronaut André Kuipers on board the International Space Station during the Dutch Soyuz Mission "DELTA" on 24 and 25 April 2004. Especially the helical instabilities part yielded immediate and surprising results: the arc channel does bend, but does not rotate under microgravity. This fact is very important in improving the performance of the lamps, especially since the instabilities occur mainly in the most efficient lamps.

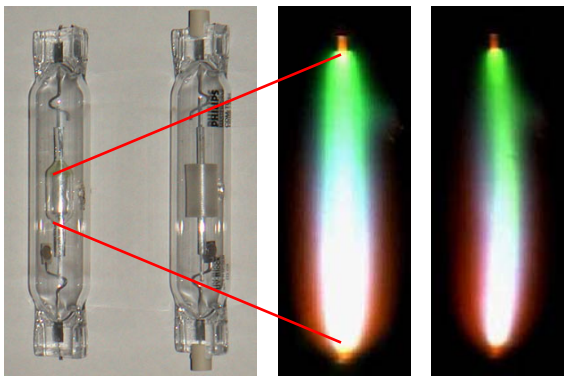
INTRODUCTION

The name of the experiment is "ARGES". This is an acronym for: **A**tomic densities measured **R**adially in metal halide lamps under micro-**G**ravity conditions with **E**mission and absorption **S**pectroscopy. The lamp geometry is quite simple: a burner made of quartz or sintered aluminum oxide contains the gas mixture (see figure 1a). The burners are contained in a second envelope made of quartz. Between the electrode in the burners, a discharge is struck in the background gas (argon) by a high voltage pulse. After ignition, the discharge quickly moves from the glow regime to the arc regime, and then the mercury rapidly evaporates. Due to this evaporation, the total gas pressure increases to several tens of Bars. The metal salts start to evaporate also. In the central arc channel the temperature can get as high as 5000 K. At these temperatures, the salt molecules dissociate into atoms, and the metal atoms even ionize to a substantial degree. Differences in diffusion velocity of atoms and molecules cause radial segregation, which in combination with convection results in axial segregation or axial de-mixing, which is apparent from the colour distribution in the lamp (see figure 1b)[1]. Probably driven by self-generated magnetic fields, the discharge channel starts forming a helix, which rotates around its axis (figure 1c).

EXPERIMENTAL

The discharge is studied with high-resolution spectroscopy and video imaging (helical instabilities). The optical emission spectrocopy has two goals: analysis of the self-inversion of the spectral lines of mercury for temperature determination and determination of the intensities of various of the very numerous spectral lines of the rare earth metal additives atoms and ions for the study of the radial de-mixing processes[2]. All measurements have to be done as a function of the radius in the lamp.

In the flight hardware, 20 lamps are combined in a caroussel. At any one time, only one lamp is in the measurement position, where it can be analysed by the two diagnostics.



(a) (b) (c)

Figure 1: HID lamps. (a): geometry of the burners inside the outer balloon. (b): axial and radial de-mixing illustrated. (c): frame of a lamp which shows helical instabilities.

The spectrometer had to be small, light weighted, and robust. The requirement for compactness is solved by using an Echelle grating with a high blaze angle (74^{o}). Because of the high dispersion, due to the high angle of incidence and the high orders used, the focal length of the main lens can be relatively small, and consequently the spectrometer can be very compact. A disadvantage of Echelle-type spectrometers is however that they have a small free spectral range (FSR), which results in wavelength overlapping of adjacent orders. By installing an interference filter in the optical system for selecting a small wavelength interval, the problem of overlapping orders can be avoided. When several interference filters can be selected, these filters can be used for wavelength selection, and the angle of the grating can remain fixed.

All hardware is integrated on one frame, which is enclosed by an aluminum dome structure. The frame holds the spectrometer, the video camera which is used to observe the Helical Instabilities (a stripped Philips Toucam webcam), and it also supports the lamp caroussel in which 20 lamps can be mounted. Figure 4 shows the flight hardware, just before the aluminium dome is mounted on the bottom plate which holds the frame.

The astronaut operates the experiment using a Human Machine Interface (HMI). The experiments have operated in the ESA Microgravity Science Glovebox (MSG), in the US Destiny lab. Figure 5 shows a picture of one of the authors (A. Kuipers) installing the Arges hardware into the MSG on board of the ISS during the Delta Soyuz Mission..

RESULTS

A modified version of the Arges hardware has participated in the 34th and 35th ESA parabolic Flight Campaigns. During parabolic flights, only 20 seconds of microgravity is available. This is largely insufficient in view of the long stabilisation times of the plasma in the lamps, which is of the order of 10 minutes, but still one can get a good impression of the proper operation of the hardware and of the phenomena to be expected during the experiments in the ISS.

A demonstration of the performance of the high-resolution spectrometer is give in figure 6, where a part of the emission spectrum of dysprosium is given. Two lines, which are seperated by only 0.5 nm, can clearly be distinguished. The line integrated measurements of the spectrometer represent lateral profiles.

They have to be converted to radial profiles by Abel inversion. This has been done for a number of experiment conditions. An extreme example of the differences to be observed for 0g and 2g can be found in figure 7. Under 2 g conditions, it is obvious that the radial de-mixing, which is strongly occuring (see the 0g measurement), is almost totally suppressed by convective mixing or “stirring”.

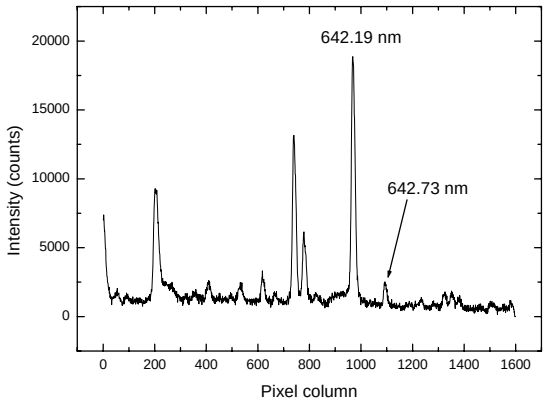

Figure 6: Measured spectrum of a Dy lamp at a certain lateral position during microgravity phase. .

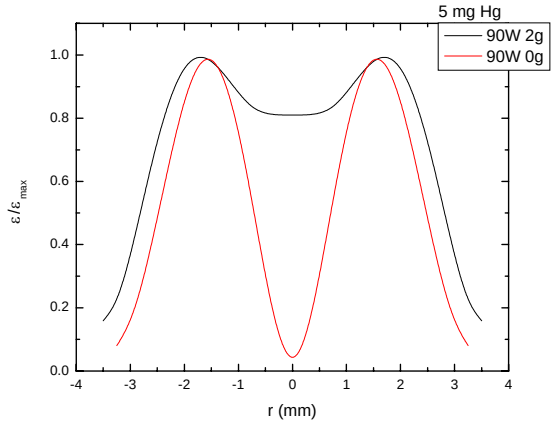

Figure 7:Radial profile of the dysprosium line emission for microgravity and hypergravity conditions..

The experiments in the ISS were a 100 % success. All foreseen measurements have been taken and all data was transported back to the experimenters. Already during the experiment operations, the results proved to be very surprising. Whereas the instabilities in the lamp were expected to be shaped as a rotating helix, they appeared to be a singly bent curve which is not rotating. Analysis afterwards has indicated that the rotation is caused by convection solely and that the curving is caused by self-generated magnetic fields. For one condition, residual gravity caused a very slow rotation.
As expected, the axial de-mixing did not occur during the Delta mission experiments, so the radial de-mixing can indeed be studied undisturbed. The analysis of the spectra is well underway.

Abstract

The study of nanosecond barrier discharge influence on flame propagation and flame blow-off velocity was carried out. The study shows that, besides proper form of energy input, proper organization of discharge is of great importance. Streamer development under different parameters was experimentally investigated. It was found that active particles (O and OH), which are produced in the discharge under its action, play the most significant role in the effect of combustion acceleration.

Keywords: plasma-assisted combustion, streamer, nanosecond non-equilibrium discharge, active particles conversion.

1. Introduction

The effect of an electric field (or electric discharge) on a flame's behavior has been studied widely and extensively since Brande has published his work in 1814. Most of these studies apply electric fields or discharges for stabilization of flames, reducing carbon formation, increasing flame velocity and extending flammability limits. Faster burning means the possibility to practice combustion of mixtures with low fuel content followed by reducing the formation of NOx oxides. Another application is SCRAMJET engines, where it's necessary to provide fast stable combustion of lean mixtures at high flow speeds. Therefore, the problem of an effective control of flame stability is actual nowadays.

The combustion of a fuel proceeds via a chain mechanism, and the rate of these processes grows according to exponential law. The delay time of ignition is limited by the rate at which active centers are produced, usually by thermal dissociation [1]. So we can accelerate the rate of combustion if we produce a number of additional active particles artificially, e.g. in gas discharge.

For discharges resulting in the formation of an equilibrium (or nearly equilibrium) plasma (e.g., sparks and arcs), the main factor of influence is local heating of gas (with dissociation rate increase) followed by ignition and flame propagation to unburned mixture. On the contrary, in the case of non-equilibrium plasma, the main mechanism of initiating chain reactions is dissociation and excitation of molecules by electron-impact. Theoretical estimations tell us that even relatively small amount of atoms and radicals (10^{-5}–10^{-3} of the total number of the gas particles) can shift equilibrium in the system and initiate a chain reaction [1]. So it's seem to be promising nowadays to use such discharges, (e.g. streamer discharge), which allow to perform volume (or nearly volume) ignition, which is of greatest interest for applications with a high rate of energy release.

The acceleration of combustion by means of non-equilibrium excitation of gas mixture components was studied in [2]. Short (nanosecond) pulses were used to provide high values of reduced electric field E/p (up to 600-800 Td) and high-performance electronic excitation. Pulsed barrier discharge was selected to avoid the transition of the streamer discharge to the spark form (dielectric barrier limits the maximum current). The form of discharge is non-equilibrium – electron's temperature is quite high (about 4-5 eV), whereas temperature of heavy particles is near to room temperature. Thus there is no gas heating by the discharge, and energy is put into the vibrational and electronic degrees of freedom of the mixture.

In this paper we analyze plasma-assisted combustion of premixed fuel – air mixtures at atmospheric conditions. The goal is to study the influence of kinetic of excited states, which takes place under a nanosecond discharge action, on combustion acceleration, and determine main factors (required type of radicals, optimal discharge parameters, optimal place for radicals injection into the flame etc.), which are responsible for combustion rate increase.

2. Experimental Setup

Detailed description of the setup you can find in [2]. Three different quartz nozzles with rectangular cross-section, with 2.2, 2.5 and 4.3 mm in width and the same length of 30 mm, were used. Stainless steel 0.8 mm thick high-voltage electrode was placed inside the nozzle (the length of the electrode is 28 mm) and the grounded electrodes were set tightly into quartz tubes and placed near the nozzle edges, parallel to them.

To fix the point of streamer's start and the number of streamers as well, the high-voltage electrode has a number of pins on its upper edge. Three electrodes were used - with 8, 15 or 28 pins, so the number of streamers could change. The nozzle and images of discharge and flame are presented in fig.1, as well as the set-up for streamers development investigations

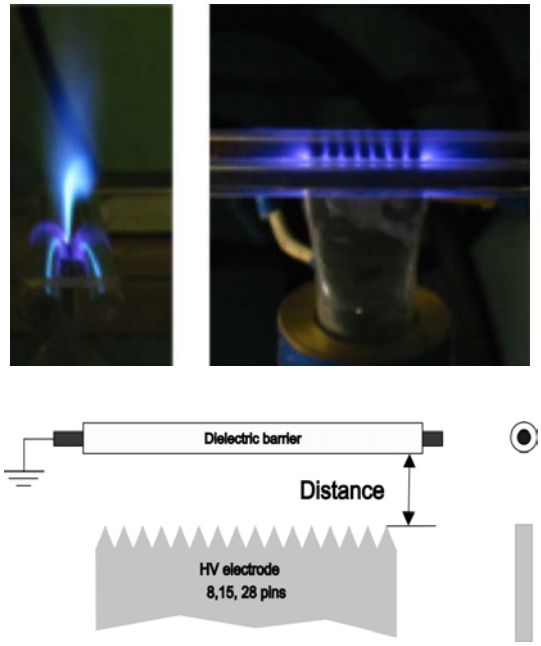

Fig.1. Overall view of the nozzle with discharge and the set-up for streamer development study.

In the present work we used three different types of nanosecond pulses: with FWHM 7, 19 and 24 ns. The voltage on the discharge gap could be 14 kV or 22 kV, pulse polarity was negative. Pulse repetition rate could be varied within the range of 400-1000Hz.

For determining of spatial and temporal characteristics of a streamer the PicoStar HR12 camera (LaVision) with a spectral range of sensitivity 300÷700 nm and time resolution up to 200 ps was used. Photos of streamer discharge were received in two modes of operation of the high-speed camera: integral and stroboscopic mode. When working in integral mode the amplifier of the high-speed camera was switching on simultaneously with coming of high-voltage pulse on electrode. Time of exposure was 50 ns and was longer than the duration of a high-voltage impulse. For working in stroboscopic mode, on the amplifier of the camera a triggering sine signal is set with frequency of 300 MHz.

The investigations of active particles and measurements of the combustion rate increase were performed by emission spectroscopy methods. The recording facility consisted of CCD-line (spectral range 200–800nm) and MDR-41 monochromator (with an operating range of 190—600 nm and a linear dispersion of 0,96 nm/mm). The optical system was calibrated using a standard emission source (a calibrated DDS-30 deuterium arc lamp emitting in the range 190–500 nm).

3. Results and Discussion

In the paper [2] mechanisms for the interaction of non-equilibrium pulse-periodical discharges with premixed propane-air flames have been investigated. A comparative analysis of dc and pulsed discharge of both polarities and their effect on the blow-off velocity was performed and presented in fig.2. From the standpoint of increasing the flame propagation velocity, a positive-polarity pulsed barrier discharge is the most efficient. The higher efficiency of this discharge in comparison with negative-polarity barrier discharge stems from the fact that, at the same pulse voltages, a cathode-directed streamer produces a larger number of active particles than an anode-directed one because of the difference in mechanisms of their propagation. In the case of a dc discharge, the situation

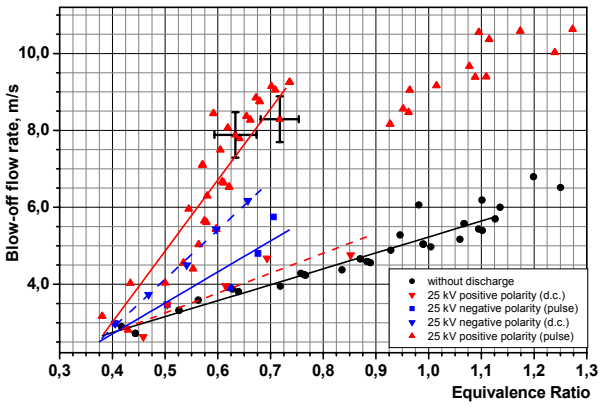

Fig.2. Flame blow-off velocity increase under the influence of different types of discharges.

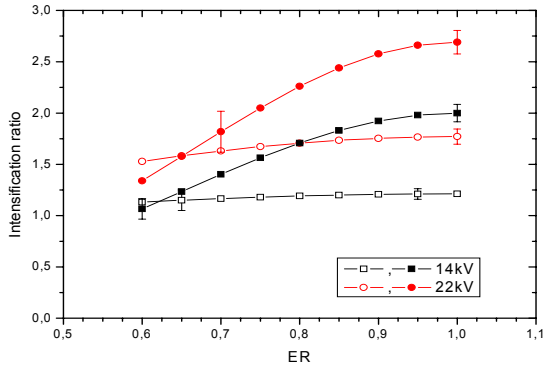

Fig.3. The comparison of the effectiveness of discharge influence. 8-pin versus 15-pin HV electrode.

Fig 4a. Photos of cathode directed streamer, 28 pins

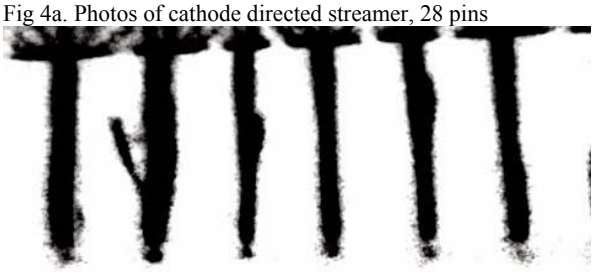

Fig 4b. Photos of cathode directed streamer, 8 pins

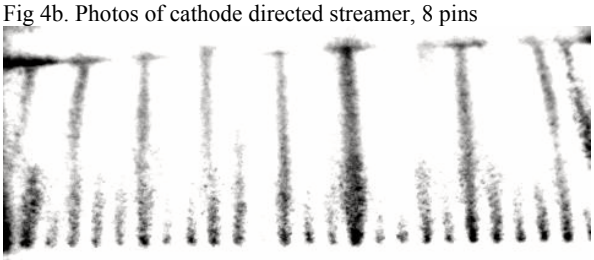

Fig 4c. Photos of anode directed streamer, 28 pins

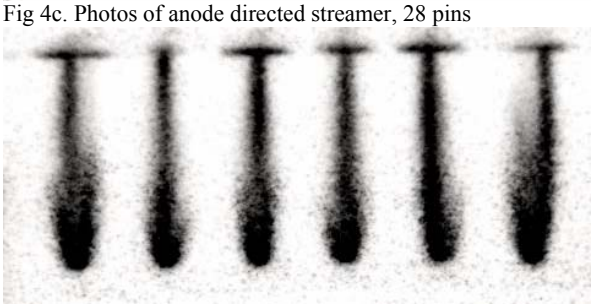

Fig 4d. Photos of anode directed streamer, 8 pins

is opposite. At a negative polarity, the tapered electrode efficiently emits electrons, which leads to the formation of a dc corona with a high current density near the points. In the given geometry, a positive dc voltage only slightly affects the flame propagation velocity. At positive polarity of a pulsed nanosecond barrier discharge, more than twofold increase in the combustion rate was achieved at the same fuel content in the mixtures. The energy input in the mixture from the discharge was less than 1% of the burner chemical power

To check a statement about possible thermal effect, in this work two different high-voltage electrodes were used - with 8 and 15 pins. It was found that both types of electrodes lead to flame acceleration for the cases of 14 kV and 22kV. The velocity increase is proportional to the pulse amplitude and energy input. We used parameter called “intensification ratio” for more convenient comparison of results in different geometries. Intensification ratio (IR) is a ratio between propane-air flame blow-off velocity with discharge and without discharge at the same equivalence ratio (ER). The results for both types of electrodes are presented in Fig.3. It’s seen quite well that the effectiveness of such influence is different - the effect is greater for 15-pin electrode, because of the larger quantity of streamers and active particles, produced by them. So, the flame stabilization occurs due to the plasma action and hardly depends on the local overheating near the steel plate pins, because estimations shows that overheating is greater in case of 8-pin electrode. The energy input in both cases was the same and was equal approximately to 2-5 mJ per pulse (2-5 W of total power). This value corresponds to 0,5% of the chemical power of the burner. The equivalent value of gas heating by this energy is 10-20 K. This fact confirms the thesis about the importance of the way we put energy in the mixture.

Here a comparison of emission intensity, which is proportional to electronically-excited nitrogen, was performed. As it was mentioned above, we explained higher effectiveness of positive streamer by larger number of active particles. Using the images from CCD, it was found that positive streamer has greater intensity (fig.4), and this confirms experimental data. It’s also shown that, beginning from a number of pins, further pin’s number increase doesn’t increase number of streamers and total amount of active nitrogen production. Streamers begin interact with each other and their velocity decreases, and this confirms theory suggested in [3].

The main area, where active particles are produced in the case of weak external electric field in comparison with streamer own field, is the streamer head, which is quite small (0.05 cm for typical voltages of 20 kV [4]), but has high values of reduced electric fields (up to 600-800 Td). If the gap is quite short, the reduced fields are high (higher than the breakdown fields in the atmospheric air), and active particles could be produced in the streamer channel as well. But in both cases it's important to have pulse duration long enough to overlap the gap, otherwise active particles are produced only in the part of the flow. The streamer velocity, measured in this work, is equal to 0.5±0.2 mm/ns under the voltage of 22 kV. In the regimes near blow-off point streamer prefers go through the weakly ionized zone just below the flame instead of the shorter way [2]. Calculations were made for the time of the gap overlapping, and the result is approx. 5 ns in the case of 2 mm nozzle, and greater in the case of 4.3 mm nozzle.

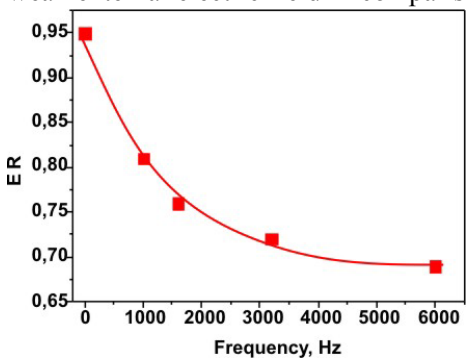

Fig.5. ER shift at different frequencies at same burner power.

Experiments with different pulses showed that with pulse length increase flame blow-off velocity increases too. Two types of additional line pieces were used to provide different pulse duration (FWHM 7 ns and 19 ns). It was found that at frequency 500 Hz and ER=0.8 19 ns pulse is much more efficient than 7 ns one for all three nozzles, and the advantage of using 19 ns pulse grows with nozzle widening [5]. So, we can draw a conclusion that we should produce plasma with sufficient electron energy longer to increase effect.

Another way to raise effectiveness is to produce larger areas filled with plasma to provide uniform discharge influence followed by flame acceleration. We increased pulse repetition rate frequency, and the flame blow-off

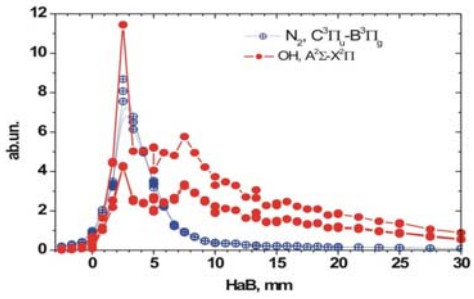

Fig.6. OH* profile along the HaB in methane-air flame.

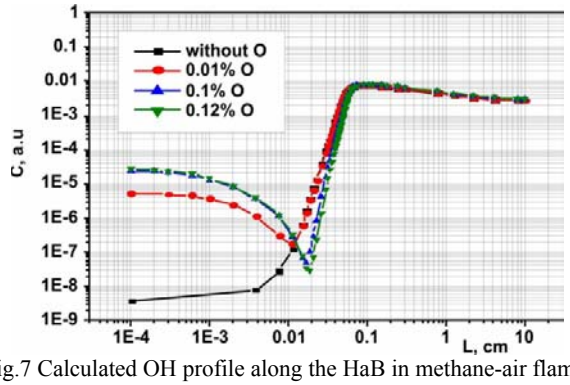

Fig.7 Calculated OH profile along the HaB in methane-air flame.

velocity increased too, because greater number of active particles per second had produced. These results are presented in fig.5 [2]. Based on this result a conclusion could be drawn that with frequency increase it's necessary to input larger amount of discharge energy to provide the same burner chemical power. We think that this fact could be explained by OH recombination rate.

On the other hand, dielectric barrier discharge with 50 Hz frequency and up to 20 kV amplitude was examined. It was found that such type of discharge does not affect on burning efficiency and flame blow-off velocity. One of the reasons is that the discharge power is two orders of magnitude smaller than in the case with 1,2 kHz discharge, and the reduced electric field in the gap is also weaker. But this power cannot be increased by voltage increase, because low frequency principally restricts maximum energy input. When the voltage was increased up to 21 kV, the canalization of the discharge took place. These effects result in quartz dielectric breakdown and development of arc discharge with high current value. These results are confirmed by ICCD-camera images.

Based on the results mentioned above, we can conclude that proper organization of discharge is important for effective power input. Depending on the gap length, mean reduced electric field in the gap could change as well as number of active particles and area where they are produced, which are responsible – directly or indirectly – for combustion intensification.

It worth mention that geometry of burner and discharge cell are of great importance. Electrodes, if placed near or inside the burner, serve as additional stabilizers and allow to increase blow-off velocity even without discharge. The way of influence in this case is changes in flow pattern and heat-transfer processes. Another mechanism for flame stabilization is creation of zones with near-zero flow rate, where ignition occurs, and than flame moves upward the stream. So, there are two types of discharge application in combustion tasks. The first is to ignite mixture in areas with low flow speed with combustion rate remaining constant, i.e., by heating, as in [6], and the second is to increase combustion rate by uniform treatment of mixture in the discharge. We think that the second way is more perspective and that's why one should use relative flame velocity increase as the main parameter of discharge effectiveness, instead of absolute values of flow speed. We should compare the discharge power to relative burner power increase, taking into account that completeness of combustion could change.

Now we'll try to describe physical processes, taking place in the flow and flame under discharge action. We'll consider 1D stationary task as an approach. In this case kinetics of plasmochemical process taking place in the pre-combustion zone in the presence of discharge can be divided into three spatially-separated parts: excitation of molecules by electron impact in the barrier discharge, kinetics of excited states and combustion processes.

On the first stage formation of excited particles by the electron impact takes place. The main processes taking place as given below:

- Elastic collisions of electrons with molecules;
- Vibrational and electronic excitation of molecules;
- Dissociation;
- Ionization.

The analysis of high-voltage pulse energy branching to the processes given above was performed using a Boltzmann approximation. The main part of energy is put into the electronic excitation of molecules (especially N_2) as well as dissociation, and into the nitrogen ionization in the case of strong fields. On the second stage that lasts tens of microseconds, processes with participation of formed excited particles take place. Let's consider the main of them:

- Quenching of electronically excited states of nitrogen molecules. We treat this channel as the main source of active radicals (O, OH) production:
$$N_2^*(A,B,C,a') + O_2 \rightarrow N_2 + O + O. \quad (1)$$
- Dissociation of oxygen molecule through its electronically-excited states.
$$O_2^* \rightarrow O(^3P) + O(^3P) \quad (2)$$
$$O_2^* \rightarrow O(^3P) + O(^1D) \quad (3)$$
According to energy levels diagram, reaction (3) goes trough $O_2(B^3\Sigma^-)$ state, and reaction(2) goes through $O_2(A^3\Sigma^+)$ state. The number of O atoms formed in reaction (3) is three times greater than that in (2), so about a half of all atoms are in $O(^1D)$ state. This fact explains appearance of electronically-vibrationally excited OH in the presence of barrier discharge on wavelength which equals 294.5 nm
- Ionization of mixture's components (N_2 mainly). The main ions – N_2^+ and O_2^+ – quite quickly transform into the N_2 and O_2 molecule through N_4^+ and O_4^+ ions
- Translational relaxation of vibrationally excited states of reagents. This is the way the gas heating occurs.

Authors draw a conclusion that at the mentioned times electronic and vibration excitation relaxes into translational movement as well as oxygen dissociation. Thus, the third stage can be treated as combustion of new mixture formed at the burner exit as a result of barrier discharge influence with non-equilibrium atomic oxygen concentration. One-dimensional numerical simulations of the propagation of a premixed flame with allowance for additional gas excitation in a discharge have been performed.

So, it is shown that the main mechanism through which the discharge plasma affects the flame parameters is the change in the initial mixture composition, which results in the onset of thermal chain reactions in the pre-flame zone. Applying a non-equilibrium discharge leads to the electronic excitation of the gas components, the production of active particles (in particular, atomic oxygen), and the acceleration of the processes governing the combustion rate and the flame propagation velocity. An advantage of employing a strongly non-equilibrium

plasma of a nanosecond discharge is that, in this case, the efficiency of energy deposition is higher as compared to other methods for flame control.

A series of additional experiments were made to prove the correctness of the model of flame acceleration and kinetic scheme. Spectroscopic investigations of the flame itself and the flame under discharge action were performed. The profile of OH radical along the height above burner in propane-air flame is presented in fig.6. The blow-off flow rate for methane-air flame has been measured and obtained results are similar to previous for propane-air mixture. This fact should be treated as the conformation of the same kinetic mechanism for flame acceleration for both cases. The simulation results (the density profiles of atoms and radicals, as well as the profiles of the flame temperature and velocity) were in qualitative agreement with the experimental data (fig.7.).

An additional proof to the suggested theory and the model of radical influence lies in the results of experiments with $Ar/O_2/C_3H_8$ mixture. We have changed the nitrogen in the mixture to argon in order to remove main channel of active particles production by quenching of electronically-excited nitrogen. This substitute was considered to reduce the atomic oxygen formation and decelerate flame in comparison with $N_2/O_2/C_3H_8$ mixture. Indeed, the results showed that the phenomenon in argon mixture is much more weaker. This is an evidence for our flame acceleration model.

Now our efforts aimed at finding the exact mechanism of excited mixture combustion and building maximally full kinetic scheme. Laser system, based on dye laser TDL-50 “Quantel”, is adjusting now to perform LIF-diagnostic of OH radical and obtain 2D picture of OH distribution in a flame and in a discharge.

4. Conclusions

The study of nanosecond barrier discharge influence on a flame propagation and flame blow-off velocity was carried out. The following conclusions could be made:

- With energy input negligible in comparison with burner's chemical power, a double propane-air flame blow-off velocity increase was obtained. It was shown experimentally that the results for methane-air flame are similar with propane-air one.
- Besides proper form of energy input, proper organization of discharge is of great importance. It was found that the effectiveness of plasma-assisted combustion depends on type of discharge, pulse duration, pulse repetition rate and other parameters, which are responsible for active particles production. One should use the discharge power ratio to relative burner power increase as the main parameter of discharge effectiveness, instead of absolute values of flow speed.
- It was found that active particles (H, O and OH primarily), which are produced in the streamer head under its action, play the most significant role in the effect of combustion acceleration. The model of flame acceleration, based on nitrogen quenching on oxygen molecules, with production of O and OH radicals, was confirmed by the new spectroscopic investigations and experiments with $Ar/O_2/C_3H_8$ mixture, where discharge influence is small because of the absence of mechanism of active particles production.

What Do We Know about Long Laminar Plasma Jets?

Xi Chen[2], Wenxia Pan[1], Xian Meng[1], Kai Cheng[2], Dong-Yan Xu[2], Chengkang Wu[1]

[1] *Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, China*

[2] *Department of Engineering Mechanics, Tsinghua University, Beijing 100084, China*

As is well known, laminar gas jets at room temperatures are unstable even at comparatively low Reynolds numbers. They can only maintain their laminar flow regime within a short distance from the exit of jet nozzle. Linear stability analysis showed that the laminar jet even becomes more unstable when the density of the gas jet is less than that of the ambient gas [1]. Since the density of a plasma jet is much less than that of the ambient air, one might consider it is not easy to generate a stable laminar plasma jet in atmospheric air. However, stable long laminar plasma jets have been successfully generated recently using a non-transferred DC arc plasma torch at atmospheric pressure [2,3]. Preliminary experimental studies [2,3] indicated that the long laminar plasma jets are characterized by stable flow state, reduced entrainment of surrounding air into the jet leading to a rather long high-temperature region length (jet length / diameter ratio may be as great as 70 or even more as shown in photographs), adjustable jet lengths, etc. So far it is still puzzling why such a stable long laminar plasma jet can be generated and maintained. Since there exists no complexity caused by turbulent effects and due to its adjustable flow field parameters, the long laminar plasma jet can become a rather ideal object for the fundamental study of the plasma flow characteristics. Preliminary attempts using the laminar plasma jets in the preparation of thermal barrier coatings, in the re-melting hardening of cast iron and in the stainless-steel surface cladding have shown encouraging results, including the fine microstructure, low surface roughness and small porosity of the prepared coatings, the good re-melting process controllability and surface morphologies, as well as the metallurgically bonded clad layer. Hence, more detailed studies of the long laminar plasma jet characteristics are highly desirable.

In our experiments, photographs of the plasma jet are taken to determine the visible high-temperature-region length of the jet (called jet length hereafter). Spectral-line intensity method is employed to measure the plasma temperature distributions over the jet cross-section at different axial distances from the plasma torch exit. A small-size, taper-head and water-cooled Pitot probe is used to measure the local stagnation pressure to deduce the jet axial-velocity. Rapid-response sensors are used to analyze the fluctuations of arc voltage, jet radiation intensity and stagnation pressure.

Experiments show that, depending on process parameters (arc current, working-gas flow rate, etc.), long laminar plasma jets or short turbulent plasma jets can all be generated with the same DC arc plasma torch. The interior configuration of the plasma torch has some effects on the plasma jet characteristics. For a given torch configuration and for a fixed arc current, there exist two different critical values of the working-gas (argon) flow-rate, i.e. G_1 and G_2 ($G_1 < G_2$), demarcating the jet flow regimes. When the gas flow-rate is less than the lower critical value G_1, the plasma jet assumes the silent laminar flow state, and the jet length increases appreciably with increasing gas flow-rate. When the working-gas flow-rate is larger than the higher critical value G_2, the plasma jet assumes the noisy turbulent flow state, and the jet length is short and almost does not depend on the working-gas flow-rate. Between the stable laminar and turbulent flow regimes (i.e. with flow-rate less than G_2 but larger than G_1) there exists an unstable transitional regime,

showing an alternative change from a silent long jet to a noisy short jet. The average jet length in the transitional regime decreases with the increase of gas flow-rate, as shown in Fig. 1.

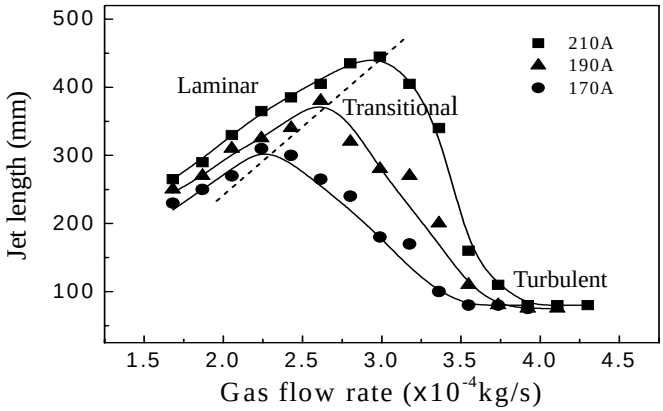

Fig. 1: Jet length vs. gas flow rate

Modeling results show that the jet length of laminar plasma jet increases appreciably with increasing plasma-jet inlet axial-velocity or temperature, while much less change in jet length is found for the turbulent jets. The axial gradients of plasma temperature and axial velocity in the laminar plasma jet are much less than those in the turbulent plasma jet. Although a temperature difference as great as 10^4 K is involved in the plasma-jet / ambient-air system, the effect of natural convection on the laminar plasma jet is negligible, in consistence with experimental observation, as shown in Fig. 2. The long laminar plasma jet has good enough stiffness to endure the impact of the lateral injection of powders and their carrier gas. The laminar plasma jet assumes only a small deflection (a few degrees) from its geometrical axis due to the carrier-gas impact [4]. Particulate matter can be injected into the jet high-temperature region with suitable injection parameters.

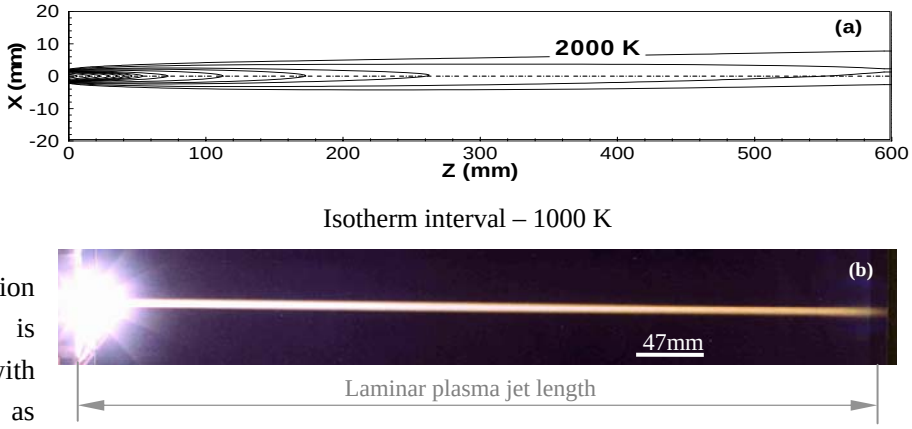

Fig. 2: 3-D modeling results of isotherms with natural convection (a) and jet photo (b)

It is found that the long laminar plasma jet can be generated in a rather wide range of plasma torch parameters (working-gas flow-rate, arc current, etc.) and rather high exit axial-velocity (~800 m/s) and temperature (~16000 K) can be achieved. Regular fluctuations often appear in arc voltage, jet stagnant pressure and optical emission intensity due to the existence of AC components in the DC power supply with the main fluctuation frequency of 300 Hz. The measured fluctuations of the arc voltage, jet stagnant pressure and optical emission intensity are almost in phase.

Abstract

Deposition of composite Ti/hydrocarbon plasma polymer films is performed by DC magnetron sputtering of Ti target in Ar/n-hexane mixture. Heterogeneous film structure is confirmed. Adhesion, proliferation and maturation of vascular endothelial cells in cultures derived from the bovine pulmonary artery (line CPAE) are studied. The cells are similarly or more active in adhesion, proliferation and maturation than those on glass or pure hydrocarbon plasma polymer.

Keywords: composites, magnetron sputtering, vascular cells.

1. Introduction

Composite metal/plasma polymer thin films have been studied for several decades now [1-4]. The benefits of composites arise from the combination of materials with very different properties, e. g. hardness, flexibility or weight, to produce structural or functional properties not present in any individual component. Methods involving sputtering and plasma polymerization have been applied to produce hydrocarbon based composites, mainly metal/hard carbon plasma polymer thin films (Me/C:H) (Biederman). The deposition of silver, molybdenum, nickel, germanium/C:H films by magnetron sputtering in Ar/n-hexane working mixture was studied in detail. It was shown that optical, electrical, mechanical properties of these composites varied in a wide range depending on metal volume fraction.

Hydrocarbon plasma polymers have been shown to increase wear resistance, smoothness, hydrophobia and blood compatibility of various polymer- or metal-based biomaterials [5-9]. For example, they have been employed for coating of femoral heads of metallic hip prostheses in order to prevent the release of metal ions and wear particles [5] or deposited on various blood-contacting devices, e.g., blood pumps, in order to enhance their resistance to protein adsorption and thrombus formation [6-8].

Titanium is widely used material for construction of bone, joint or dental implants, and it has been reported to support adhesion and growth of osteogenic and vascular smooth muscle cells [10, 11]. The aim of this study is to evaluate the physicochemical properties of these films as well as adhesion, growth and maturation of vascular endothelial cells in cultures on Ti/hydrocarbon plasma polymer films.

2. Experimental

Ti/hydrocarbon plasma polymer films were deposited using unbalanced magnetron with Ti target operated in the DC mode in a working gas mixture of Ar/n-hexane. The depositions were performed at a working mixture pressure of 2 Pa. The flow rate of argon was automatically adjusted by a flow-controller (MKS instruments) and set to the constant value of 20 sccm. The flow rate of n-hexane was manually controlled by a needle-valve to the value of 0.4 sccm. The depositions in pure Ar and n-hexane were also performed. The substrate holder was placed opposite to the magnetron at a distance of 50 mm from the target. Direct current generator MDX 1.5K (Advanced Energy) powered the magnetron in a constant current mode (0.2 A).

The elemental composition of the Ti/hydrocarbon plasma polymer films was determined by Rutherford back-scattering spectrometry (RBS) and elastic recoil detection (ERD) methods using a Van de Graaf accelerator. The α-particles at kinetic energiy of 2.68 MeV have been used. RBS spectra were evaluated by computer code GISA 3, whereas ERD spectra by the SIMNRA code, both using cross-section values from SigmaBase.

Optical Emission Spectroscopy was applied using a self-built OES apparatus consisting of an optical fiber, an ARC SpectraPro-300i monochromator with a grid, and a Hamamatsu photomultiplier R928.

Transmission Electron Microscopy (Jeol FX 2000) was performed on the films deposited on carbon foil supported with copper mesh grids (S160, Elektronenmikroskopie, Austria).
Surface morphology of composite Ti/hydrocarbon plasma polymer films was studied by means of Atomic Force Microscopy (AFM) (Q-Scope^{TM} 850, Quesant). The measurements were performed in intermittent contact mode in air immediately after depositions. AFM was also used for thickness measurements.
A set of different substrates was treated. Silicon was used for RBS/ERDA and AFM analysis. Glass substrates were used for water contact angle measurements and for biological tests. The samples (size 8 x 8 mm) were sterilized by UV irradiation, inserted into Nunclon Multidishes (NUNC, Denmark; 24 wells, diameter 15 mm) and seeded with bovine pulmonary artery endothelial cells (line CPAE, ATCC CCL 209, 17 000 cells per cm^2). The cells were incubated in 1.5 ml of Dulbecco's Modified Eagle Minimum Essential Medium supplemented with 20% of fetal bovine serum for 1, 3 or 7 days at 37^{o}C in air atmosphere with 5% CO_2.
Adhesion of endothelial cells on the Ti/hydrocarbon plasma polymer films were evaluated by the number of initially adhering cells on day 1 after seeding, cell-material contact area (i.e., cell spreading area) and formation of focal adhesion plaques, detected by immunofluorescence staining of vinculin [12]. Cell proliferation was estimated by the percentage of cells newly synthesizing DNA. The nuclei of these cells were visualized by 30-min-incubation of cells with bromodeoxyuridine (BrdU), followed by anti-BrdU immunoperoxidase staining [12]. Markers of endothelial cell maturation, used in this study, were represented by formation of confluent cobblestone-like cell layer, content of von Willebrand factor and formation of distinct beta-actin cables. The latter two parameters were evaluated by immunofluorescence staining [12].

3. Results and discussion

The deposition process was monitored by OES (Fig. 1). A considerable decrease in Ti emission intensity when sputtering in Ar is observed when adding n-hexane. In this case, two concurrent processes contribute to the film formation: sputtering of titanium and plasma polymerization of hydrocarbon precursor leading to partial or complete poisoning of the Ti target.

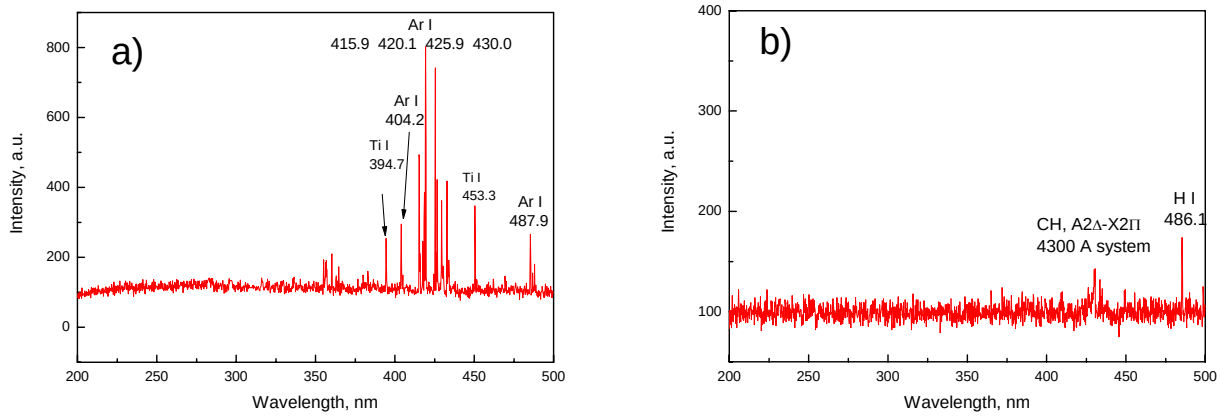

Fig.1. The OES spectra taken in discharge of: a) pure Ar, b) mixture of Ar and n-hexane and c) pure n-hexane.

A ratio of Ti line [363.5 nm] and Ar line [420.1 nm] served as an indication of the amount of Ti built in the depositing composite film.
Table 1 gives the elemental composition RBS/ERDA of the films deposited in n-hexane and Ar/n-hexane mixture. Both films contain 3-4 at. % of oxygen, which is believed to appear as a result of post-deposition oxidation reactions. The films are deficient with hydrogen as is typical for plasma polymers as such. The C/H ratio is 2.3 for the n-hexane monomer. However, it reaches only 1 for the plasma polymer and is even lower (C/H=0.7) for the composite film. This let us assume that polymeric part of the films is highly cross-linked. Film prepared with n-hexane only resulted in plasma polymer with negligible amount of Ti. Using Ar/n-henxane

mixture we prepared maximum up to 3 at. % Ti. We selected these two cases for cell experiments (deposition conditions, please, see Table 1).

Table 1 The elemental composition determined by RBS/ERDA.

Film	Flow rate	Elemental composition			
		C, at. %	H, at. %	Ti, at. %	O, at. %
Ti/hydrocarbon plasma polymer	Ar 20 sccm hexane 0.4 sccm	54	40	3	3
hydrocarbon plasma polymer	hexane 5.5 sccm	48	48	-	4

TEM image (Fig. 2) demonstrates that the film deposited by magnetron sputtering in Ar/n-hexane mixture is a composite hydrocarbon plasma polymer with the embedded titanium aggregates (dark regions).

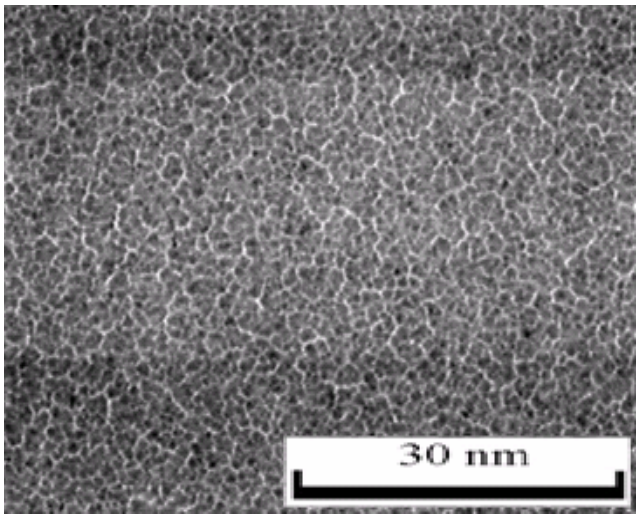

Fig. 2. TEM image of composite Ti/hydrocarbon plasma polymer film with 3 at. % Ti.

Biological tests showed that the endothelial cells adhered in higher initial numbers and by a large cell-material contact area on Ti/hydrocarbon plasma polymer layers than on pure hydrocarbon plasma polymer (Figs. 3A, B). Similar results were obtained earlier on vascular smooth muscle cells, osteoblast-like MG-63 cells or bone marrow cells cultured on carbon-fibre reinforced carbon composites (CFRC) or titanium discs coated with Ti-containing a-C:H [10, 11]. The synthesis of DNA in cells on Ti/hydrocarbon plasma polymer samples, measured by BrdU incorporation, tended to be lower than on pure hydrocarbon plasma polymer, although these differences were not significant (Fig. 3C). The latter result is consistent with the findings that the proliferation activity is the highest at the intermediate strength of cell adhesion. When the adhesion is very high, the cells skip the proliferation phase and enter sooner the differentiation program [12].

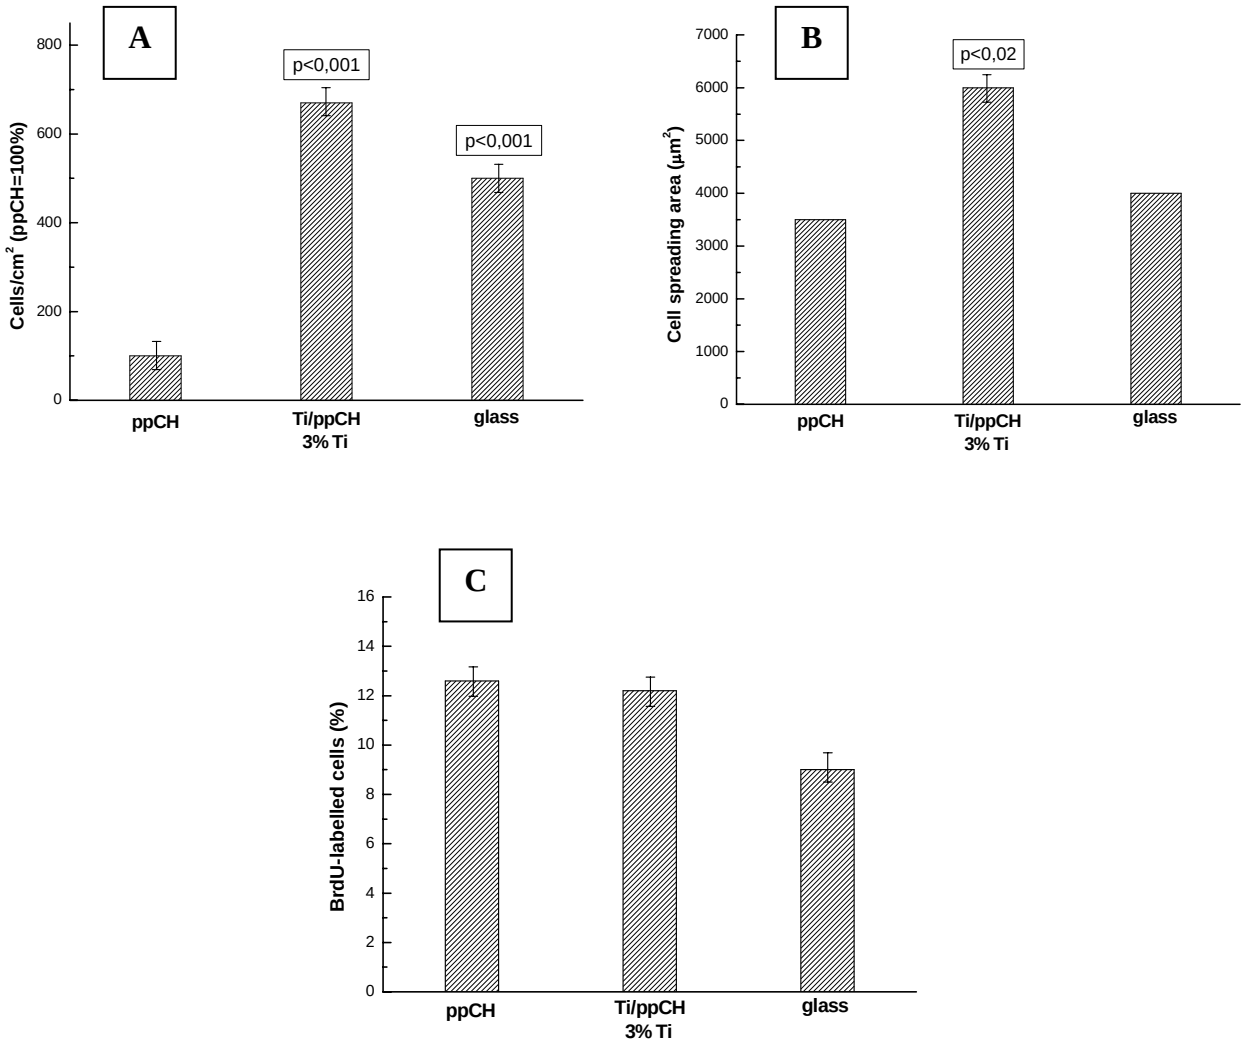

Fig. 3. Number (in % of values obtained on pure ppCH; A), cell-material contact area (B) and percentage of DNA synthesizing endothelial cells (C) on Ti/ppCH layers with low concentration of titanium on day 1 (A, B) or day 3 (C) after seeding. Average ± SEM from 9-38 measurements, Student's t-test for unpaired data, statistical significance: $p<0.02$, $p<0.001$ in comparison with values obtained on pure ppHC.

Ti/hydrocarbon plasma polymer films allowed formation of continuous layers of cobblestone-like endothelial cells (Fig. 4). Thus, the Ti/hydrocarbon plasma polymer films showed a good compatibility with endothelial cells, so that these materials could be used for cardiovascular applications, such as coating of vascular prostheses or heart valves in order to improve their lining with endothelial cells. Another possible application is surface coating of bone implants.

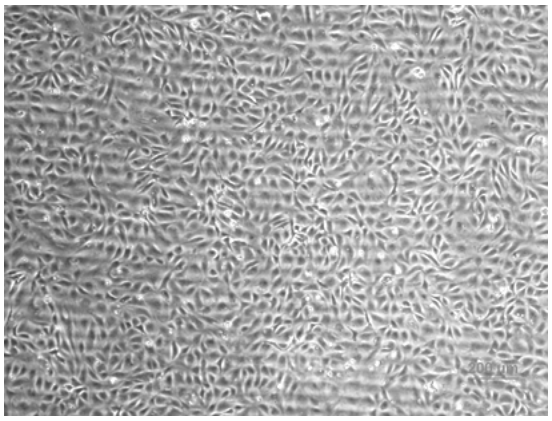

Fig. 4. Formation of a confluent cell layer on Ti/ppCH with low concentration of Ti. Day 7 after seeding, bar=100 μm.

4. Conclusions

DC magnetron sputerring of titanium in Ar/n-hexane mixture deposits composite films with Ti aggregates randomly dispersed in a hydrocarbon plasma polymer matrix. Ti/hydrocarbon plasma polymer films support adhesion, growth and maturation of vascular endothelial cells in cell culture conditions. These films could be used for construction of long-term artificial implants into human body, e.g. for coating of the inner surface of vascular prostheses or surface modification of bone implants.

Abstract
We exposed the preliminary results and interpretations concerning a new method of organic aqueous waste treatment by underwater electrical arc. First experimentations permit to produce a combustible gas corresponding to syngas (50 % vol. H_2 and 35 % vol. CO) from a diluted glucose aqueous solution. High temperature due to electrical arc decomposes organic material into simple molecules. Development and process potential applications are also detailed.

Keywords : Syngas, organic liquid waste, underwater electrical arc, gasification

1.Introduction

Primary energy consumption reached ten billions of tons of oil equivalent petrol (toe) in 2000. After being decupled during the last century, it increases now with a rate of 3% each year. Development is linked to the access at cheap energy. Global warming due to greenhouse effect gas emissions shows us the limits of fossil fuel use. The use of hydrogen as energetic vector can be a good perspective with the decrease of fuel cell cost. Hydrogen gas is not a native species, its production consumes energy. Nowadays, 90 % of production is issued of natural gas reforming with an harmful effect on carbon dioxide balance. Electrolysis produces clean hydrogen if electrical power is produced by a process without carbon dioxide emission.

Waste treatment is also a problem now for industrialized society and on the future for emerging countries. Yet, the source of carbon and hydrogen included in waste is not totally used. Waste gasification is another way to treat waste and to recover energy [1]. So, for an industrial country, waste can be a real resource of energy with a good effect on carbon dioxide balance.

Plasma gasification processes have been developed for specific applications such as naval waste incineration, municipal solid waste or toxic waste [2], [3], [4], [5]. Units are in operation and permit to eliminate waste without harmful emission. But, some waste can not be eliminated with such a process, in particular, waste issued from agribusiness industries. The main reason is the high moisture content of this kind of waste. So, drying stage needs much energy to permit the valorization of this material. Sewage sludge and wet waste are eliminated by co-firing or spread on fields. Co-firing is the combustion of two combustibles, in this case, sewage sludge and high calorific value combustible such as natural gas or heavy fuel oil. Most of energy is used to evaporate waste water content.
Besides, different patents claim the feasibility of syngas production from water by use of an electrical arc between graphite electrodes [6], [7]. The global reaction seems to be steam reforming of electrode carbon.
The work, reported here, deals with a syngas synthesis process where a DC arc is stricken between two electrodes inside an aqueous waste, carbon oxides being formed mainly from organic content.

2. Process basis

Water decomposition study is one of the fundamental works of modern chemistry. Water decomposition is actually made by alkaline electrolysis to produce pure hydrogen and oxygen. But, water thermal decomposition is also a possible way to produce hydrogen. This process needing a large thermal energy source, the use of concentrated solar energy is a possible solution. In the process presented in this work, an electrical arc provides high temperature gradients within the aqueous solution. Water and organic molecules are decomposed. Atomic hydrogen, oxygen, carbon are quenched by solution whose temperature is maintained under water boiling temperature, and recombination of atoms leads to simple molecules such as gaseous hydrogen, carbon monoxide and carbon dioxide.

Our hypothesis is that thermal energy is the main actor for gas production but photochem ical and electrochemical phenomena can also take place in our process.
Benefits of this process are numerous :

- no preliminary drying,
- soot washing in reactor without filter,
- thermal quench preventing dioxin formation,
- pure syngas production (H_2, CO, CO_2), no NOx formation,
- no incombustible gases (except carbon dioxide).

3. Experimental

In order to simulate organic liquid waste, a mix of glucose and fructose diluted in drinking water is used. The choice of these molecules is due to its chemical formula $C_6H_{12}O_6$ which is proposed for an phantom of agribusiness waste (sugar industry liquid waste, milk waste, blood from animals). It is soluble in water and easy to prepare.

3.1 Experimental setup

An electrical arc is produced between two graphite electrodes connec ted to a DC power supply (Intensity: 100 - 400 A, DC Voltage: 10 - 100 V). Two reactors are used to treat aqueous solution: they are different by volume, electrode motion and electrode fitting. The reactor 1 in Figure 1 has been designed to allow experiments with a long duration (few hours). The anode is a rotating graphite disk (for these experiments: ω = 150 rad.s^{-1}, v_t = 10 m.s^{-1}) to move the anodic spot on a larger surface. A graphite cathode has a translation motion to control inter-electrode space, and so to compensate anode erosion. Reactor 1 volume is about 60 litres. Reactor 2, on Figure 2, uses two graphite electrodes. The anode is fixed and the cathode has a translation motion. Reactor 2 volume is about 8 litres. This confers to reactor 2 a lower thermal inertia than reactor 1 and an easier utilization.

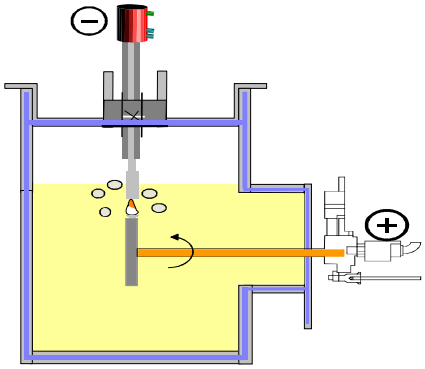

Figure 1: Reactor 1 with rotating disk and translating cathode

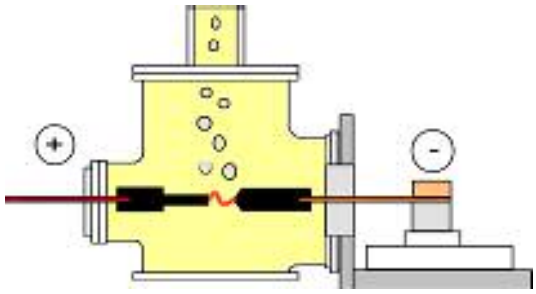

Figure 2: Reactor with coaxial electrodes

Exhaust gas flow rate is measured by a FURNESS CONTROLS volumetric flow meter (0 - 30 NL/min). Gas composition analysis is realized by mass spectroscopy (Gaslab 300 FISONS) with Ar as inner standard gas after calibration. The process full block diagram is represented on Figure 3.

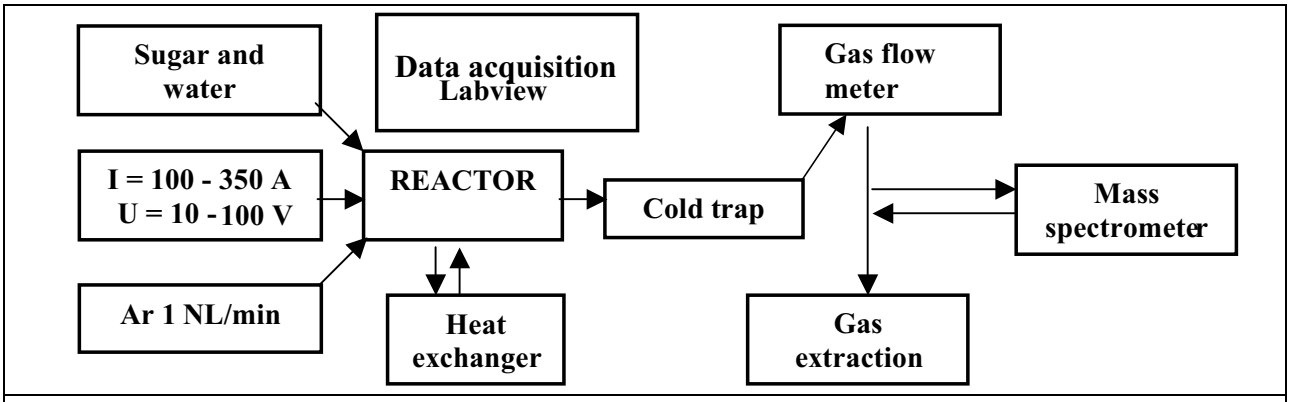

Figure 3: Process block diagram

3.2 Experiments

3.2.1 Electrical arc and electrode observations

Initially, the reactor is filled with sugar solution (sugar concentration between 100g/L and 650g/L) and the electrodes are brought closer at zero voltage. Then, voltage is applied and a small gas production is observed, corresponding to water electrolysis. When inter-electrode space is set closer, the electrical arc is stricken. Intensity is controlled by the DC supply regulator; voltage, function of the arc length is self adjusted. To increase voltage, the arc is drawn by moving the cathode. To observe the location of gas formation, a high speed camera (1000 pictures/s) is used. Gas bubbles and electrical arc have been observed. Photos of experiments in reactor 1 are exposed on Figure 4:

Figure 4: Immerged electrical arc in sugar solution

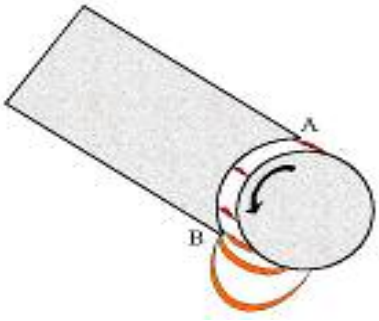

Figure 5: Electrical arc motion

On Figure 5, we can see the extension of the arc due to the anode rotation. The arc begins at A point a nd extends to B point until it cuts off and strikes again at point A. According to anode velocity and voltage, arc lifetime is very short. The high speed camera observation has confirmed that lifetime is shorter than 10 ms. Pink flashes are observed at each experiments and could be due to H_α emission line (656,3 nm) (cf. Figure 6).

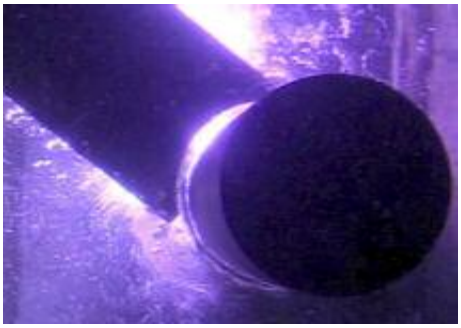

Figure 6: Pink flashes in reactor 1

Experiments on anode rotation velocity showed that erosion is both chemical and mechanical, perhaps sublimation. Oxygen and hydrogen recombination induces shock waves which erode electrodes (in reactor 1, the inversion of rotation moves cathode erosion area). Micrometric carbon particles are produced darkening quickly the solution. If, at the moment, the characteristics of produced carbon are not known, some studies indicate that fullerens and nanotubes can be obtained with this type of process [8], [9]. In reactor 1, with drinking water, with I = 200 A and V ~ 30 V, the erosion of the electrodes is of about 30 g/h for the anode and 10 g/h for the cathode. In reactor 2, the consumption is similar for the anode but there is no erosion of the cathode. During sugar solution treatment, a graphite deposit was noticed which could be an electro-deposition due to electrical field and presence of carbon cations in the electrical arc (cf. Figure 7) [9].

Considering that when treating drinking water, there is no deposit: it can be deduced that carbon comes from sugar.

Figure 7: Graphite deposit

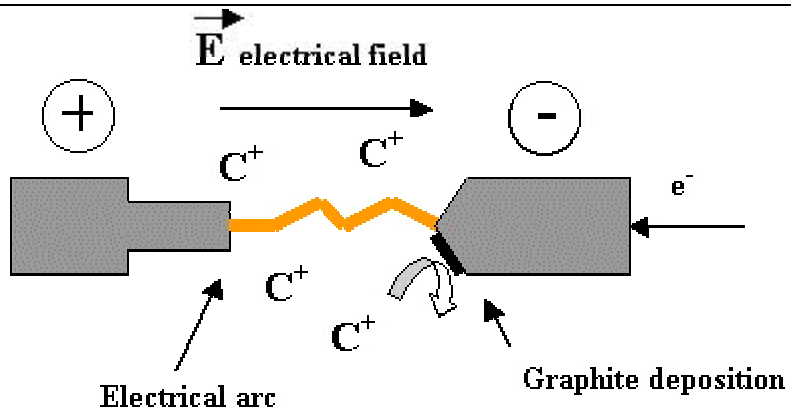

Figure 8: Graphite electro-deposition on cathode in sugar solution

3.2.2 Gas composition versus time

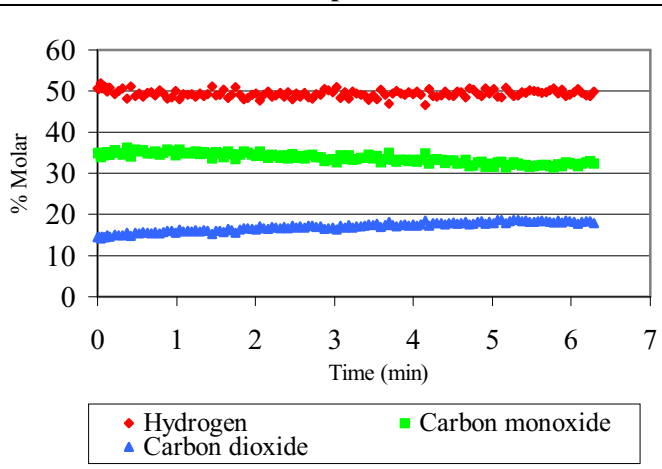

Figure 9: Major gas contents versus time

During treatment of aqueous sugar solutions, mass spectroscopy showed that the exhaust gas mixture is mainly composed of H_2, CO and CO_2 with very small amounts of light hydrocarbons (CH_4 and C_2H_2). On Figure 9 is presented versus time, the evolution of the major gases for a sugar solution. Considering that thermodynamic equilibrium is quickly reached at high temperature, no significant evolution in gas composition should be expected. However, if the percentage of H_2 is constant since the beginning, about 5 minutes are necessary to reach a quasi steady state for CO and CO_2. We can notice that the global amount ($CO+CO_2$) is constant. The evolution observed for the ratio CO/CO_2 could be due to dissolution of CO_2 until saturation.

According to this gas analysis, the high calorific value is about 8 MJ/Nm^3, (~10 MJ/Nm3 for pure H_2 or pure CO).

3.2.3 Gas flow rate versus intensity and electrical power

In order to quantify produced gas, efficiency of the process and sugar behavior in r eactions, we have measured gas flow rate while parameters are changed (type of solution, intensity, inter electrode space). Results for drinking water are shown on Figure 10. The electrical arc is very erratic in drinking water and does not allow to work easily at constant power. On Figure 11, results for sugar solution treatment are exposed and we can see that, for the same power, the gas flow rate for the sugar solution is widely higher than for drinking water. Sugar addition increases the gas flow rate.

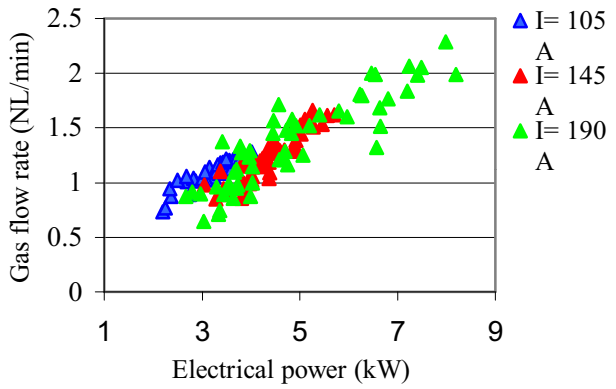

Figure 10: Gas flow rate versus electrical power for drinking water in reactor 1

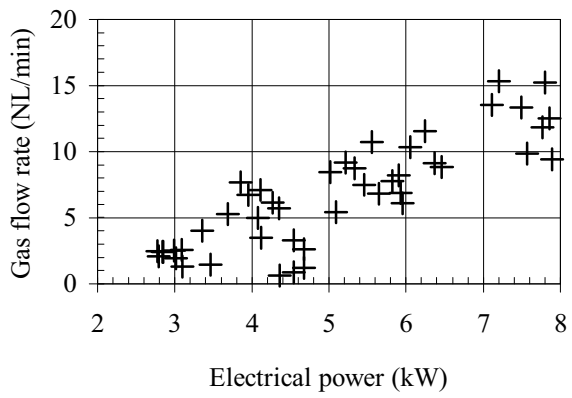

Figure 11: Gas flow rate versus electrical power for a sugar solution (550 g/L) in reactor 2

It has also been noticed that longer is the arc, higher is the gas production. This indicates that chemical reactions are not only taking place at graphite electrode edges. Yet, experiments with dr inking water and graphite electrodes produce carbon monoxide due to reactions with graphite electrodes and a chemical consumption of electrodes. Nevertheless, gas flow rate with drinking water is very low compared to gas flow rate with sugar solution (magnitude order between 5 – 10).

3.2.4 Gas composition versus sugar concentration

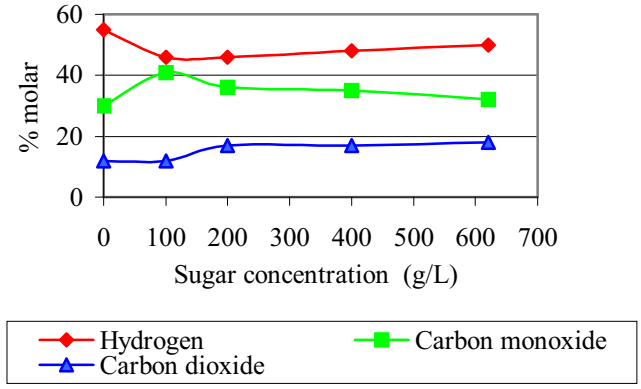

Figure 12: Gas composition versus sugar concentration

Reactor	Intensity (A)	Time average voltage (V)	Sugar concentration (g/L)
2	150	40	0
1	150	40	100
2	100 - 250	40	200
2	150	45	400
1	100	25	620

Figure 13: Operating parameters

Results are exposed on Figure 12 obtained with different parameters (cf. Figure 13). Power control is quite difficult because of arc motion. We may observe that hydrogen ratio is higher for drinking water than for sugar solution.

We suppose that after water thermolysis due to high electrical arc tempera ture, hydrogen gas and oxygen gas are recombined to water. Studies on water thermolysis by concentrated solar energy showed that hydrogen gas flow rate is a function of thermal quench [8]. In our process, quench is not fast enough to inhibit this reaction.

But carbon presence at sublimation temperature and oxygen gas permit the production of carbon monoxide. Hydrogen and oxygen consumption exposed in equations (2) and (3) assists water (steam) decomposition (equation 1).

$$H_2O_{(g)} \rightleftharpoons H_{2(g)} + O_{2(g)} \quad (1)$$

$$C_{(g)} + \tfrac{1}{2} O_{2(g)} \rightleftharpoons CO_{(g)} \quad (2)$$

$$CO_{(g)} + \tfrac{1}{2} O_{2(g)} \rightleftharpoons CO_{2(g)} \quad (3)$$

$$H_2O_{(g)} + CO_{(g)} \rightleftharpoons CO_{2(g)} + H_{2(g)} \quad (4)$$

According to gas analysis, there is very few oxygen (< 1 %) in produced gas. Equations (2) and (3) are almost quantitative and reaction (4) must be considered despite low pressure and low temperature conditions in solution.

4. Perspectives

Organic molecule gasification in aqueous solution is feasible: an hydrogen rich gas is obtained from aqueous sugar solution (about 50 % H_2, 35 % CO, 15 % CO_2). Experiments with tracker elements (deuterium via heavy water, ^{13}C via sugar) could about carbon and hydrogen origins in gas. Works on electrode material and shapes could improve the process and reduce electrode erosion. Concerning fundamentals phenomena, spectroscopy emission measurements may provide some information about reactive species such as H, O and C. Our further experiences will concern aqueous suspensions of organic material in order to show or not the feasibility for insoluble materials such as sewage sludge.

This process aims to propose an alternative way to co-firing process. Several applications are conceivable such as reduction of sewage sludge volume or treatment of milk or wine industry residues with high moisture contents.

It appears that our process eliminates some problems of usual gasification processes and can find its place in aqueous waste treatment. Ratio between hydrogen and carbon monoxide indicates that produced gas can be used in liquid fuel making processes like Fischer-Tropsch or Mobil. With a high calorific value (8 MJ/Nm^3), cogeneration units can use it to produce electrical and thermal energy.

Remarkable Enhancement in the Dispersion and Stability of Catalysts Using Novel Plasma Treatment

Chang-jun Liu

Key Laboratory for Green Chemical Technology and School of Chemical Engineering, Tianjin University, Tianjin 300072, China

The supported metal catalysts have been extensively employed in chemical industries. The catalytic performance of these supported catalysts is mostly dependent upon the preparation of the catalyst, which determines the acidity, dispersion, activity and stability of the catalyst. A sufficiently high dispersion of metal active species is normally required. To improve the dispersion and thereby to improve the catalytic performance, various promoter elements have usually been applied. However, the addition of promoter elements may not work well with those catalysts for high-temperature reactions, for example, oxidations. Many groups have also attempted to use some innovative catalyst preparations to improve the catalytic performance of the supported metal catalysts. These preparations include applications of plasmas, sonic treatment and microwave.

We previously reported a novel plasma catalyst preparation, with which the catalyst is first treated by a glow discharge and then the plasma treated catalyst is thermally calcined [1-3]. During the plasma treatment, the metal ions loaded will be normally reduced. A plasma reduction is thereby occurred. And, during calcination thermally after plasma treatment (no plasma employed in this step), the metal particles will be oxidized again. We nominated this preparation as Plasma Reduction and Calcination (PR&C) method. This PR&C preparation can lead to a better catalyst preparation with a high dispersion of metal active species, a significantly enhanced acidity, an improved low-temperature activity and a remarkable promotion of catalyst stability, which will be summarized in this paper.

The catalyst preparation using PR&C method has been reported in detailed elsewhere [10-18]. The procedure for this method includes: the conventional incipient wetness impregnation, drying (sometimes no drying needed), plasma treatment and calcination thermally. For the plasma treatment, several plasma phenomena, e.g., glow discharge, dielectric-barrier discharge and microwave discharge, can be employed. The different discharge plasma treatment would induce a very different catalytic performance. In this work, we focus on the discussion of PR&C method with glow discharge plasma treatment. Glow discharge is a kind of plasma that is created by inserting two electrodes in a cell filled with gas at low pressure (e.g.,1 Torr). During the glow discharge plasma treatment, the catalyst was hold in a quartz container and placed in a glow discharge tube. A high-voltage (DC or AC) generator is used to generate the glow discharge plasma. The catalyst powder or particles are usually placed in the “positive column” of glow discharge where it was characterized with highly energetic electrons at low gas temperature. To confirm the low gas temperature process, we have applied IR thermal imaging to measure the gas temperature during the glow discharge treatment of catalysts. The gas temperature is normally below 50 °C during the plasma treatment of all catalysts we investigated by far. We can therefore ignore the possible thermal effect during the glow discharge plasma catalyst treatment. After the plasma treatment, the catalyst is then calcined thermally.

As mentioned above, during plasma treatment, the catalyst is normally reduced. Evidently, some metal species present after the plasma treatment. A plasma reduction is thereby addressed. XPS analysis of the plasma treated catalysts gives us further evidences of the plasma reduction.

The reduced metal species would play an important role in the plasma-enhanced dispersion. During the oxidation of the reduced metal species in calcinations thermally, the new-formed metal oxide will induce an intense electric field. The metal species with the same electric properties will therefore exclude each other, which induces a highly dispersion. For example, the Ni-supported catalysts prepared via PR&C method exhibit an unusual dispersion characteristic. From hydrogen chemisorption, XRD characterization and TEM analysis, no metal particles can be identified. The metal species is ultra-highly dispersed over the support. Moreover, the calcination temperature has a significant effect on the dispersion of the catalysts prepared via PR&C method. From the results of palladium dispersion of PR&C prepared Pd/HZSM-5 catalysts, the palladium dispersion of the catalyst calcined at 673 K exhibits the highest palladium dispersion, 13.4%. With the increasing of calcination temperature, the palladium dispersion reduces because of the agglomeration of palladium particles at higher temperatures. The palladium dispersion of the catalysts calcined at 773 K and 873 K is 10.95% and 9.89%, respectively. To achieve a high dispersion, the calcination temperature of 673 K or 773 K would be the best.

All the catalysts prepared by PR&C method and tested by far for methane conversion show a better low-temperature activity. We take methane combustion here as an illustration, the methane conversion over the PR&C prepared catalyst is close to 100% at 450 °C, but it is only 50% at the same temperature over the conventional catalyst. The alumina supported Pd catalysts exhibit a similar plasma-enhanced low-temperature activity. The light-off temperature of the PR&C prepared catalyst is 370 °C, 50 °C lower than that obtained from the conventional catalyst. A remarkable enhanced stability for methane combustion from the PR&C preparation has also been achieved.

The principal procedure of the catalyst preparation using PR&C method can be summarized: 1) impregnation conventionally; 2) drying or no drying needed; 3) plasma treatment; and 4) calcination thermally. The PR&C preparation will normally induce significantly plasma-enhanced acidity and dispersion, which further leads to a low-temperature catalytic activity, upon the experimental investigations on methane conversion (including partial oxidation of methane, methane combustion, CO_2 reforming of methane and NO reduction by methane). A remarkable improved in the stability of catalysts has also achieved with the PR&C catalyst preparation. This improved stability is achieved principally thanks to the plasma-enhanced acidity and the improvement in the interaction between metal species and the support. Further improvement in the PR&C preparation is leading to a development of a novel and practical catalyst preparation technology.

Abstract

We have examined how various deposition conditions affect plasma parameters important for superhard thin film deposition in a supersonic thermal plasma jet chemical vapor deposition system through Langmuir probe measurements. These measurements have revealed that the plasma floating potential is affected by a positive substrate bias, ion density is increased most effectively by increasing the torch power, and introduction of hydrogen decreases both electron temperature and electron density.

Keywords: Langmuir probe, superhard coatings, B-C-N composites, substrate bias

1. Introduction

Thermal plasmas have various advantages for materials deposition applications. Their high energy densities allow for the rapid dissociation of a wide variety of precursors, facilitating rapid deposition over large areas. Also, the rapid quench rates and high flow velocities inherent in thermal plasma deposition methods lead to strong temperature and reactant species gradients near the substrate, enhancing the potential for nanostructured materials deposition. Further advantages of thermal plasma deposition methods may be realized when the plasma is expanded into a low pressure environment and a low-power secondary discharge is superimposed over the plasma, as such expansions may lead to supersonic flows and lower heat fluxes to the substrate compared to deposition at higher pressure, while secondary discharges may lead to higher degrees of species dissociation, increased film growth rates, and film composition modification [1-2].

We are currently studying a supersonic thermal plasma jet chemical vapor deposition process with secondary discharge for the deposition of nanostructured B-C-N composites. Materials from the B-C-N ternary system hold particular advantages and potential for use in superhard coatings ($H > \sim 40$ GPa) for machine tools, as such coatings could potentially reduce the cost of high speed machining applications by up to 40% [3] by eliminating costs associated with the use and disposal of environmentally hazardous coolants. While two materials from the B-C-N system, diamond and cubic boron nitride (cBN), are respectively the hardest and second hardest known materials, both materials have notable limitations. Specifically, diamond dissolves with ferrous materials at temperatures greater than $\sim 1000^{o}$C, and cubic boron nitride films have limited thicknesses due to residual stress caused by the ion bombardment necessary for their deposition. As a potential solution to these limitations, it has been proposed that B-C-N materials could possess intermediate properties between those of diamond and cBN, namely superhardness, low residual film stress, and chemical stability at high temperatures [4]. Various deposition methods have been employed for diamond [7], cBN [8-9], and B-C-N deposition [4-6]. However, relatively few B-C-N deposition methods have involved thermal plasmas. Similarly, while there exist a few publications of diagnostic measurements of operative deposition parameters in cBN [9-10] and diamond deposition [7], measurements of such parameters for B-C-N film deposition are also quite rare. Such measurements in a thermal plasma B-C-N deposition system could potentially enhance the understanding of a superior superhard coating deposition process.

Our current research is focused on understanding how various processing conditions such as torch power, plasma chemistry, and substrate bias affect plasma parameters such as ion density, electron temperature, and precursor distributions in the plasma, which are assumed to play important roles in deposited film qualities. Substrate bias is of particular interest as ion bombardment of the substrate, facilitated through negative substrate bias, has been widely accepted as necessary for cBN deposition. For example, it has been shown that the cBN content scales with the total amount of momentum transferred to the substrate and growing film due to ion bombardment rather than the momentum transferred in a single binary ion collision [11]. Therefore, a higher total ion flux to the substrate is preferable for cBN deposition. Negative substrate bias also increases boron carbide film density [1], and potentially plays an important role in B-C-N film composition [4]. Positive substrate bias has been shown to increase boron carbide deposition rates by an order of magnitude and greatly increase optical emission from the plasma [1]. Diagnostic measurements of the previously mentioned plasma

parameters under various substrate bias conditions could provide insight towards the origins of these film enhancements. Values of these parameters may be obtained from Langmuir probe measurements.

2. Experiment

The supersonic plasma jet deposition system (SPJR) is shown schematically in Figure 1. Mixtures of argon and, depending on the material being deposited, hydrogen or nitrogen flow through the torch. A bias is applied to the cathode and an arc strikes between the cathode and grounded anode nozzle. The gases are heated by the arc, form a thermal plasma, and accelerated towards the substrate at supersonic speeds. Reactants such as boron trifluoride, methane, hydrogen, and mixtures thereof are injected in the expanding portion of the nozzle, dissociated in the plasma jet, and transported to the substrate where they react to form a film. To enhance the deposition process a secondary discharge is superimposed over the plasma jet by applying a positive or negative bias to the substrate with respect to the grounded anode. The distance from the substrate to the nozzle exit for all results reported here is approximately 6 cm, and the pressure is approximately 2.7 to 3 torr.

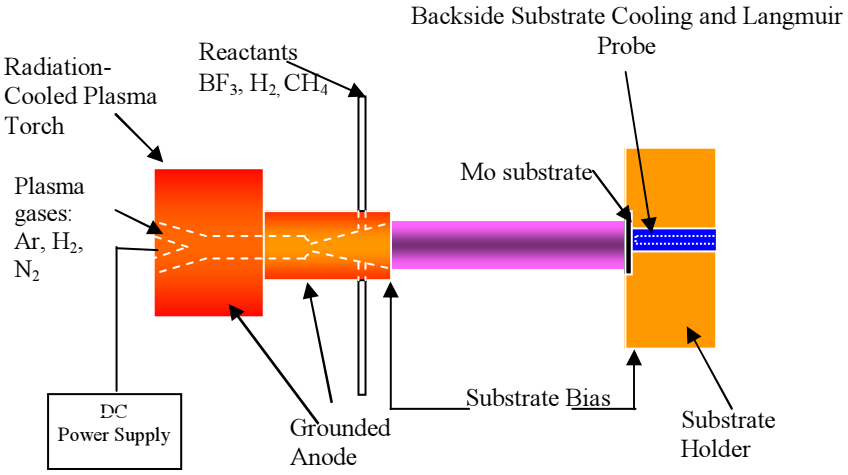

Figure 1: Schematic of the supersonic plasma jet deposition system

To enhance our understanding of the film deposition process in the SPJR we are using a Langmuir probe to measure the effects of deposition conditions such as torch power, plasma chemistry, and substrate bias on plasma parameters such as plasma potential, electron temperature, and electron density, which are assumed operative in the deposition of B-C-N materials. These measurements are carried out by inserting a 0.023-inch diameter tungsten wire through the back of the molybdenum substrate. The probe tip is flush with the substrate surface and insulated from the substrate by an alumina sleeve. The electrical circuit used to obtain probe characteristics is shown in Figure 2. A bias is applied to the probe with respect to the grounded torch anode and amplified by a Kepco bipolar power amplifier. The probe current is calculated by measuring the voltage drop across two resistors with two Lecroy differential amplifiers. The floating potential and ion saturation current, typically on the order of 100 microamps, are measured across R_2 with a resolution of 2 microamps. The retardation region and electron current, which may be measured up to 0.25 A with this circuit, are measured across R_1 with a resolution of 100 microamps. The diode configuration shown in Figure 2, adapted from [12], allows us to take both high and low resolution measurements simultaneously. Each current-voltage probe characteristic consists of one thousand points. Each of these points consists of the average current of one thousand voltage pulses at a given voltage obtained at a frequency of 59.96 Hz in order to filter out electrical noise from the torch power supply. Between each data point the probe is cleaned by applying one thousand pulses of the highest probe voltage for the given characteristic. All probe biasing and measurement is automated using National Instruments LabWindows software.

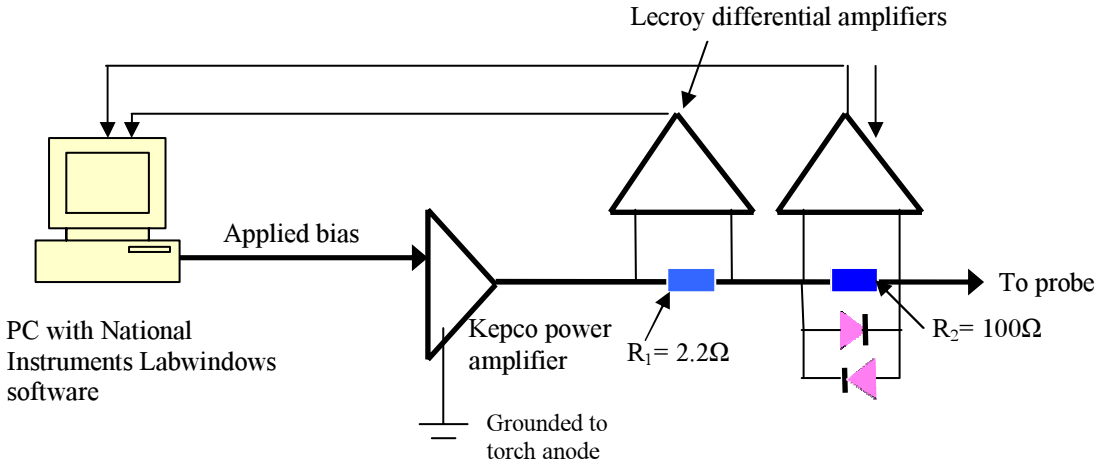

Figure 2: Schematic of electrical setup used for Langmuir probe measurements

Values of the plasma parameters of interest are obtained as follows. The floating potential is simply identified as the probe potential where no current flows between the probe and the plasma. The saturation ion current density for each condition is determined by taking the average current over the ion saturation region. The electron temperature is obtained, assuming a Maxwellian electron velocity distribution, from the electron retardation region of the probe characteristic using equation (1):

$$T_e = \frac{e}{k_B}\frac{1}{\tan\alpha} \tag{1}$$

where T_e is the electron temperature in Kelvin, e is the electron charge, k_B is Boltzmann's constant, and α is the slope of the natural log of the current density as a function of probe bias. This slope is corrected for the possibility of a non-constant ion saturation current by fitting the ion current with a polynomial and subtracting this from the current in the electron retardation region. The plasma ion density, assumed equal to the electron density, is calculated from the Bohm criterion shown in equation (2):

$$n_i = \frac{j_i}{e}\cdot\left(\frac{k_B T_e}{M}\right)^{-1/2} \tag{2}$$

where n_i is the ion density per cubic meter, j_i is the saturation ion current density, and M is the ion mass in kg. It should be noted that equation (2) assumes a collisionless sheath in front of the probe, or that the plasma Debye length is much smaller than the ion mean free path. Estimations of these parameters for the SPJR using the elastic collision momentum transfer cross-section [15] indicate that the mean free path for ion-neutral collisions in argon is approximately ten to fifteen times larger than the Debye length, indicating that the assumption of a collisionless sheath is reasonable.

3. Results and Discussion

Langmuir probe measurements have been completed in plasma compositions consisting of pure argon and argon with 0 to 30 sccm of hydrogen added through the reactant portion of the nozzle under various substrate biases and torch powers. Substrate bias as been varied from -15V to +15V with torch powers ranging from 1.6 to 3.3 kW. Parameter measurements from these conditions are presented in the following section.

3.1. Floating Potential Measurements

Considering the previously mentioned phenomenon that cBN deposition scales with the momentum transferred to the substrate and growing film by bombarding ions, as well as other results showing the enhancement of deposited film properties resulting from ion bombardment, determining how the degree of ion

bombardment is affected in the SPJR is quite important. One way to gain such insight is to measure the change in plasma potential as a function of various parameters. If we assume our probe does not thermionically emit electrons during measurement, it is reasonable to assume that changes in the plasma potential scale proportionally with changes in the floating potential. Figure 3 shows a plot of plasma floating potential as a function of the applied substrate bias in a pure argon plasma. The plotted points represent averages of three to five measurements at each bias condition while the error bars represent two standard deviations of the data. Conditions such as torch power and hydrogen addition had a negligible effect on the floating potential.

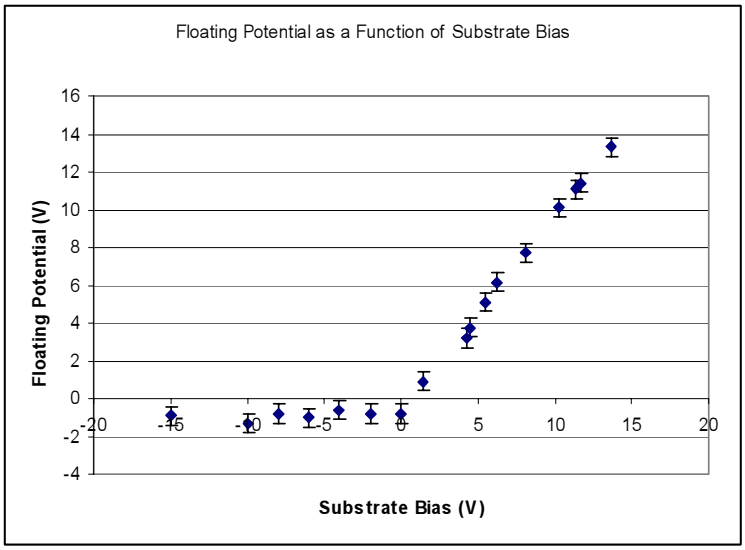

Figure 3: Plot of floating potential as a function of substrate bias

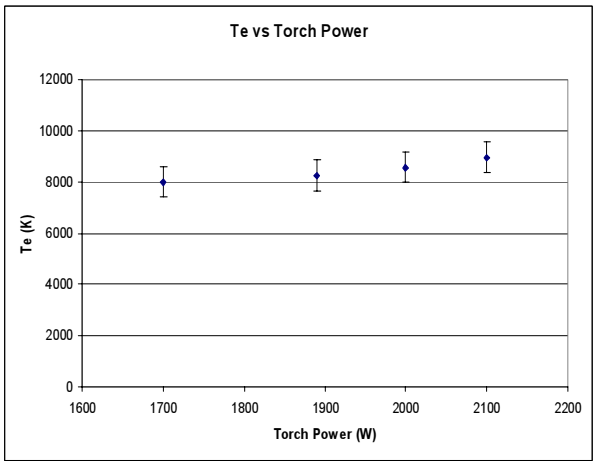
From Figure 3 it is evident that a negative substrate bias has little effect on the floating potential, while the floating potential increases linearly with positive substrate bias. Since negative substrate bias is the instrumental parameter in changing the degree of ion bombardment, the result presented in Figure 3 reveals that, since the plasma potential is assumed to remain relatively constant as a function of negative substrate bias, the bombarding ion energy is not affected by the plasma potential as negative bias is increased. Therefore, the bombarding ion energy scales with the ion mass and substrate bias, and effects of the plasma potential are negligible. This result is consistent with assumptions made by Berns et al [13] in estimating bombarding ion energy in cBN deposition via Monte Carlo simulations.

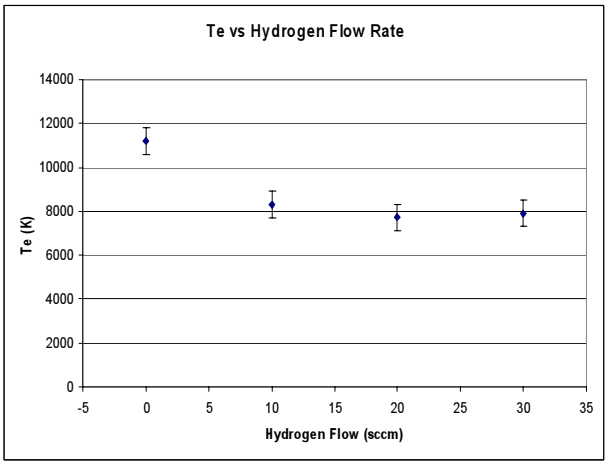
3.2. Electron Temperature Measurements

Electron temperatures were calculated using equation (1) for various conditions. Figure 4a shows a plot of electron temperature at different torch powers, showing a very slight increase in electron temperature with torch power. Figure 4b shows the electron temperature as a function of the hydrogen flow rate, showing a decrease in electron temperature with the introduction of 10 sccm of hydrogen to the plasma, and a much more modest decrease as hydrogen flow is increased further. These results are significant for film deposition if we consider that higher electron temperatures will affect the amounts of dissociated precursors in the plasma through promoting dissociation through bond-breaking collisions of free electrons with reactant species. Therefore, Figure 4a indicates that higher torch powers could promote slightly higher concentrations of dissociated precursors, while Figure 4b indicates addition of hydrogen may inhibit precursor dissociation. However, Figure 4b also indicates that the electron temperature decreases with addition of 10 sccm of hydrogen, but remains relatively constant with increasing amounts of added hydrogen. Substrate bias had a negligible effect on electron temperature.

3.3. Electron Density Measurements

Electron densities were calculated using equation (2) for various conditions as well. The measured electron densities as a function of substrate bias at three different torch powers in a pure argon plasma are shown in Figure 5. Figure 5 shows that the density increases





Figures 4a (left) and 4b (right): Measured electron temperatures as functions of torch power (4a) and hydrogen flow (4b)

most drastically with torch power, increasing by approximately 60% to 80% with a torch power increase from 1738 W to 2200 W at a given substrate bias. The density also increases with a positive substrate bias by approximately 30% at a given torch power. Addition of hydrogen decreased the density by approximately 30%, regardless of the amount of hydrogen added. These results are significant when considering the effects of ion bombardment in film deposition. According to the Bohm criterion, the flux of ions to the substrate follows the relationship in equation (3):

$$F_{ion} \alpha n_i \left(\frac{k_B T_e}{M} \right)^{1/2} \tag{3}$$

where F_{ion} is the ion flux to the substrate and n_i is the ion density at the sheath edge [10]. Therefore, if one considers the total amount of momentum transferred to the film from bombarding ions to be instrumental in cBN deposition, and important in B-C-N deposition, a higher ion flux is desirable. However, one must also consider that large degrees of compressive film stress, which limit attainable deposited film thickness, are a result of high degrees of momentum transfer due to ion bombardment [1]. With knowledge of these effects of ion density, the results shown in Figure 5 could allow one to select appropriate operating conditions with regard to the desired degree of ion bombardment.

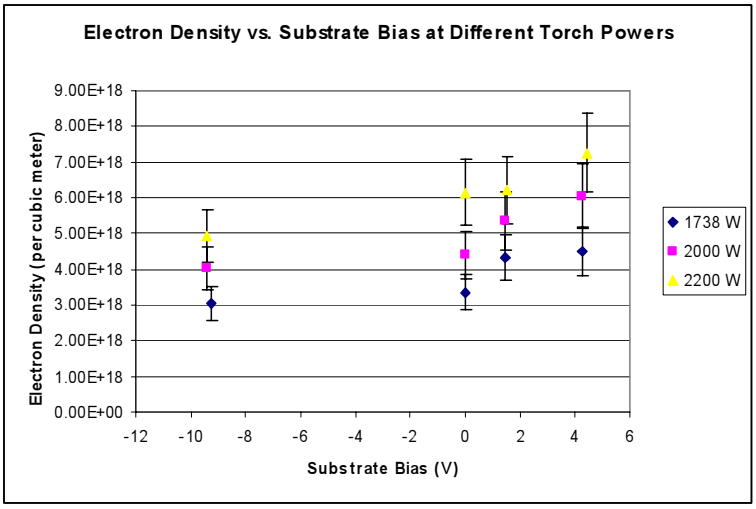


Figure 5: Measured electron /ion density as a function of substrate bias at 3 different torch powers

4. Conclusion

We have presented Langmuir probe measurements of plasma parameters under different conditions in the SPJR. These measurements have shown that the floating potential, assumed to scale with the plasma potential, is unaffected by a negative substrate bias and increases linearly with positive substrate bias, that electron temperature decreases slightly with increasing torch power and more drastically with addition of hydrogen, and that the ion/electron density increases with positive substrate bias, and more drastically with increasing torch power. These results are potentially useful in thin film deposition when one considers the importance of ion bombardment and potential for precursor dissociation. Work planned for the immediate future includes examining the effects of nitrogen and hydrogen incorporation as plasma gases on the parameters discussed above, as well as integrating optical emission spectroscopy measurements of precursor distribution in the plasma under different deposition conditions. Spectroscopic measurements of electron densities via Stark broadening will also be implemented. Ultimately, the data obtained from these plasma diagnostic techniques will enhance our understanding of the B-C-N film deposition process in the SPJR.

Spectral Emission of Ar_2^* in the 300 - 650 nm region: Effect of O_2 Addition

Abdulaziz Al-Jalal and Mohammad Aslam Khan

Department of Physics
King Fahd University of Petroleum and Minerals
Dhahran 31261, Saudi Arabia

Abstract

We have recently reported a significant enhancement in the atomization of O_2 in an Ar-O_2 glow discharge. During our investigations of energy transfer between Ar and O_2, we have observed a strong emission from Ar_2^* dimer in the 300-650 nm spectral region in pure Ar discharge. However, addition of a small amount of O_2 to Ar virtually wiped out this emission. This provides direct evidence of a strong channel of energy transfer between Ar and O_2 in a glow discharge under our experimental conditions.

1. Introduction

Atomic oxygen (O) is highly useful in many chemical and material processing applications [1]. However, production of a large number of O atoms for these applications in sources such as glow discharges has been difficult due to several reasons. On the other hand, the intriguing result of adding a small amount of O_2 in Ar discharge leading to a manifold increase in the creation of O atoms has attracted considerable interest in recent years [2,3,4].It is believed that the energy transfer between Ar and O_2 does not proceed in a simple collisional process. Instead, this involves formation of Ar_2* dimer followed by resonant collisional energy transfer to O_2, possibly through appropriate potential energy curve-crossings. These excited O_2 molecules subsequently dissociate into oxygen atoms.

The main collisional processes between O_2 and Ar atoms exited by energetic electrons in the discharge may be outlined as below.

$$e + Ar \rightarrow Ar^* + e \quad (1)$$

$$Ar^* + O_2 \rightarrow 2O + Ar \quad (2)$$

$$Ar^* + Ar^* \rightarrow Ar_2^* \quad (3)$$

$$2Ar^* + O_2 \rightarrow 2O + 2Ar \quad (4)$$

Spectral emissions attributed to Ar_2* dimer in a pure Ar gas discharge have been reported in several spectral regions below 250 nm [5,6,7]. In particular, strong emission bands were reported in the regions around 130, 155 190, and 213 nm. In some studies, production of highly excited Ar_2 states was monitored indirectly by recording peak intensity of Ar lines at 811.5 and 810.4 nm assuming that these states are partly a result of predissociation of Ar_2*[8].

We have observed a considerably strong emission in the spectral region 300-650 nm from a pure Ar glow discharge that is attributed to Ar_2* dimer spectra. To the best of our information, this is the first observation of spectral emission from Ar_2* in this region. More importantly, however, we observed that the addition of a small amount of O_2 to Ar virtually wiped out this emission. This is in line with the report of Moselhy et. Al. [4] and provides further evidence of energy transfer between Ar and O_2 in a glow discharge.

2.Experimental detail

We used a DC glow discharge to study the energy transfer between Ar and O_2 at low pressures, up to a few mbar.

The experimental set up has been described in a previous paper [2]. Briefly, it consisted of a cross-shaped discharge cell with an adjustable gap between the electrodes. The light emitted by the discharge could be collected through one of the two side ports of the cell for the purpose of monitoring and analysis. The cell was first evacuated to pressures of the order of 10^{-3} mbar and then filled to the appropriate pressure of O_2 or Ar-O_2 gas mixture under carefully controlled conditions. A constant current mode of the discharge was used with 150 mA current.

The population densities of O atoms were monitored through spectrally resolved light emitted by the discharge using a scanning monochromator coupled to a thermoelectrically cooled photomultiplier. A compudrive unit provided precise scanning of the monochromator in the selected wavelength region. The signal from the photomultiplier was transferred to a boxcar averager and signal processing system linked to a PC.

Two modes of data acquisition were used. In the wavelength scanning mode, emission in the 250-850 nm region was recorded. Typical scan times were 15 minutes. On the other hand, for the time evolution of different atomic and molecular species present in the discharge, spectral emission on a particular wavelength belonging to a particular species was recorded as a function of time.

3.Results and discussion

Our main interest was in maximizing the atomization of O_2 in low pressure glow discharges where the main control parameters are gas pressure, gas composition, and discharge current.

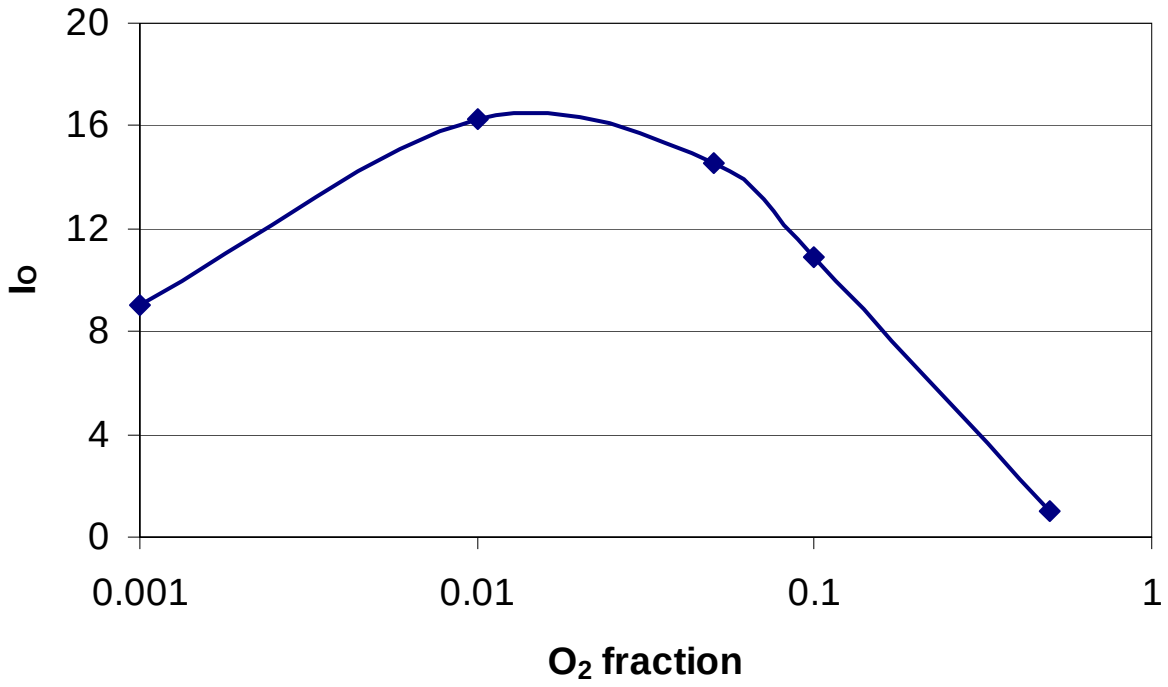

Figure 1. O atom yield as a function of O_2 fraction in Ar-O_2 mixture.

We carried out a detailed study of the effect of gas composition in the Ar-O_2 gas mixture on the overall yield of O atoms. Figure 1 shows a large enhancement of O atoms as seen from the spectral emission on 777.4 nm

transition (3s ^{5}S – 3p ^{5}P) of O atoms in the Ar-O_2 gas mixtures as a function of O_2 fraction. The total pressure was 0.5 mbar.

We note that with a decreasing fraction of O_2 in the mixture, the atomization increases significantly. In particular, for O_2 component around 1 %, the number of O atoms increases manifolds. However, below 1% O_2, the O atom yield decreases, understandably due to a smaller number of available O_2 molecules.

We investigated possible channels of energy transfer between excited Ar atoms and O_2 molecules leading to enhanced O atom yields by comparing the intensities of Ar transitions at 750.4, 715.4, and 763.5 nm with the 777.4 nm transition of O atoms. Figure 2 shows the behavior of intensity ratios as a function of O_2 fraction.

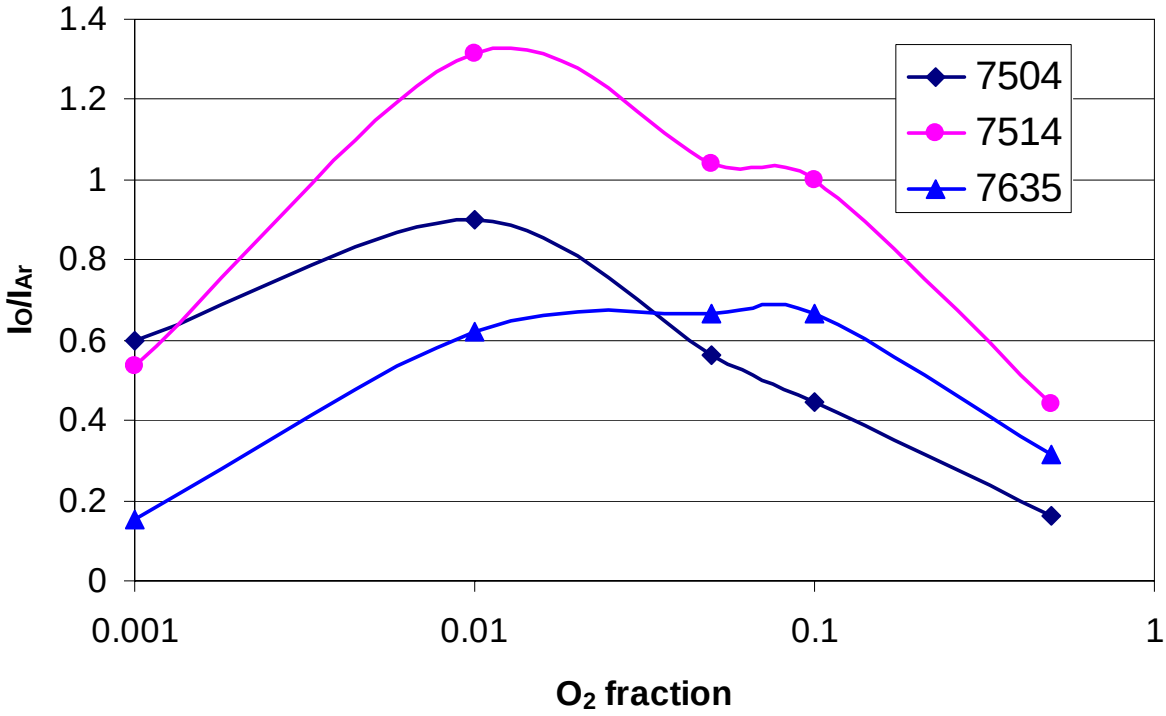

Figure 2. Line intensity ratios of O atom transition at 777.4 nm and Ar transitions at 750.4, 751.4, and 763.5 nm as a function of O_2 fraction in Ar-O_2 gas mixtures.

Apparently there is a maximum around 1% O_2 component. However, this alone can not explain the large enhancement in atomization of O_2.

We tried to explore other possible channels of energy transfer between Ar and O_2. For this, we recorded the spectra covering the range 250-850 nm. We investigated emission from pure Ar, pure O_2 and Ar-O_2 gas mixtures. An important observation is a strong continuum emission in the spectrum of Ar in the 350-650 nm region. More interesting, however, is the fact that this continuum totally disappeared when O_2 was added to Ar. Figure 3 compares the spectra in the three cases.

Several recent reports have suggested the presence of Ar_2^* dimer in the gas discharges containing Ar [5-8]. However, no reports of emission from Ar_2^* in the above-noted region have so far appeared. The total disappearance of Ar emission accompanied by a large enhancement in O atom yields is a strong evidence of energy transfer between Ar_2^* dimer and O_2 molecule.

To further investigate the continuum emission from Ar_2^* dimers, we investigated the spectral emission as a function of O_2 fraction for a constant total pressure of 0.5 mbar. We observed that the continuum emission decreases in intensity with increasing fraction of O_2, and completely disappears when the O_2 fraction reaches about 10% as in Figure 4. This is consistent with our understanding that a reasonable number of O_2 molecules are needed to affect the energy transfer.

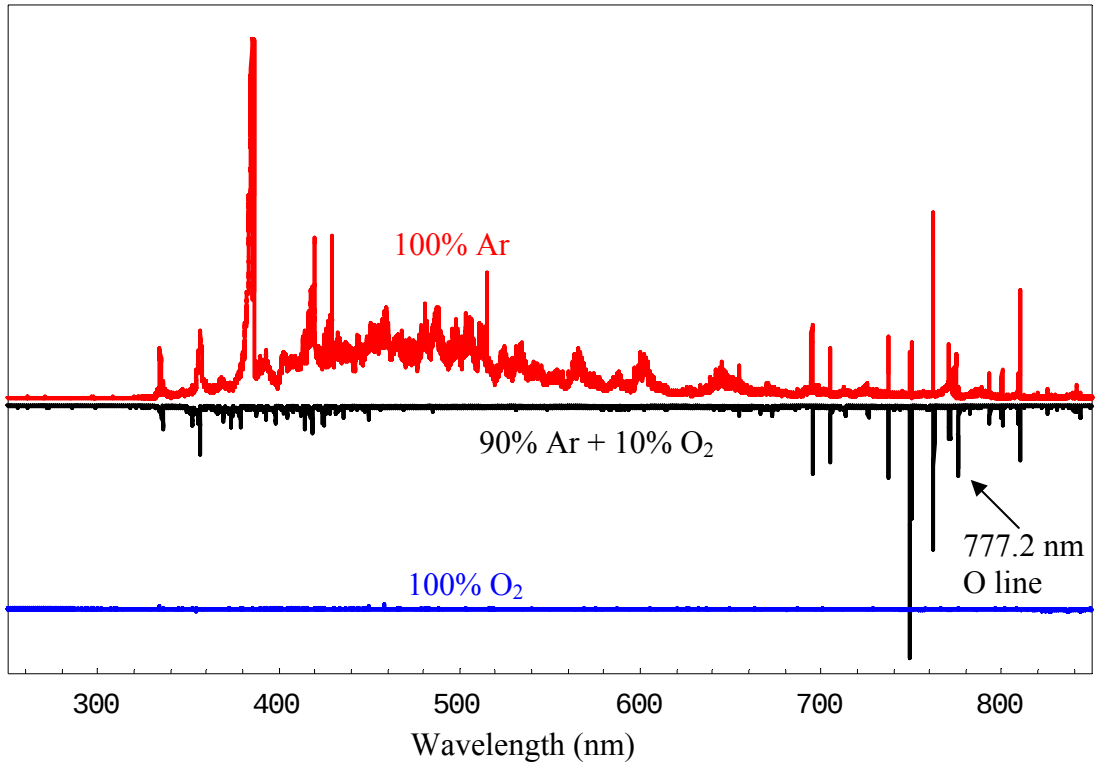

Fig. 3. Spectral emission from glow discharges in pure Ar, Ar+O_2 (9:1), and pure O_2 under identical pressures of 0.5 mbar and 100 mA discharge current. The spectrum of Ar+O_2 mixture is inverted and shifted to facilitate visual comparison. The spectrum of pure O_2 is also shifted downwards and shows weak emission. The intensity scale is the same for the three cases.

4.Conclusion

We have recorded a strong emission in the 300-650 nm spectral region from Ar_2^* dimers in glow discharges in Ar. Interestingly, addition of O_2 to Ar virtually wiped out this emission. This suggests that the formation Ar_2^* in an Ar discharge plays a critical rule in the energy transfer between Ar and O_2 leading to large enhancement in O atoms yields.

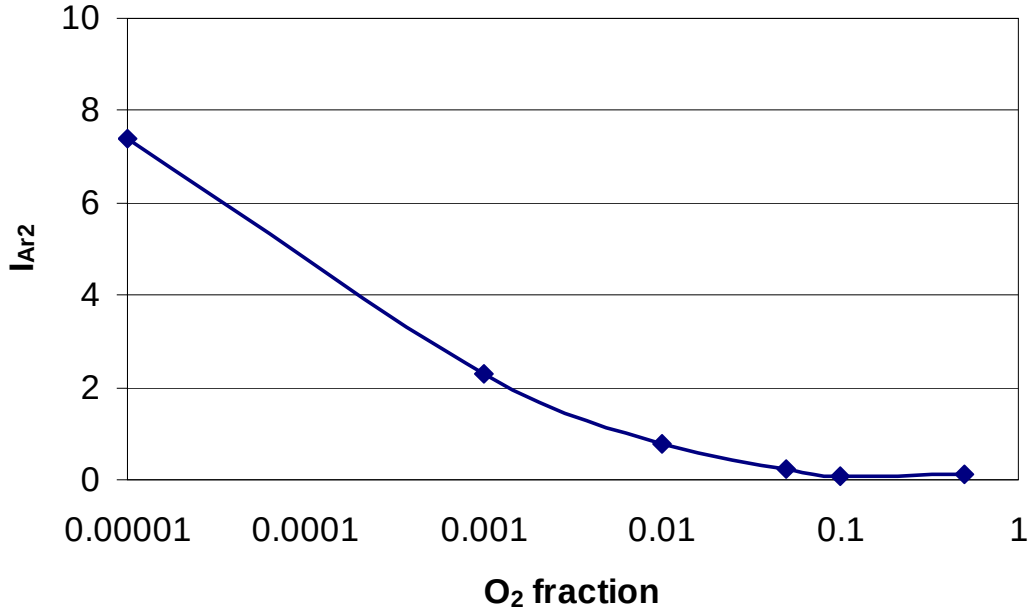

Figure 4. Variation of Ar_2^* continuum intensity as a function of O_2 fraction in Ar-O_2 gas mixture.

Abstract
RF magnetron sputtering, sputtering induced evaporation, and thermal evaporation of polyimide with and without simultaneous activation by glow discharge were studied. Deposition rate in the case of evaporation is an order(s) of magnitude faster than in sputtering. Evaporated films are similar in chemical composition to the orginal material. Application of glow discharge results in formation of cross-linked plasma polymers.

Keywords: evaporation, polyimide, plasma polymers

1. Introduction

Thin polymeric films can be deposited by several methods utilizing bulk polymer as the source of material. In particular, RF magnetron sputtering can be used for preparation of films from a broad range of conventional polymers [1-4]. However, the molecular structure of such films usually does not match well the molecular structure of the source bulk polymer due to inevitable fragmentation and crosslinking of the target material. If vapours of melted polymer are used for physical-vapour deposition [5] a resulting film has more similar molecular structure. However, such films are composed of low molecular weight fragments and often reveal poor adhesion and mechanical properties.
Both methods can be combined either by inducing evaporation of a polymer or its precursors by heating from plasma [6, 7] or by activating the vapours of the heated polymer with independently generated plasma [8]. The study is focused on studying these processes on polyimide.

2. Experimental

Polyimide sheet 1 mm thick was used as a source material (Fig. 1, Cirlex CL-HN, Goodfellow, pyromellitic dianhydride – oxydianiline (PMDA-ODA) type) for both sputtering and evaporation experiments.

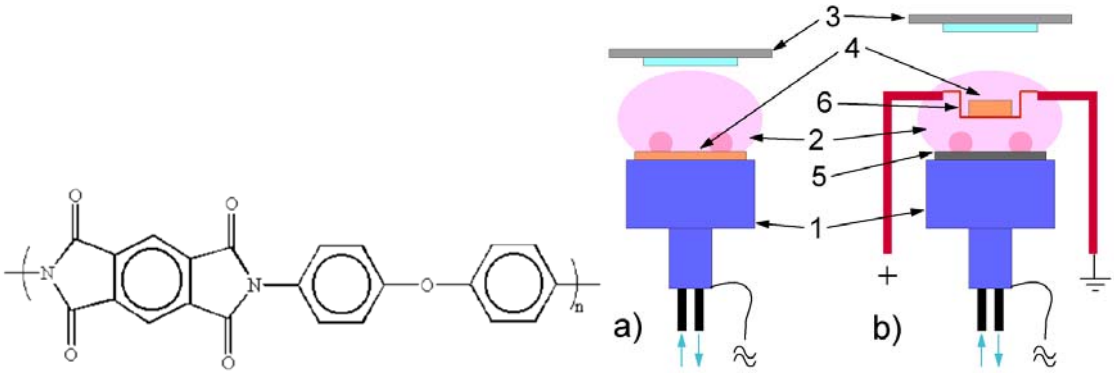

Fig. 1 Chemical formula of polyimide and the scheme of the experimental setup.a) RF magnetron sputtering b) evaporation with activation by plasma (1 - water-cooled magnetron, 2 - plasma, 3 - substrate, 4 - polyimide, 5 - graphite, 6 - heating boat)

In the case of RF (13.56MHz) magnetron sputtering (Fig.1a), a steel bell-jar reactor was used (volume 50 l, diameter 40 cm, pumped by a diffusion pump with liquid nutrogen trap backed by oil rotary pump, base pressure $<10^{-3}$ Pa). Sputtering was performed using a planar magnetron with 80 mm diameter. Substrates

were placed 4 cm above the magnetron. Argon was used as a working gas (pressure 2 Pa, flow rate 8.5 cm^3(STP)/min).
In the case of polyimide evaporation (Fig. 1b), another steel bell-jar chamber was utilized (volume 50 l, diameter 30 cm, pumped by the diffusion pump backed by oil rotary pump, base pressure 1×10^{-3} Pa). A planar magnetron covered by 5 mm thick graphite target was used as a plasma source. Graphite known for the low sputtering yield was chosen to minimize the contribution from sputtering to evaporation process. Argon pressure 0.5 Pa and flow rate 33 cm^3(STP)/min were used in this case. Polyimide was heated in a molybdenum heating boat, which was mounted 4 cm above the magnetron and 11 cm below the substrates. The temperature of the heating boat and substrates was measured by a thermocouple. It was found that during the deposition the temperature of samples was only slightly higher than the room temperature. Approximately 100 mg of polyimide was placed into the heating boat before each experiment.
Volatile species were monitored by means of neutral species mass spectroscopy (Hiden HAL 301 RC) and optical emission spectroscopy (Acton Research SpectraPro 300i). The deposition rate was measured by 5 MHz quartz-crystal microbalance sensor.
Glass, silicon and silver-coated glass were used as substrates. Deposited films were characterised by means of Fourier-transform infrared spectroscopy (Bruker Equinox 55) in reflection-absorption arrangement (FTIR-RAS), both in- and ex-situ. AFM topography (Quesant Q-Scope 850) and water contact angle measurements were performed to characterize surface of prepared films.

3. Results and discussion

a) RF magnetron sputtering

The initial stages of sputtering are characterized by an increase of deposition rate (Fig. 2). This is typical for polymer sputtering processes. At extended times of sputtering with lower powers (<40 W) deposition rate slightly decreases to reach a constant value. However, the sputtering at 75 W leads to drastic increase of the deposition rate. We attribute this effect to sublimation of lower molecular weight polymeric chains. The polyimide target rests on the water-cooled electrode, but because of poor thermal conductivity of the polymer surface exposed to plasma is at elevated temperature. When a certain plasma power is applied the local surface temperature in the erosion zone can reach the values sufficient for thermal degradation of polymeric chains and emitting of lower molecular weight fragments. Hence, both sputtered and evaporated fragments of the target material can contribute to the deposition process. In the particular system used, the effect started at magnetron power about 75W with the deposition rate reaching 30 nm/min after 15 minutes of discharge operation (compare with 2-5 nm/min without evaporation).

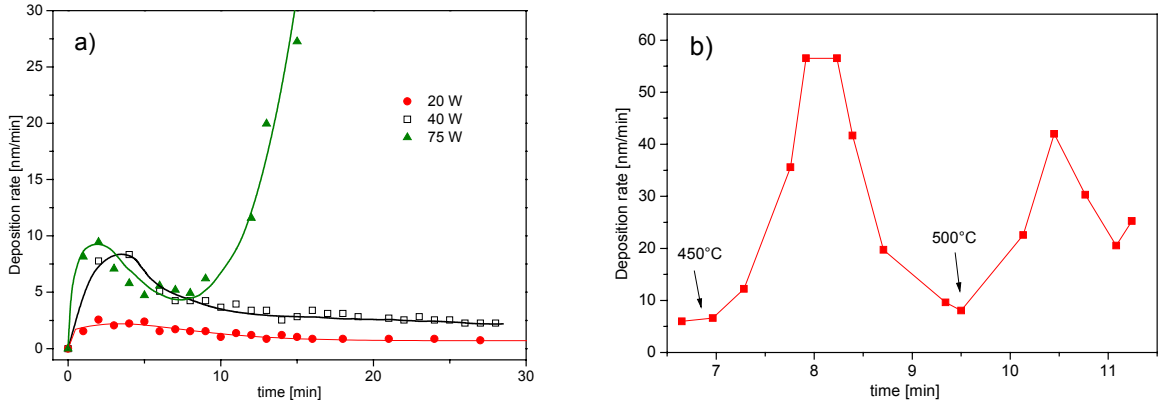

Fig. 2 Time dependence of the deposition rate. a) RF magnetron sputtering with various magnetron powers b) evaporation with activation by plasma.

The effect of sputtering with co-evaporation was observed also by mass spectroscopy (Fig. 3a) and optical emission spectroscopy of the plasma. At low power, weak signal of water trapped in the target and the fragments of polyimide molecule ($C_{1\text{-}3}H_x$, CN and especially CO) were detected. The onset of evaporation is visible as a significant increase of the mentioned polyimide fragments signal. The CO proved to be an

especially good indicator, since it is detected both by mass spectroscopy and optical emission spectroscopy and partly by in-situ FTIR.

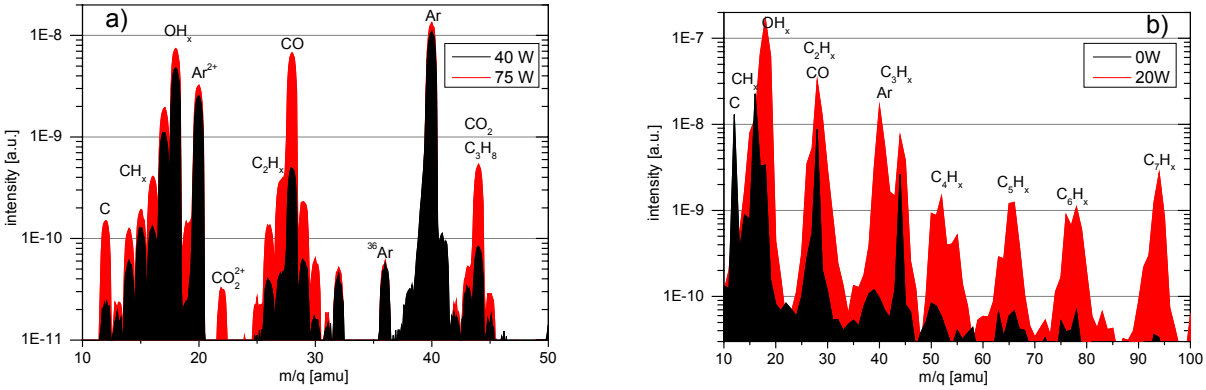

Fig. 3 Neutral species mass spectra. a) RF magnetron sputtering b) evaporation with activation by plasma, spectrum obtained without plasma was without Ar as well.

Only limited structural information can be obtained from the infrared spectra of films prepared by RF magnetron sputtering (Fig. 4). Broad peak centered near 3350 cm^{-1} can be assigned to the OH and NH stretching vibrations. Peak at 3000-2800 cm^{-1} shows aliphatic CH_2 and CH_3 groups stretching vibrations. The C≡C and C≡N stretching vibrations are present around 2200 cm^{-1}. The peak at 1700 cm^{-1} can be assigned to C=O stretching vibrations with some contribution of C=C and C=N stretching vibrations (1650 cm^{-1}). The peaks at 1450 cm^{-1} and 1375cm^{-1} are attributed to absorbtion of the CH_2 and CH_3 groups (deformation vibrations). In general, no signs of aromatic structures are present. Structure of the film is probably highly disordered and cross-linked, what is a typical feature of plasma polymers. With increasing power an increase in the NH/OH peak to aliphatic CH peaks ratio can be observed, the amount of triple bonds decreases and amount of C=O bonds increases.
AFM topography gives roughness of the films about 1-3 nm and water contact angle is 40°-55°.

b) plasma polymerized vapour deposition
When heated, polyimide started to emit volatile species at the temperature around 450°C. Polyimide was sublimating in a step-like manner without going through a liquid state. At a particular temperature only a part of the source material was transferred to the gas phase. The deposition almost stopped unless the temperature was raised again (Fig. 2b). The evaporation process was effective up to approximately 650°C. By this point, an extreme degradation of polymer chains probably occured. During evaporation, the peak deposition rate reached almost 60nm/min regardless with or without the plasma. However, due to surface decompostion of the material at higher temperatures (which probably prevents evaporation from the bulk of the sample), utilization of polyimide was never complete. Approximately 70-80 wt.% of partly decomposed polyimide remained in the heating boat. The material consumption increased to 40% by grinding the source material prior to experiment.
Evaporation of the material was clearly observable in the mass spectra (Fig. 3b). The start of the heating is characterized by increase of intensity of the species with m/q 17-19 (the spectrum not shown), which is attributed to trapped water emerging from the material. As the evaporation temperature is reached the hydrocarbon fragments appear. Most of them can be assigned to various C_xH_y species. Another visible specie is CO. During evaporation without a discharge the signal was rather weak. On the contrary, it increased considerably when the discharge was applied. This can be probably explained by the fragmentation effect of the discharge. As expected, during evaporation various fragments with a wide distribution of molecular weights are emitted from polyimide. The maximal mass detectable by the spectrometer used was 300 amu and its sensitivity to masses beyond 100 was low. The discharge can fragment higher molecular weight fragments (not detectable in our case) to lighter species, which are within the detection limit of the spectrometer. Such fragments as CO and CN were detected in the plasma by optical emission spectroscopy.
The infrared spectrum of the film deposited without discharge is remarkably similar regarding the positions of individual peaks to those reported for polyimide prepared by solution formation [9], vapor deposition

polymerization [10], cluster beam deposition [11] and by glow discharge vapor deposition polymerization [12]. The region below 1800 cm^{-1} is of major importance because the imide structure absorbs here: 1780 and 1730 cm^{-1} bands belong to imide C=O symmetric and asymmetric stretching, and imide C-N stretches at 1380 cm^{-1}. Furthermore, the aromatic ring exhibits stretching vibrations at 1500 cm^{-1} and deformation vibrations at 1120 and 830 cm^{-1}. The peak at 1240 cm^{-1} is assigned to aromatic ether stretching [12]. A broad band at the wavelengths higher 3000 cm^{-1} is attributed to OH and NH stretching vibrations. A lack of significant peaks at 3000-2800 cm^{-1} indicates a deficiency in aliphatic CH_2 and CH_3 groups stretching vibrations. However, at lower discharge powers some CH on double or aromatic bond stretching vibrations are present around 3050 cm^{-1}. This reflects well the structure of the source molecule.

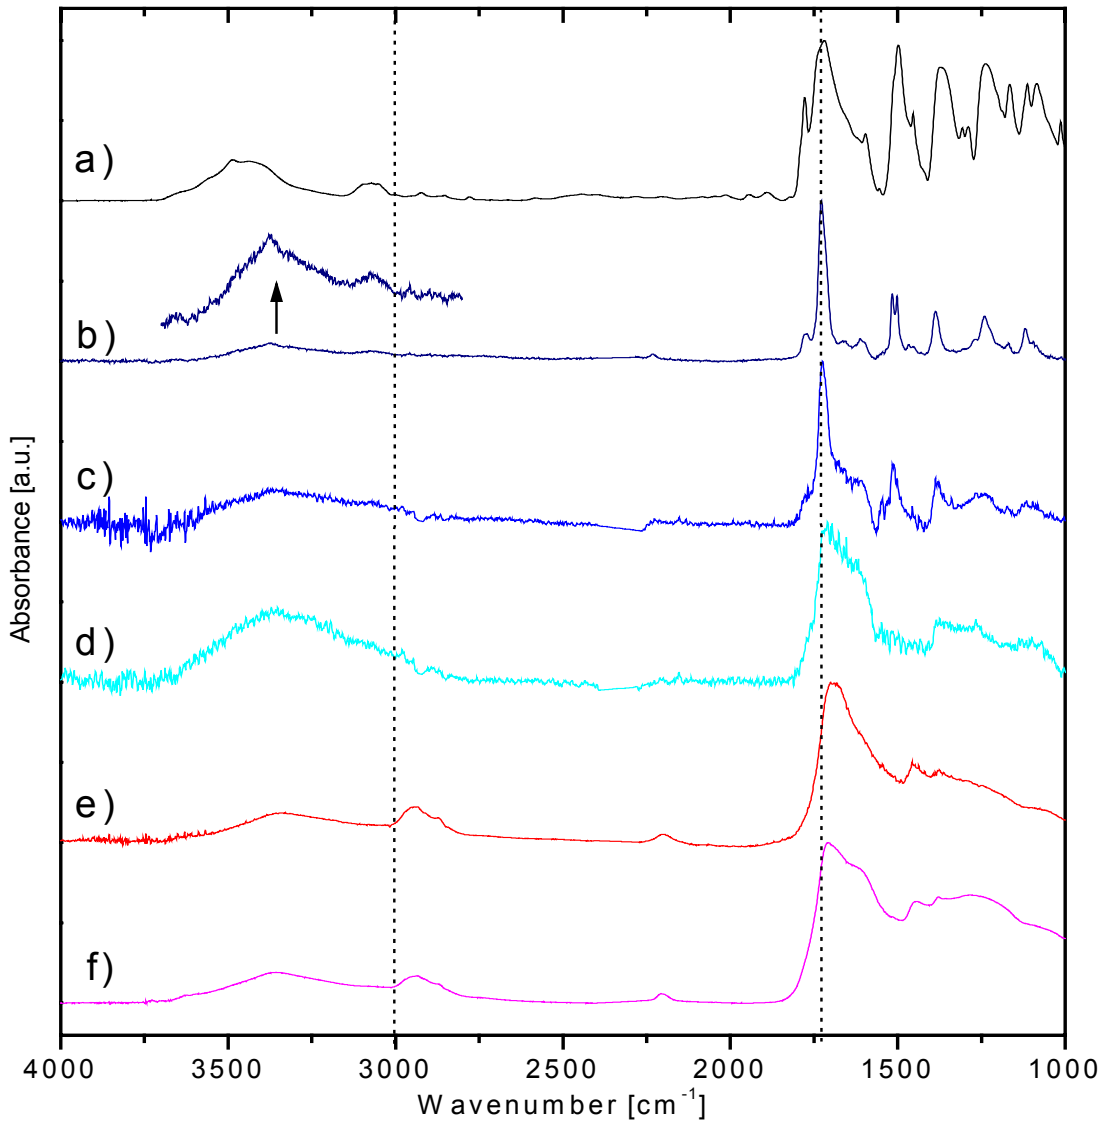

Fig. 4 Infrared spectra of source and deposited material. Spectra are normalised on the highest peak.
a) source material (powder form)
b) evaporation without plasma (part of the spectra magnified in intensity for clarity)
c) evaporation with activation by plasma (magnetron power 40W)
d) evaporation with activation by plasma (magnetron power 160W)
e) RF magnetron sputtering (magnetron power 20W)
f) RF magnetron sputtering induced evaporation (magnetron power 75W).

For the deposition with the discharge, the structure of the fingerprint region becomes less distinct with increasing power. The individual peaks degrade in intensity and broaden into the wide bands. The C=O peak at 1730 cm^{-1} remains dominating. However, it shows a developing shoulder at 1620 cm^{-1}, which is attributed to the contribution from various C=C and C=N species. Stretching of C=O bound in amide structure may also contribute to the shoulder and this is consistent with a considerable increase of the NH_x peak at 3400 cm^{-1}. At 160W power, the spectrum becomes unresolved and more similar to the films prepared by the magnetron sputtering. The mentioned changes of FTIR spectra suggest that the application of plasma leads to the loss of imide and aromatic structures and to the formation of cross-linked plasma polymer.
AFM shows rather flat surface of the films (roughness several angstrom at 1 micron scan size). Water contact angle decreases from 82° without plasma to 53° at 80W power with a small increase at higher powers.

4. Conclusions

Polyimide starts to thermally emit volatile species during RF magnetron sputtering at higher powers applied. This leads to significant increase of the deposition rate and changes in the plasma and film composition. One of the most important specie in the discharge is CO fragment of the polyimide molecule.
When polyimide is heated sufficiently the vapour phase produced by emitted fragments can be used as a working medium for plasma polymerization. In this case, the high deposition rate is achieved, although the deposition is limited in duration. The films deposited without plasma are similar in chemical composition to the original material. Plasma polymerization induces some fragmentation and crosslinking within the film structure. At high discharge powers such films are similar to plasma polymers prepared by RF magnetron sputtering.

Abstract

Continuous and modulated discharges fed with divyniltetramethyldisiloxane (DVTMDSO) and allyltrimethylsilane (ATMS) mixed with oxygen and argon carrier gas, were used to deposit ultralow-*k* films. The effect of various process parameters on the dielectric constant of films as well as on their chemical composition were investigated. For both monomers, lowering the oxygen content in the discharge allowed for a continuous decrease in *k* values down to 2.3 for DVTMDSO and 2.2 for ATMS.

1. Introduction

Enhancements in integrated circuit performance over the past four decades stem mainly from the periodic scaling down of device features, however interconnect cross-talk (RC delay) limits performance as feature sizes are reduced below 1 micron. Efforts to minimize delay through new materials introductions are well underway. With respect to wire materials, the migration from Al to Cu metallization reduced line resistance by ~30% and it is expected to remain the interconnect of choice for the near future. Further reduction of RC delay can also be achieved with low-permittivity dielectrics [1].

Intense research efforts have focused on developing inorganic and organic low-*k* materials that meet the stringent requirements for successful integration, but few exhibit the proper combination of low-permittivity plus thermal, chemical and mechanical stability. Current estimates suggest that ultralow-*k* dielectrics with *k*=2.1-2.4 will be needed for 2007-2012 [2]. To achieve *k* values below 2.5 in the next generation of dielectrics, pores must be introduced into the network, as air, with *k*~1, reduces the total dielectric constant in accordance with Lichtenecker`s law of mixed dielectric materials. Two synthetic approaches have emerged as the likely candidates for the first generation of porous dielectrics; spin-on and PECVD [1]. Porous spin-on dielectrics are typically prepared by spin coating the substrate material with a dual phase gel/porogen mixture which is annealed to give a rigid glass-like matrix. Annealing at higher temperatures removes the labile porogen phase, leaving pores within the organosilicate glass (OSG) matrix. While this strategy to produce low-*k* dielectrics has made extraordinary progress, commercialization has been slowed because of integration issues as well as the additional cost of new equipment.

Over the next decade PECVD solutions are preferable because they have shorter integration cycles and don't require new equipment. PECVD methods for depositing porous OSG have only recently become available. Basically, two approaches for the synthesis of porous dielectrics are currently under investigation: (1) codeposition of a porogen and an organosilane or organosiloxane precursor [3, 4], (2) deposition of an organosilane or organosiloxane precursor with a labile side-group [5]. In both cases, an annealing step is then required to generate pores. It is still unclear whether the pore formation mechanism is driven by –OH group elimination, through condensation reactions, or by C_xH_y loss.

In this contribution we report our latest results on the deposition of ultralow-*k* films from continuous and pulsed glow discharges fed with divyniltetramethyldisiloxane (DVTMDSO) and allyltrimethylsilane (ATMS) mixed with oxygen and argon carrier gas. The effect of process

parameters such as feed mixture composition and RF input power onto dielectric constant and chemical composition of films are reported.

2. Experimental

Organosilicate films were deposited using a capacitively coupled parallel plate reactor. The upper electrode is driven by a 13.56 MHz power supply (RF POWER PRODUCTS, model RF5). Impedance matching was accomplished with a LC network. The lower electrode was grounded and can be heated up to 600 °C through a heating element. RF input power can be modulated by a pulse generator implemented into the RF generator. An oscilloscope (TEKTRONIX, model TDS 200) was used to check pulse duration and amplitude. The flow rates of the gases (O_2, Ar) and of the monomer vapor (DVTMDSO, ATMS) were controlled by MKS flow meters, and the pressure was monitored with a MKS capacitive gauge. The reactor was pumped by a turbomolecular and a rotary pump. For continuous mode deposition, the discharges were sustained at various feed mixture compositions and power values, keeping constant all the other process parameters. Finally, the effect of modulating the RF power, by changing the duty cycle (DC) at a fixed period (T=320 ms), was evaluated on the discharge leading to the film with the lowest *k*. Table I summarizes the deposition parameters.

Table I: Experimental Conditions

Process Parameters	
Monomer	DVTMDSO, ATMS
RF Power	30-100 W
Pressure	750 mTorr
O_2 flow rate	0-16 sccm
Ar flow rate	270 sccm
Monomer flow rate	3 sccm
Deposition temperature	150 °C
Annealing temperature	400 °C

Films were deposited at 150 °C and then annealed in vacuum at 400 °C for 30 min. Dielectric constants of films were determined before and after annealing using a mercury probe (MDC). For dielectric measurements films were deposited onto *n*-type Si (100). Film chemical composition was investigated through FT-IR and X-ray photoelectron spectroscopy (XPS). FT-IR spectra were recorded using a Bruker Equinox 55 spectrometer at 4 cm^{-1} resolution. In order to minimize effects of water vapor and carbon dioxide, the spectrometer was purged with nitrogen for 15 min between each measurement. XPS spectra were acquired with a PHI ESCA 5300 with a non-monochromatic Mg K_α radiation (1253.6 eV).

3. Results and discussion

Figure 1 shows the trends of the dielectric constants, before and after annealing, for films deposited from continuous plasmas fed with mixtures of Ar, DVTMDSO and increasing amounts of O_2. The effect of varying the RF power delivered to the discharge is also reported. Data clearly show that the annealing is always responsible for a decreasing in the dielectric constant values and this effect becomes more pronounced as RF power gets lower. Lowering the oxygen flow rate in the feed allows for a continuous decrease in *k* values. Finally, for both as deposited and annealed films, higher RF power inputs lead to higher dielectric constant. All results for ATMS are similar to those presented for DVTMDSO, unless specified otherwise. For the sets of conditions investigated, the lowest *k* values after annealing at 400 °C, are 2.3 for DVTMDSO and 2.2 for ATMS.

Another key consideration is the reduction in film thickness upon annealing. Figure 2 shows the loss in thickness as a function of oxygen flow rate, at various RF powers. At 30 and 60 W the decay of the thickness loss is nearly exponential with oxygen flow rate, while it is pretty reduced

when 100 W is considered. The lowest dielectric constant of 2.3 for DVTMDSO corresponds to a shrinkage of 11%. The best result for ATMS is accomplished by adding a very small amount of oxygen to the discharge which yields films with a shrinkage of 10%.

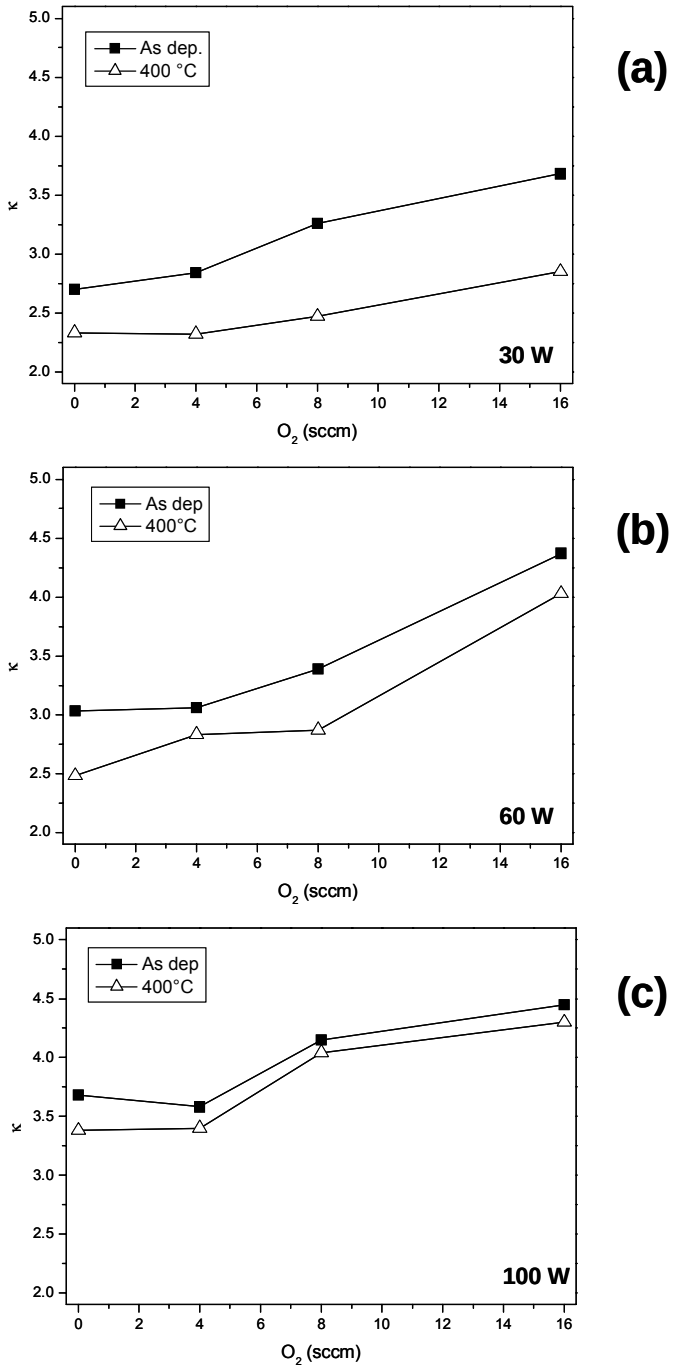

Figure 1: Trends of dielectric constants for films deposited from DVTDSO as a function of oxygen flow rate in the gas feed, at different RF powers: (a) 30 W, (b) 60 W, (c) 100 W.

In order to understand if a less extent in monomer fragmentation could allow for a further reduction in *k* values, modulation of RF input power was introduced in the discharge resulting in the films with the lowest dielectric constant. In this set of experiments , the duty cycle was varied in the range 10-60% while keeping the period fixed at 320 ms. Neither film electrical properties nor shrinkages improve by using pulsed plasmas.

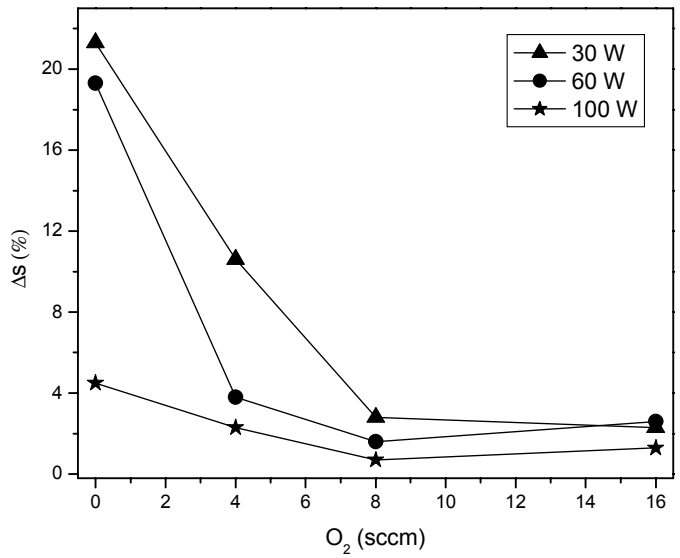

Figure 2: Loss in thickness during annealing as a function of the oxygen flow rate in the gas feed, at three RF powers.

Figure 3 shows normalized FT-IR spectra of films deposited from DVTMDSO/Ar/O_2 with the lowest and highest dielectric constant to highlight major differences in chemical composition of the films. Switching from the discharge sustained at 30 W and 4 sccm of oxygen content in the feed to the one at 100 W and 16 sccm of oxygen, an organic to inorganic crossover in deposited films is observed.

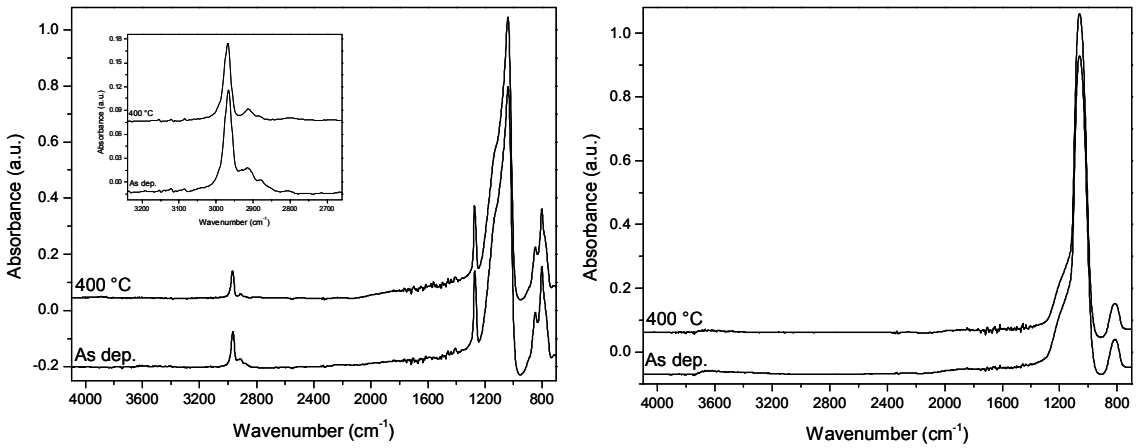

Figure 3. FT-IR spectra of films deposited from DVTMDSO with very different k values after annealing. (a) k= 2.3, (b) k= 4.3. The inset in figure 3(a) shows the change in CH_x absorption after annealing.

The spectra in figure 3b display the absorption bands typical of SiO_2 network: stretching and bending at about1060 and 800 cm-^{1}, respectively and a weak absorption band at 3650 cm^{-1} due to isolated SiOH groups. As oxygen flow rate is reduced and the RF power is decreased from 100 to 30 W, some carbon related bands appear: the CH symmetric and asymmetric stretching in CH_x (x=1-3) around 2915 and 2970 cm^{-1}. Moreover the absorption due to $SiCH_3$ is observed at 1275 cm^{-1}. The

band around 800 cm-1 in this case can be assigned to $Si(CH_3)_2$ and $Si(CH_3)_3$, overlapping the one due to SiO bending mode. The marked organic content of this films leads to a shift of the most intense band from 1060 cm^{-1} to 1037 cm^{-1}. Spectra of figure 3b does not reveal any change upon annealing while the one in figure 3a basically shows a reduction in CH_x and $SiCH_3$ absorptions. Thus, the larger reduction in the k value of this film is correlated to the loss of CH_x fragments. The latter may lead, in turn, to a rearrangement of the network resulting in the formation of nanopores in the films, as suggested by other researchers [4-5].

4. Conclusions

Low-k films were deposited from continuous and modulated discharges using DVTMDSO and ATMS as precursors, in mixture with Ar and variable oxygen flow rate. The effect of varying RF power delivered to the discharge was also evaluated. Results presented so far can be summarized as follows.

For both monomers, lowering the oxygen content in the discharge allowed for a continuous decrease in *k* values down to 2.3 for DVTMDSO and 2.2 for ATMS. The corresponding reduction in film thickness upon annealing are 11% and 10%, respectively. Comparison of FT-IR spectra before and after annealing for these samples clearly revealed a reduction in the CH absorption upon annealing. The reduction in carbon content was confirmed quantitatively by XPS analysis. Lowest dielectric constants are achieved by introduction of porosity in the films through the removal of organic fragments upon annealing. Finally, no further improvement was observed by using pulsed plasmas.

Abstract

Surfaces containing nanofeatures have become recently of paramount importance in many areas of the modern Material Science, for very diverse applications. Recent advances in biomedical materials and biomaterials engineering, for example, have shown the possibility to use random and geometrically micro- and nano-patterned surfaces as effective tools to address specific interactions between cells (and/or proteins) and materials to be applied in fundamental and applied studies on cell physiology, cell engineering, tissue engineering, micro-fluidic systems, bioreactors, bioMicroElectroMechanical Systems (bio-MEMS), and sensors.

This contribution will provide an overview of various methodologies to modify surfaces at micro- and nano-metric scale in which RF (13.56MHz) Glow Discharges are involved. In particular, the attention will be focused on two aspects of this matter, which are under scrutiny in our laboratory for different projects, namely: nanopatterning procedures and synthesis of nanocomposite coatings.

Different lithographic methods, including colloidal lithography and soft lithography in genera[1,2] and the deposition of nano-patterned polymers [3,4] make use of non-equilibrium, low temperature plasma processes (deposition of thin films, grafting of chemical groups, etching) in several approaches, with the aim of producing nano-patterned surfaces on large areas. This is possible because of the many advantages ("cold" processes, no change of bulk properties) and of the cost effectiveness of plasma processes. In lithography plasma processes can be involved either in the patterning procedure, to obtain differently shaped nanofeatures [5], either, in a final step, to custom-tailor the chemical composition of the patterned surfaces [6]. Another approach, that uses "physical masks", allows to produce geometrical micro-domains with different chemical composition and properties at the same surface [7,8]. With all these approaches it is possible to disentangle the effects of surface chemical composition and surface topography/morphology on cell-material adhesion and interactions.

Plasma chemistry could be also involved in producing nano-composite films; in these cases the nanofeatures are represented by metal nanoclusters embedded in an organic matrix. Such nano-composite coatings could be used for controlled drug-release systems in which, for example, a controlled delivery of antibiotics or antimicrobial agents could exert a tight control on adhesion and growth of bacteria at the surface of materials of biomedical interest. For its broad antimicrobial activity [9], silver and related compounds, as well as other antimicrobial agents, are often directly applied at the surface of biomedical devices. It has been shown that silver-based coatings exert a remarkable toxic effect against a wide range of bacteria including, among others, *Escerichia Coli* and *Psaeudomona Aeruginosa* [10]. Silver-containing coatings are widely used, nowadays, as a antimicrobial barrier layers for partial and full-thickness healing of wounds, such as leg ulcers, as well as for coating catheters. Nevertheless, especially for long periods of contact with physiological fluids, like blood, a non controlled release of silver from the device could promote pathologies. Plasma-deposited nano-composite films with silver clusters embedded, therefore, could be preferred because by carefully tuning the structure of the coating (density/dimensions of the clusters; composition/crosslinking of the matrix) it is possible to control the quantity of silver released as a function of time. A combined procedure, where the plasma deposition of an organic

coating occurs while a sputtering process takes place from a metal target will be discussed in this contribution as a method to embed metal clusters into the organic matrix, resulting in nano-composite films with interesting tailored physical and chemical properties [11,12]. Results about the release of silver during the time and about the antibacterial effect of plasma deposited nano-composite films will be discussed.

Acknowlegdements
This research has been developed in the framework of the MIUR-FIRB RBNE01458S_006 and "NANOMED" QLKE-CT-2000 projects, whose financial contribution is gratefully acknowledged.

Abstract
We realized a parametrical study concerning the conversion of ethylene by atmospheric cold plasma. The electric parameters such as the frequency, the high voltage applied to the reactor and the value of capacitors of the pulsed generator were studied. The influence of the water vapour on the rate of conversion was also studied.

Keywords: Non thermal plasma, VOCs, DBD

1. Introduction

Among the emergent techniques envisaged to treat the polluting and harmful emissions of the human activities, cold atmospheric plasmas took a considerable development these last ten years. Energy speed deposition and voltage rise time are fundamental parameters of a dielectric barrier discharge reactor.
At constant energy rate, weak variations of these parameters could modify the conversion efficiency and also by-products. In numerous applications the pulsed generators showed their superiority compared to AC conventional generators. Strong energetic electrons and chemical active species can be easily produced using a pulsed generator. Active species such as hydroxyl radicals ($^{\bullet}OH$) and [1,2] oxygen atoms initiate the chemical processes of the pollutant conversion. The efficiency of the conversion process depends too strongly on electric parameters of the pulsed generator. The parametric study presented here allows defining adjustments of electric parameters leading to an optimal efficiency of conversion.

2. Experimental set-up

The gas mixture used in this study was composed of dry or water saturated air with 460 ppm of ethylene at ambient temperature, see figure 1. The gas mixture flow at atmospheric pressure was regulated at 830 $cm^3.mn^{-1}$ by mass-flow controllers. Chemical analyses were made by a Fourier Transform Infra-Red spectrometer (FTIR) equipped with a 10 m absorbing chamber heated at 110°C. The reactor cell has a tubular shape with a 12 mm inner diameter and a 16 cm^3 active volume. The dielectric wall is made of a quartz tube (thickness : 1 mm). The inner electrode is a 2 mm diameter tungsten centred on the tube axis, an aluminium outer electrode covers the dielectric layer.

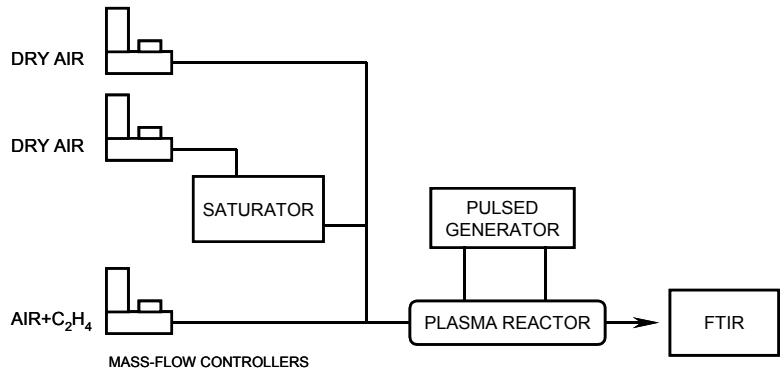

Figure 1: Experimental arrangement.

The reactor was powered by a triggered pulsed high voltage generator (working frequency: from 1 to 300 Hz, applied voltage: from 4 to 30 kV). This generator [3] is able to produce short voltage pulses (FWHM = 30 ns) with very steep front voltages $dV/dt > 10^{12}$ $V.s^{-1}$. Figures 2a and 2b show time evolutions of voltage and current respectively.

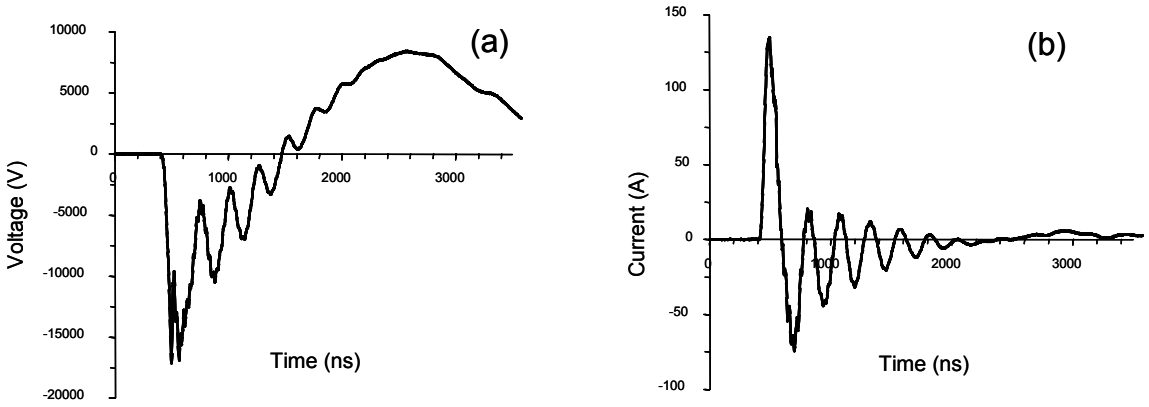

Figure 2: (a) Breakdown voltage, (b) current, at the reactor cell for 10 kV applied voltage.

3. Experimental results

Electrical parameters were adjusted in the following range : frequency from 1 to 10 Hz, high voltage from 10 to 14 kV and capacitors 2, 4 or 6 nF. These values correspond to an energy domain of injected energy from 20 to 150 $J.l^{-1}$. The flow-rate of the gas mixture was maintained at a fixed value of 830 $cm^3.mn^{-1}$ and the frequency was varied, in order to modify the pulse number that the gas undergoes during the reactor cell crossing.

3.1. Dry gas mixtures

Frequency effect

For dry gas mixtures, the increase of the frequency shows a linear increase of the conversion rate for all the tested combinations (capacitor/high voltage), figure 3 illustrates this behaviour. It suggests that in our experimental conditions, the increase of the frequency corresponds to an increase of the number of sites of destruction of the ethylene without appearance of saturation phenomenon.

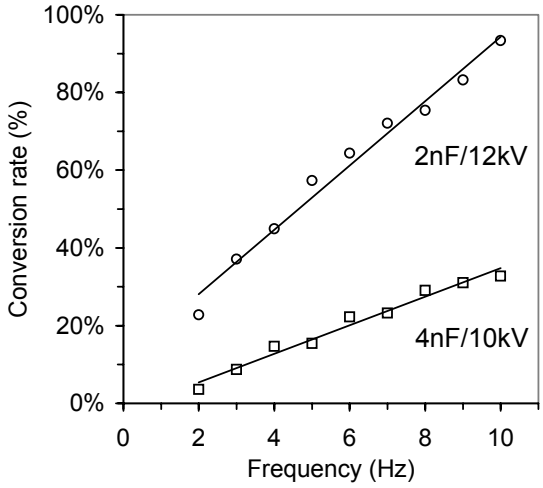

Figure 3: Frequency effect for two sets of parameters (2nF/12kV and 4nF/10kV).

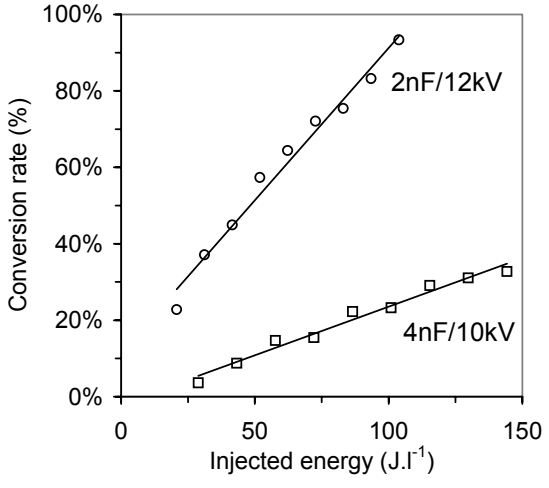

Figure 4: Frequency effect in term of injected energy for two sets of parameters (2nF/12kV and 4nF/10kV).

In term of energy consumption, it is more interesting to consider the injected energy than the frequency, see figure 4. We note that for the same consumption, we obtain widely different rates of conversion according to the choice of electrical parameters. For our experimental conditions, in particular for our geometry of reactor

(inter-electrode gap, inner electrode diameter, nature and thickness of the dielectric), it seems preferable to work on the weakest values of capacitor and on the strongest applied voltage.

Applied voltage effect

Figure 3 shows the effect of capacitors according to the applied voltage at a fixed frequency. It appears a phenomenon of saturation which occurs when almost totality of ethylene molecules are destroyed in the neighbourhood of streamers, see figure 5. As previously it is not necessary to work with too strong values of capacitor, as we can see it on the figure 6.

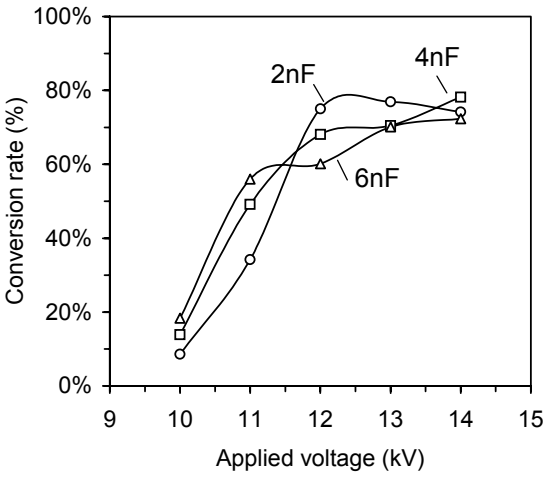

Figure 5: Applied voltage effect for N = 5 Hz and for various capacitors.

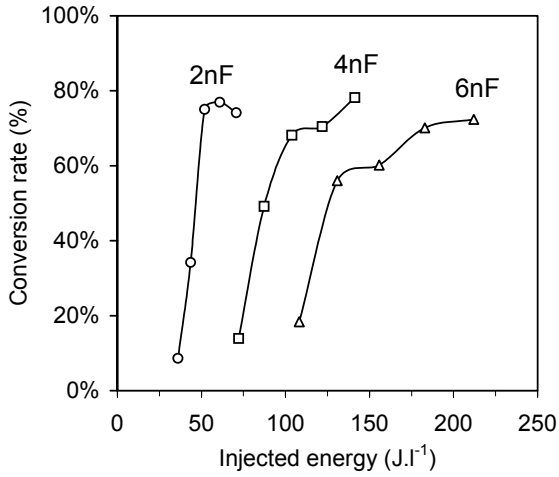

Figure 6: Applied voltage effect in term of injected energy for N = 5 Hz and for various capacitors.

The representation in term of energy cost informs us about the selectivity of the process, as we can observe it on the figure 7. It seems that it's better to work with the combination 2nF / 12 kV to minimize the energy cost.

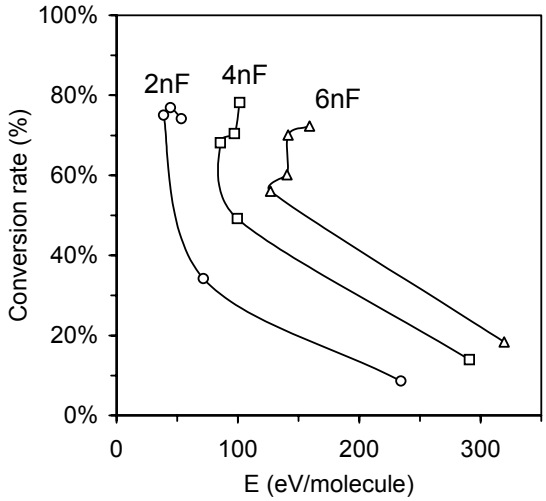

Figure 7: Applied voltage effect in term of energy cost for N = 5 Hz and for various capacitors.

3.2. Humid gas mixtures

Similar parametrical study on water vapour saturated mixtures at ambient temperature was performed, see figures 8 and 9. On the other hand the rate of conversion remains widely lower in the majority of the cases, this divergence which can reach 40 % at most. On the figure 10 we can compare, for the same discharge conditions, the conversion rate in dry and humid mixtures.

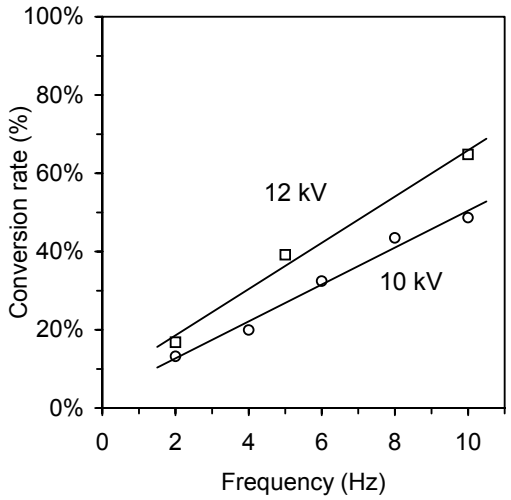

Figure 8: Frequency effect for two sets of parameters (○ 4nF/10kV, □ 4nF/12kV).

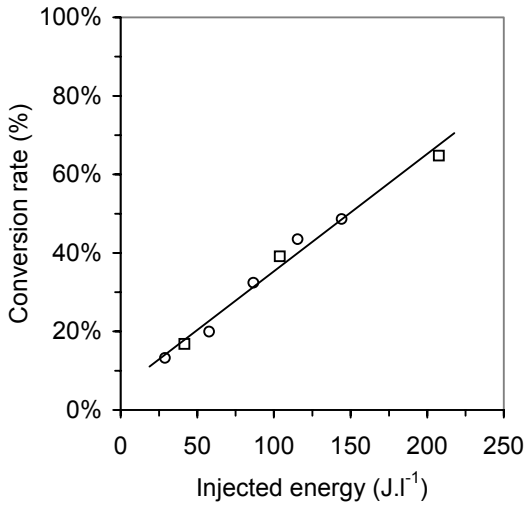

Figure 9: Frequency effect in term of injected energy for two sets of parameters (○ 4nF/10kV, □ 4nF/12kV).

Only for the lower value of applied voltage (10 kV), this tendency was inverted. This behaviour was confirmed by a frequency study at 10 kV, see figure 11.

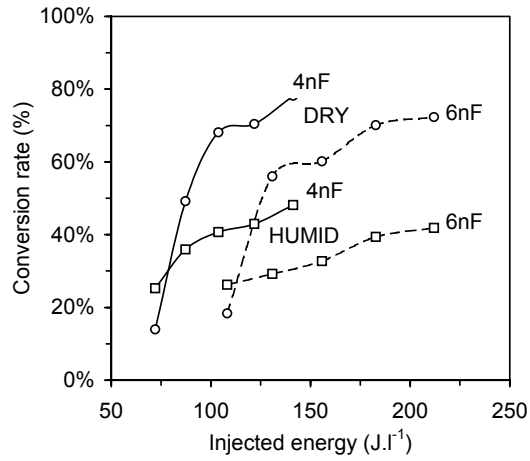

Figure 10: Comparison between dry and humid mixtures versus applied voltage in term of injected energy (○ dry mixtures, □ humid mixtures, continuous line 4nF/5Hz, dashed line 6nF/5Hz).

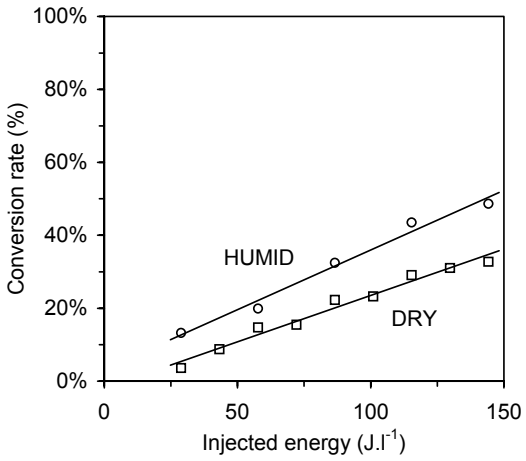

Figure 11: Frequency study at 4nF/10 kV, in dry and humid mixtures.

This behaviour could be explained by a consumption of oxygen atoms, responsible for the first step of ethylene molecules destruction, by hydroxyl radicals produced by the decomposition of water molecules. For low applied voltages, the water dissociation stays at a moderate level and affects slowly ethylene conversion.

4. Conclusion

A constant specific energy supplying can be easily obtained by adjustment of peak voltage value, frequency or capacitors but do not produce a constant effect. Our results show that the specific energy is not the only parameter to determine the conversion rate and products. Rise time of applied voltages is considerably effective on the dynamics of the excitation as well as the radical's initiators production. According to the choice of electric parameters, strong variations of the conversion rate can be observed.

Using the following combination of electric parameters: 2nF/12 kV, good results are obtained with our experimental device. In the future, correlations could be achieved with a 0D model in order to explain the specific behaviour of humid mixtures.

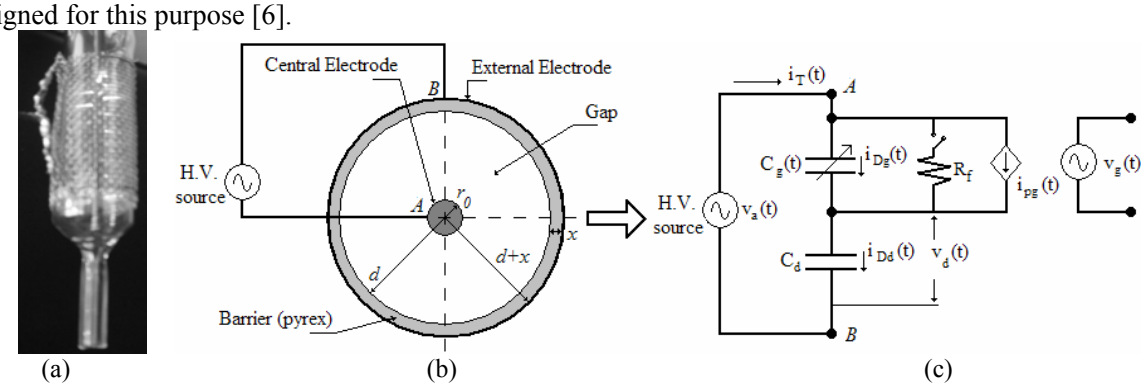
Abstract
A Dielectric Barrier Discharge (DBD) model is here proposed based on theoretical analysis and experimental signals obtained at different ionization frequencies and captured from a cylindrical reactor with Helium gas flow. The physical dimensions and configuration of the reactor are also considered in this model. All the signals occurring inside the reactor are measured and the power consumption of the micro discharge is evaluated as a function of the operating frequency.
Keywords: Dielectric Barrier Discharge, resonant converter, DBD Model, ionization frequency

1. Introduction

Dielectric Barrier Discharges (DBD) occurs generally in a filamentary form because they are created as a number of individual breakdown channels (microdischarges) with short period of time The approach the accumulation of charges on the dielectric barrier to reduce the electrical field in the gap and finally to quench the discharge. This kind of discharges has several applications such as materials surface treatment, toxic gases decontamination, and lighting, among others. DBD prevents large current intensities because of the use of glass as a dielectric, quenching the current and distributing the discharge over the whole surface [1-3]. In this work a cylindrical DBD reactor is used. It is composed of a Pyrex glass tube of 24.6mm of external radius $d+x$, 1.2mm of thickness x and 175mm of length is used as reactor; outside the glass tube, a grounded mesh electrode is wrapped covering 82.2mm length l. A stainless steel central electrode of 2.54mm of radius r_0 is used to establish a radial discharge homogenously distributed along the reactor. Due to its physical characteristics and the material employed, the electrical behavior is associated by two capacitors connected in series, one of them, C_g, has dielectric permittivity of air (Helium in this case) and the other, C_d , has the dielectric permittivity of glass (Pyrex) [4, 5]. The microdischarges occur in the region limited by the central electrode and the dielectric barrier, this region is denominated gap and its radial distance is 20.86mm. Considering these conditions the model was designed and employed to estimate the microdischarges power in function of the ionization frequency.

2. Description

The configuration and equivalent electrical model of the DBD reactor above mentioned are presented in figure 1. Being C_d the equivalent capacitance of the dielectric barrier and C_g the equivalent capacitance of the gap where the microdischarges occur. The voltage $v_a(t)$ is applied to the reactor and was supplied by a voltage source with variable operating frequency (from 10kHz to 100kHz) produced by a series-parallel resonant converter, specially designed for this purpose [6].



(a) (b) (c)

Figure 1. (a) DBD reactor, (b) transversal section of DBD reactor, and (c) electrical model of a DBD reactor.

The cylindrical geometry allows a homogeneous distribution of the discharge along the whole reactor, avoiding undesirable effects in edges and corners. A second advantage of this geometry consists in the possibility of mixing the effect corona with DBD discharge obtaining remarkable electrical field strength in the gap. When a tension of 1.2kV is applied, the electrical field distribution depicted in figure 2 is obtained, according to the next equation [7]:

$$E(r) = \frac{v_a}{r \ln\left(\frac{d}{r_0}\right)} \tag{1}$$

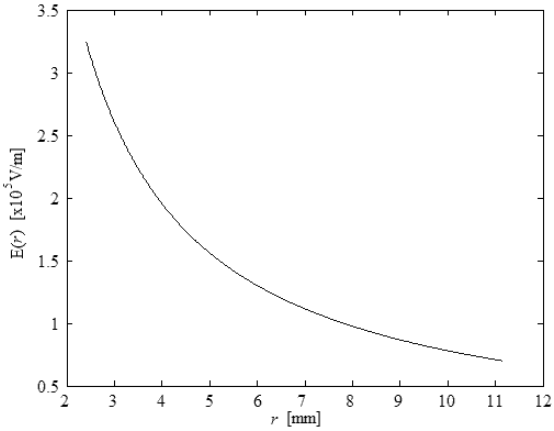


Figure 2. Distribution of the electrical field E(*r*) along the gap.

The equivalent capacitances of the cylindrical reactor are:

Table 1. Equivalent capacitances of the reactor.

Gap equivalent capacitance C_g	Dielectric equivalent capacitance C_d
$C_g = \frac{2\pi\varepsilon_0\varepsilon_{r_1} l}{\ln\left(\frac{d}{r_0}\right)}$ (2)	$C_d = \frac{2\pi\varepsilon_0\varepsilon_{r_2} l}{\ln\left(\frac{d+x}{d}\right)}$ (3)

where ε_0 is the permittivity of vacuum, ε_{r_1} is the relative permittivity of Helium (1.000065) [8], and ε_{r_2} is the relative permittivity (4.5) of the Pyrex glass. By substituting these values in equations (2) and (3), the obtained equivalent capacitances in off state (without discharge) are 3.1pF and 200.37pF respectively. The total capacitance of the whole reactor is:

$$C_T = \frac{C_d C_g}{C_d + C_g} \approx C_g \tag{4}$$

Being $C_g << C_d$ the total capacitance C_T is strongly dependent of the gas capacitance C_g which cannot be considered to have a constant value, because the ionization degree is different when the microdischarge are occurring and when there are not. That's why, it's better to decompose this gap capacitance into two different values.

The analysis aimed to diagnose the internal parameters begins with the Kirchhoff's theorem obtained from figure 1(c):

$$\frac{dv_d(t)}{dt} = \frac{1}{C_d} i_T(t) = \frac{1}{C_d} i_{Dd}(t) \tag{5}$$

$$\frac{dv_g(t)}{dt} = \frac{i_{Dg}(t)}{C_g} = \frac{1}{C_g}\left[i_T(t) - i_{pg}(t)\right] \tag{6}$$

$$v_a(t) = v_d(t) + v_g(t) \tag{7}$$

By differentiating equation (7) with respect to time and substituting equations (5) and (6) into equation (7), the following equation is obtained:

$$\frac{dv_a(t)}{dt} = \frac{i_T(t)}{C_d} + \frac{1}{C_g}\left[i_T(t) - i_{pg}(t)\right] \tag{8}$$

Rearranging equation (8), the expression to diagnostic the current of the discharge is

$$i_{pg}(t) = \left(1 + \frac{C_g}{C_d}\right) i_T(t) - C_g \frac{dv_a(t)}{dt} \tag{9}$$

Finally, by integrating equation (5) respect to time, the voltage of the dielectric equivalent capacitance C_d is determined by

$$v_d(t) = \frac{1}{C_d}\int_0^t i_T(\tau)d\tau + V_d(0) \tag{10}$$

From equation (7) and by substituting equation (10) the voltage of the gap equivalent capacitance C_g is:

$$v_g(t) = v_a(t) - \frac{1}{C_d}\int_0^t i_T(\tau)d\tau - V_d(0) \tag{11}$$

With equation (9) and (11) it is possible to determinate internal parameters from external ones. This is the fundamental part for the model developing here proposed.

Respect to the breakdown condition, when $v_a(t)$ reaches the breakdown voltage (V_{bd}) amplitude, the occurrence of microdischarges begins, and their magnitude is added to the displacement current intensity. This magnitude is decreasing by an effect caused by $dv_a(t)/dt$ modulation. The microdischarges occurrence ends when $v_a(t)$ is maximum ($dv_a(t)/dt=0$). Figure 3 shows the waveforms of the total current ($i_T(t)$) and the applied voltage $v_a(t)$ for the DBD generation.

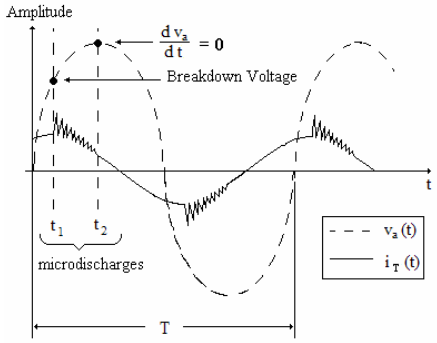

Figure 3. Wave forms of the applied voltage and the total current of a DBD.

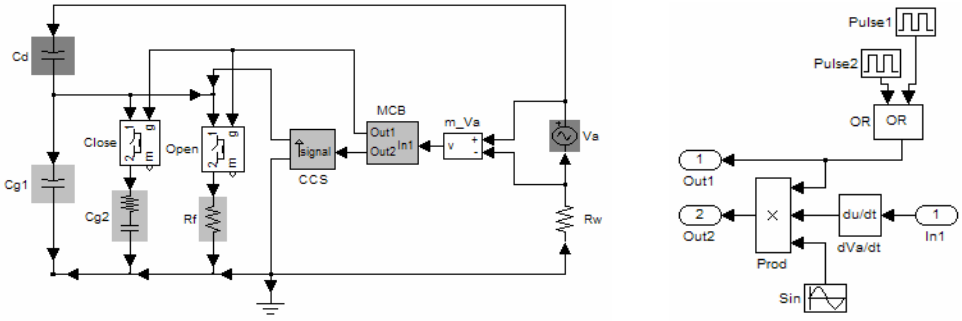
The resultant model is depicted in figure 4 by using Simulink blocks of Matlab ® software. The two values assumed by Cg are implemented by two capacitors in a parallel connection, Cg1 and Cg2. At the time t_1, (refereed to Fig. 3) Cg2 is disconnected and only Cg1 participates in the microdischarges. Its equivalent value corresponds to the value of about $0.7C_g$ (in off state) according with electronic densities (10^{13} cm-3) obtained from references [3, 5], with the value of the ionization frequency and the constants established. Consequently, Cg2 needs to be $0.3C_g$, to give a C_g value when both capacitance (Cg1 and Cg2) are connected in parallel. When the microdischarges cease, the capacitor Cg2 is reconnected in parallel and C_g returns to its off state value at t_2. This sequence is repeated for each semi period. Simultaneously to this, a resistance Rf is also connected as

indicated in figure 4(a), to simulate the equivalent impedance of the filamentary microdischarge. A controlled current source (CCS) is connected, to provide the microdischarges impulsions flowing through C_g and the signal designated to control it consists of a high-frequency sinusoidal source (with period of nanoseconds order) which is modulated by the corresponding value $dv_a(t)/dt$.

Inside of MCB subsystem (Fig 4b), the Pulse1 and Pulse2 blocks switch ON and OFF the elements Cg2 and Rf respectively, which are designated to modify the C_g value during the microdischarges. They have a high logic state (1) when the conditions of breakdown are valid (from t_1 to t_2), and a low logic state (0) in the rest of the semi period. At the same time, these pulses are also used to allow or deny the microdischarges flow by controlling the controlled current source block (CCS).

A resistor called Rw is included to simulate the resistance of the wires from the voltage source to the reactor and because of the good performance during the simulation calculations. The model designed and the corresponding subsystem that controls the current source are shown in the figure 4.



(a) (b)

Figure 4. (a) Simulation model, (b) subsystem of the microdischarges conditions (MCB block).

The model can work with any value of frequency and amplitude in the Va block which represents the high voltage source applied to the reactor. All the measurement blocks are not exhibited in Figure 4 for best appreciation of the DBD model.

3. Results

The Helium gas flow (1LPM) passing through the reactor was ionized at different operating frequencies (19kHz, 46kHz and 66kHz). The external parameters ($v_a(t)$ and $i_T(t)$) which were captured with a digital scope Tektronix® Model THS710A are presented in figure 6 for all these frequencies. The displacement current is 90° dephased respect to the applied voltage. The microdischarges are present when the applied voltage reaches the breakdown voltage value. It is clear that the microdischarges magnitude is diminished conforms the applied voltage reaches the maximum level. With respect to the displacement current intensity, the experimental results obtained shows that its magnitude increases with frequency.

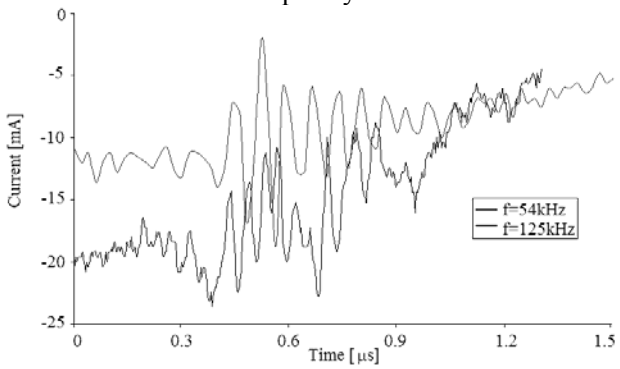


Figure 5. Zoom of microdischarges

It was also observed by zooming at the microdischarges registered at 54kHz and 125 kHz in figure 5, that the microdischarge signal has almost the same period independent of the ionization frequency.

Simulation test where realized at different frequencies (19kHz, 46kHz and 66kHz). These results are shown in figure 7.

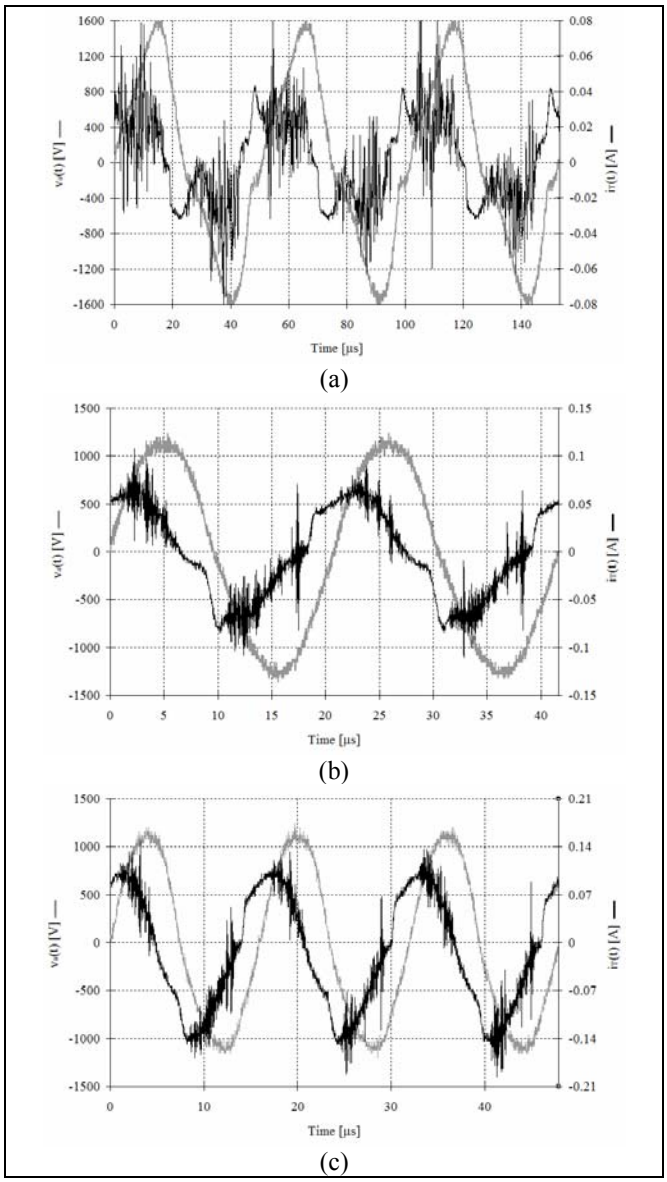

Figure 6. Experimental $v_a(t)$ and $i_T(t)$ at: (a) 19kHz, (b) 46kHz, and (c) 66kHz.

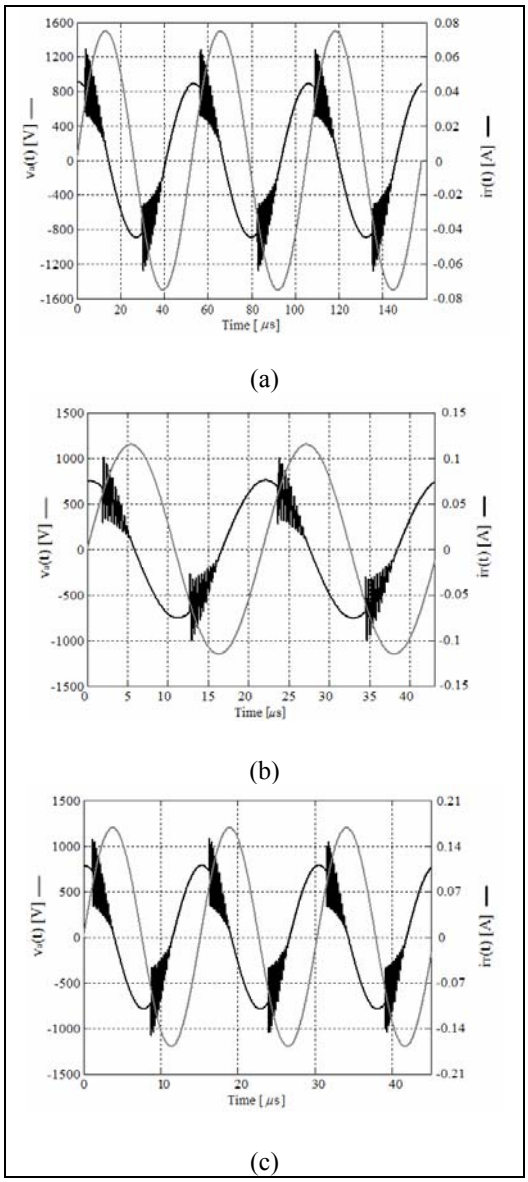

Figure 7. Theoretical $v_a(t)$ and $i_T(t)$ at: (a) 19kHz, (b) 46kHz, and (c) 66kHz.

The comparison of experimental signals in figure 5 with theoretical ones in figure 6 shows that the amplitude values of current, consequence of the applied voltage, are of the same order. The distortion that exists in the experimental signals of current is not presented in the theoretical model because the simulation model contains ideal components. This is the reason of clean signals. Due the correspondence in the magnitude and basic behavior of both signals (experimental and theoretical), the model can be applied to study different parameters such as the power of the discharge generated respect to the ionization frequency. By running the model and

sweeping the frequency from hundreds of hertz to hundreds of kilohertz, and maintaining the amplitude in the applied voltage, the RMS applied power to the reactor had the following behavior.

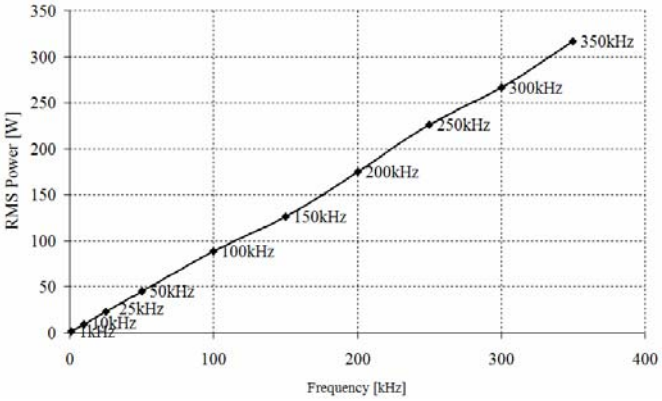

Figure 8. Variation of RMS power respect to ionization frequency ($v_a(t)$=1.25kV)

This figure obeys to well known equation of Manley [10] used for calculate the power consumed by dielectric discharges. The formula establishes that power depends directly on ionization frequency

4. Conclusion

According to the experimental results, the electrical simulation model of a DBD was developed and validated. After validation, the model was examined to acquire knowledge of the effect that the ionization frequency produces directly on the discharge. It is clear that by increasing the frequency, the power will also increase. It means that if the reactor is operated at low frequency, then it is necessary more amplitude of the applied voltage to produce the same intensity of the discharges than at high frequency. This result gives the option to construct high voltage sources with high operating frequency in order to feed DBD reactors with the purpose of generating discharges with greater intensity and small electrical devices. On the other hand, the model can be useful to determine the best conditions of the reactor by modifying its physical dimensions and composing materials.

Formation of soot particles in Ar/H2/CH4 microwave discharges during nanocrystalline diamond deposition : a modelling approach

F. Mohasseb, K. Hassouni, F. Bénédic, G. Lombardi, A. Gicquel
LIMHP, Université Paris Nord – CNRS UPR 1311 – 99 Avenue J.B. Clément – 93430 Villetaneuse (France)
E-mail:hassouni@limhp.univ-paris13.fr

This work deals with the modeling of $Ar/H_2/CH_4$ discharges ignited in microwave cavity systems and used for nanocrystalline diamond film deposition. These discharges are characterized by a strong thermal and chemical non-equilibrium, and the gas mixture is typically composed of an argon amount greater than 90% and a CH_4 concentration of around 1 %. As far as chemistry is concerned, the plasmas obtained exhibit H/C ratio ranging between 8 and 18 so as heavy hydrocarbons and soot particles may form in some discharge conditions. Soot formation also depends on pressure and input power values. Thus, in order to investigate the plasma chemistry various thermochemical models were developed and used under quasi-homogeneous plasma assumption.

To probe the soot particle sources a numerical model, previously developed for conditions where the formation of heavy hydrocarbons and soot particles may be neglected [1], was extended to take into account Poly-Aromatic Hydrocarbons (PAHs) growth, following several mechanisms. The first one took into account large neutral PAHs up to 4 aromatic rings (A4 model) from which the particle nucleation was assumed to take place. This study was performed in such a way to investigate the whole temperature domain that characterize both the plasma bulk, the plasma-substrate boundary layer and the regions outside the discharge (plasma edges and post-discharge regions). This was achieved by exploring a large domain of input microwave power which includes conditions that do not correspond to those used for NCD deposition. The variation of the gas temperature with the input microwave power at a pressure of 200 mbar is shown in figure 1. The gas temperature varies between 1000 K and 4000 K when the input power is increase from 10 to 600 W. The A4 model indicate that soot formation with a nucleation rate as high as 10^8 part./cm^3/h takes place for gas temperature values below 1500 K (figure 2). Such low gas temperature are found in two regions : the boundary layer between the plasma and the substrate surface and the post-discharge region between the discharge-plasma and the reactor walls.

The second mechanism that was considered in this work, take into account the formation of PAH compounds with up to 9 aromatic rings (A9 model). The soot is assumed to nucleate from an A9—A9 complex. The purpose was to investigate how the assumption on the size of the PAH-species that lead to soot nucleation affects the nucleation rate predicted by the model. Results showed that the values found for this rate by the A4 and A9 models are quite similar (see figure 3) and therefore that the A4 model is adequate for studying PAHs formation and soot nucleation in $Ar/H_2/CH_4$ microwave discharges.

The chemical model was then extended to take into account the formation of large hydrocarbon ions. Ions with up to four aromatic rings were considered (A4+ model). Results showed that the growth of PAHs and the nucleation of soot through this ionic mechanism is significant especially at high temperatures (>1500K). Note however that the nucleation rate at temperatures greater than 2000K is two orders of magnitude lower that the values obtained around 1000-1200 K. Note also that although nucleation seems to be possible in the bulk of the plasma at very high temperature (>2500 K) the predicted rate would be very small and almost 5 orders of magnitude smaller than the values obtained at 1000-1200 K.

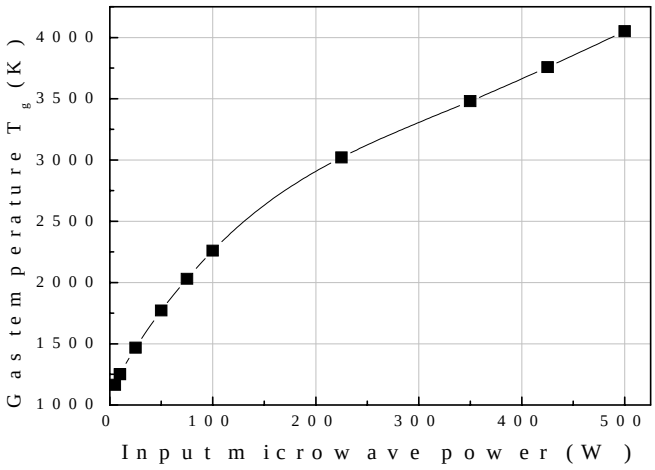

Figure 1 : Variation of gas temperature as a function of the microwave power absorbed by the discharge

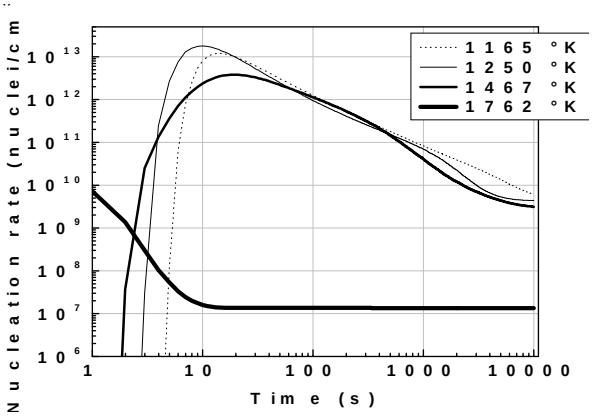

Figure 2 : Time-variation of the soot nucleation rate for different gas temperature values corresponding to several microwave power absorbed in the plasma (see figure 1)

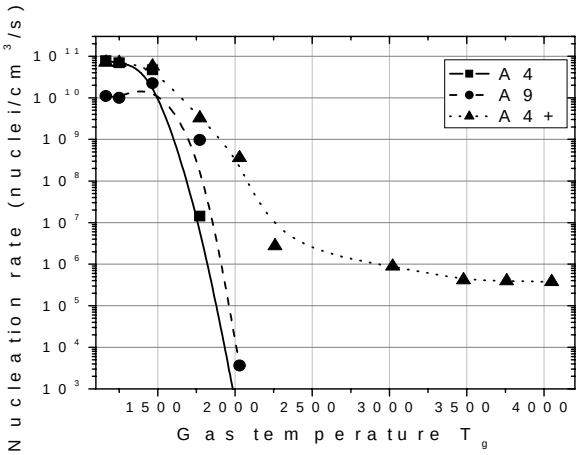

Figure 3 : Variation of the soot nucleation rates predicted from the A9, A4 and A4+ models as function of the gas temperature in plasma

Thermal Spray: Past, Present and Future

Richard Knight, Ph.D., FASM*
Department of Materials Science and Engineering, Drexel University,
3141 Chestnut Street, Philadelphia, PA 19104, USA

*2004-2006 President ASM International Thermal Spray Society.

Thermal spray is a family of versatile particulate/droplet consolidation processes which deposit overlay coatings onto surfaces to provide improved wear, corrosion and/or thermal protection to the underlying substrate. This group of 5 or 6 processes is capable of forming metals, ceramics, intermetallics, composites and polymers into coatings or freestanding structures. During processing, powders, wires, rods and/or sol-gel suspensions are introduced into combustion, DC arc, DC or RF plasma heated gas jets, where they are heated, melted or softened, accelerated and directed towards the surface being coated.

This talk will trace the evolution of the technology from the first processes developed almost a century ago to today's current state of the art, together with example applications. Recent process, process-control, materials, and applications will also be presented, together with some "crystal ball" speculations on what lies ahead in the future.

Biography

Dr. Richard Knight, FASM received his Ph.D. in Electronic and Electrical Engineering from Loughborough University in the UK in 1985, having previously completed his M.Sc. in Electroheat and Industrial Process Heating, also at Loughborough University, in 1978. Dr. Knight was a Postdoctoral Fellow at the University of Minnesota, Minneapolis, MN, from 1985 to 1989, prior to joining Drexel University in 1989, and since 1997 he has directed the Center for the Plasma Processing of Materials.

Dr. Knight has over 20 years of experience in the design, development and use of electric arc and thermal plasma systems for materials processing, including electrodes and torches, furnaces/reactors, and DC power supplies. Dr. Knight has more than 15 years experience in the development of parameters and techniques for the thermal spraying of materials, including metals, ceramics, composites, polymers and polymer-ceramic nano-composite coatings. His current research interests include thermal spray technology and education, thermal spraying of polymers, plasma recycling and treatment of waste and plasma synthesis of materials. His research has been funded by NSF, DoE, NASA and a number of industrial sponsors.

Dr. Knight was elected as a Fellow of ASM International in 2003 and is currently President of ASM International's Thermal Spray Society (TSS). He previously chaired the TSS Program and Training Committees and served as Secretary/Treasurer of TSS. He has published over 60 papers related to plasma, arc and thermal spray coating technology, has given ~60 presentations at National and International Conferences, holds 3 Patents and has co-organized several technical sessions at conferences. Dr. Knight serves as proposal reviewer for NSF, DoE, EPA and CRDF, and is a member of the editorial boards of the *Journal of Thermal Spray Technology* and *Plasma Chemistry and Plasma Processing*.

Production of reactive species by atmospheric-pressure streamers in N_2-O_2 mixtures

M.Šimek, M.Člupek, V.Babický, and P.Šunka

Department of Pulse Plasma Systems, Institute of Plasma Physics, Academy of Sciences of the Czech Republic, Za Slovankou 3, 18221 Prague, Czech Republic

A filamentary streamer is a rather frequent form of a high-pressure transient discharge usually occurring between metallic electrodes in high-voltage pulse systems. It may also develop between electrodes fully or partially covered with a dielectric barrier or on the interface between gaseous and liquid phases. Streamer discharges in atmospheric gases are currently receiving increasing attention in connection with environmental issues (*e.g.*, air pollution control, atmospheric chemistry, ozone synthesis) or material treatment technologies (*e.g.*, surface modification). The main reasons for the current interest in these topics are the low efficiency of conventional pollution control technologies, such as carbon adsorption and catalytic/thermal oxidation, and the incompatibility of vacuum-based low-pressure plasma treatment techniques, such as surface modification of polymers or surface hardening of ferrous metals, with industrial process lines. A non-equilibrium low-temperature high-pressure plasma produced by filamentary streamers is an interesting option to tackle the above-mentioned challenges in an economical way.

The reactivity of "streamer plasma" is a critical parameter for most application areas. Depending on electrode configuration, electrical power supply and gas composition, streamer discharges can produce a variety of transient species (e.g., vibrationally and electronically excited molecules, atomic species, molecular positive and negative ions), as well as many post discharge products (e.g. nitrogen oxides or ozone). The most important issue for applied plasma technology research today is the necessity to optimize efficiency and to scale-up laboratory plasma reactors so as to achieve maximum performance at minimal cost. To this end, advanced physical and chemical modeling of streamer discharges are often necessary so as to predict the performance of a streamer discharge for a selected application. As the physics of streamers has not been completely understood to date, numerical codes currently-used are based, because of the lack of knowledge, on many assumptions and estimates. Therefore any new or improved experimental measurements of streamer properties might always be of fundamental importance.

The diagnostics that have been used up to now (*e.g.*, cloud chamber tracks, streak pictures, fast photography, Schlieren photography, emission spectroscopy and electrical measurements) provided useful information on some streamer fundamentals (*e.g.*, avalanche-streamer formation, streamer propagation and branching, gas and electron temperatures). Detailed information on many other important physical and chemical processes "responsible" for streamer properties (*e.g.*, photo-ionization and recombination processes, diffusion processes, vibrational relaxation, streamer channel heating and expansion, production and quenching of atoms, molecular metastable species and radicals) is, however, strongly limited.

In an attempt to get further insight into the streamer discharge physics and chemistry, several diagnostic approaches based on optical techniques have been applied recently and their further development may help to investigate streamer basics. Especially promising are methods capable of characterizing several key reactive species, such as, *e.g.*, free electrons, $N_2(A^3\Sigma)$ metastables, N^I and O^I atoms, and vibrationally-excited $N_2(X^1\Sigma, v)$ species. In the case of $N_2(A^3\Sigma)$ metastables, a new method based on the pooling and resonant energy transfer was recently developed and tested to investigate streamers in pure nitrogen [1-3]. Essentially, the method of "normalised HIR curves" tracks the evolution of $N_2(A^3\Sigma^+_u)$ species through the square root of the $N_2(C''^5\Pi_u \rightarrow A'^5\Sigma^+_g)$ Herman infrared (HIR) emission intensity. Relative $N_2(A^3\Sigma^+_u)$ time-course is then placed on an absolute scale by applying proper normalisation procedure. Considering that HIR has been observed only in connection with the pooling, the HIR provides an interesting tool whenever the pooling mechanism becomes a predominant $N_2(A^3\Sigma_u^+)$ (self)quenching process.

The objective of this lecture is to give an overview of current research in the field of streamer discharges in IPP labs and to discuss basic characteristics of streamers generated in atmospheric gases. Various optical

diagnostic techniques suitable for investigating streamer discharges will be reviewed and their potential use in quantifying important reactive species will be examined. Finally, the latest results in the field obtained by various research groups will be compared.

Electrical diagnostic and control of dust particle forming radio-frequency plasma.

M. Ch. Jouanny, L. Boufendi, M. Cavarroc, and M. Mikikian
GREMI, Ecole Polytechnique de l'Université d'Orléans, 14, rue d'Issoudun BP 6744,45067 Orléans cedex2

Abstract
The plasma chemistry of a radio-frequency silane based dust forming plasma is analyzed thanks to an electrical diagnostic. This diagnostic gives the possibility to follow and control the particle nucleation and growth from the negative ion formation stage. A correlation with the evolution of the electrical parameters of the plasma is performed.

1. Introduction

Physics and chemistry of dusty plasma are considered now as one of the important branches of science and technology. Besides its importance for laboratory plasmas and applications for environment control, electronics, powder chemistry and metallurgy, dust in plasma also plays an important role in many extraterrestrial situations, from planetary science to interstellar clouds. The presence of dust particles in industrial reactors can lead to the production of defects in the deposited thin layers. However, Recently, it has been shown that nanocrystallites embedded in an amorphous matrix give very interesting opto-electronic and mechanical properties to these thin layers and open the way to many potential applications of these nanostructured thin films such as polymorphous silicon based solar cells with high and stable efficiency. They can be used as quantum dots in a wide range of new generation of microelectronic devices such as memories for tera bit storage, single electron devices, cold electron emitters, etc…

It is well known now, for silane based low-pressure plasma, that the dust particle formation is a four-step process. The first one corresponds to the chemical reactions involving negative ions and vibrationaly excited silane molecules.

$$Si_nH_{2n+1}^- + SiH_4^* \rightarrow Si_{n+1}H_{2(n+1)+1}^- + 2H$$

This phase ends with the formation of 2-3 nm in size nanocrystallites that accumulate in the gas phase. When their number density reaches a critical value of about 10^{12} cm^{-3}, they start to coagulate to form big particles. Thus, the most interesting and important phenomena take place in the early beginning of the process. To understand and control this phenomenon needs to control the formation of the nanocrystallites. Also, the small deviation in plasma and gas parameters in this period (gas temperature, pressure, electron concentration etc.) could change completely the law of cluster growth, particle formation and following discharge behavior [1]. For example, the first phase is strongly slowed down when the gas temperature is increased.

In this contribution we will focus on the study of the physical and chemical characterization of the earlier phase of the dust particle formation.

2. In situ particle detection

An electrical diagnostic has been developed and used. It is based on the measurements of the modifications induced by the occurrence of the nanoparticles in the electrical characteristics of the discharge. Indeed, their presence affects the electrical conductivity of the plasma [2]. The electrical measurements have been correlated to the time evolution of the electron density measured by means of a microwave resonant cavity method. By increasing the time resolution up to 100 µs we can detect the formation of the negative ions which are the first nuclei of the particle formation. This allows the

understanding of the effects of the most sensitive plasma parameters, which is the gas temperature that has a drastic effect on the earlier chemical reactions.

3. Results and discussion

Figure 1 shows the time evolution of the electron density during the nanocrystallites formation and accumulation in the plasma for different gas temperatures. The drastic decrease observed around 200 ms for room temperature curve (green one) corresponds to the agglomeration phase of the nanoparticles. In the first few milliseconds of this curve one can observe a peak (inserted figure) which corresponds to the formation of the negative ions. These ions are formed by dissociative attachment of the silane molecules. As it can be seen, the gas temperature as reported in previous works [3] does not affect this process. However the growth of the nanocrystallites is strongly affected. Two raisons can explain this phenomenon. The first one [4] is related to the temperature induced vibrational -translational relaxation of the vibrationaly excited silane molecules involved in the growth chemical reaction. The second one [5] is related to the radical loss at high gas temperatures. This behavior is well correlated to the evolution of the electrical characteristics of the discharge.

Deposition of hard coatings in a high vacuum ambient

Jochen M. Schneider[1], Johanna Rosén[1], Stanislav Mráz[1], and Adil Atiser[1]

[1]Materials Chemistry, RWTH Aachen University, D-52056 Aachen, Germany

ABSTRACT

In this topical review the effect of the presence of residual gas on the plasma chemistry and the composition and properties of hard coatings grown by physical vapour deposition is discussed. Furthermore, the effect of magnetic fields on the plasma composition for low pressure discharges is reviewed.

The synthesis of hard coatings in industry takes place in high vacuum growth systems. The residual gas in such systems is dominated by water. Cathodic arc deposition and magnetron sputtering are often used for the industrial synthesis of hard coatings. The chemistry of cathodic arc plasmas is investigated by time-of-flight mass spectrometry as well as by energy resolved mass spectrometry. We describe the hydrogen incorporation from residual gas during cathodic arc and magnetron sputtering and discuss the implications for the elastic and plastic properties of the coatings. The temporal development of the plasma composition of a pulsed aluminium plasma stream in the presence of oxygen as well as the charge state resolved plasma composition of a pulsed zirconium arc in a nitrogen atmosphere is reviewed. Furthermore, the charge state resolved ion energy distributions of aluminium ions in a cathodic arc plasma are measured and analyzed.

These results are of importance for the understanding of the evolution of the hard coatings composition and structure evolution during deposition.

Biological Applications of Plasma Polymers

R. D. Short
Department of Engineering Materials, University of Sheffield, Mappin Street, Sheffield S1 3JD, United Kingdom

Radio frequency glow discharge (rfgd) or plasma polymers have been applied to biomaterials and biomedical devices since the 1960's [1]. In the process of plasma deposition, an electric field (usually radio frequency) is applied across a vapour or gas filled chamber of a suitably "polymerisable" compound (termed "monomer"). This ionises a fraction of the molecules and generates electrons, ions, free radicals, photons and molecules in both ground and excited states within the gas plasma. Polymer film growth then occurs within this environment [2]. The deposition of polymer films from plasma for biomedical applications, has a number of specific advantages over alternative surface modification techniques, including the deposition of sterile, pinhole-free conformal films onto objects of complex geometries and different materials.

By judicious choice of monomer and control over the deposition environment, films retaining the original chemistry of the monomer compound (e.g. carboxylic acid from acrylic acid) can be obtained [3,4]. This paper reviews the application of plasma deposited films (plasma polymers) in biological applications. The uses of plasma-deposited films are now so widespread that a comprehensive review is beyond the scope of a single paper, and, therefore, the author will concentrate on the more typical applications of plasma-deposited films and trends in the field.

Perhaps naively, the view some 30 or more years ago was that the provision of a synthetic polymeric coating (on a traditional engineering material) would elicit a specific biological response *in vivo* (in the patient) and could improve the long term implantability of the material. However, experience has taught that this is not generally the case – with a few notable exceptions - and the rapid progress that has been made in the past decade in understanding the material-biological interface has helped explain why. Simple ideas that "biocompatibility" may correlate with a single surface property have rarely been supported by the data from animal or patient trials. Commonly observed reactions to implanted biomaterials include those associated with the adsorption of biomolecules e.g. protein adsorption/retention and lipid absorption, those associated with normal/abnormal wound healing e.g. platelet activation, macrophage adhesion, phagocytosis, macrophage release, neutrophil attachment and angiogenesis; and unwanted events such as bacterial adhesion, platelet adhesion and fibrous encapsulation.

Notable successes for plasma-deposited films include surface coatings to reduce the discomfort of wearing non-permeable contact lenses, leads for pace maker devices, surgical instruments and a cell transport vehicle for the delivery of cells to a wound bed. Better correlation between a single material property and biological utility is seen in *ex-vivo* devices e.g. in a study of baboon A-V shunts, it was shown that platelet consumption increased with the water content of hydrogel-coatings on the shunts [5].

The knowledge and materials developed thus far are finding applications elsewhere, in new, emerging technologies, such as microarray analysis and microfluidics, where the problems encountered are similar to implantable devices but coating performance is required only for a short period of time (minutes to hours). In these technologies the biological complexity is significantly reduced (cf. *in-vivo*), and, in general, on the solid-phase support (e.g. glass slide) only one single specific biological event is being controlled (e.g. hybridization of a nucleic acid).

Abatement of greenhouse gases using surface-wave microwave discharges sustained at atmospheric pressure

Y. Kabouzi[*], M. Nantel-Valiquette, M. Moisan and J. C. Rostaing[†]

Groupe de physique des plasmas, Université de Montréal, Montréal, Québec.

[†]Air Liquide, Recherche et développement, Les Loges-en-Josas, France.

Reducing perfluorinated compound (PFC) emission from chamber cleaning and dielectric etch tools continues to be an important challenge for the semiconductor industry. In some cases, there are advantages to the use of abatement techniques using plasmas at atmospheric pressure. To date, this approach has received less attention than plasma abatement at low pressure. Microwave surface-wave plasmas can be operated at atmospheric pressure and have been successfully used to eliminate PFCs gases. As an example, we present results from the abatement of SF_6/CF_4 diluted in nitrogen gas with concentration ranging from 0.1 to 2.4% of the total flow rate. Oxygen or water vapor is added to the gas mixture to ensure efficient oxidation of PFC fragments and to provide scrubbable byproducts (acid-like byproducts). The destruction and removal efficiency (DRE) of SF_6/CF_4 is investigated as functions of microwave power, field frequency, nitrogen flow rate and PFCs concentration. The DRE is found to increase with increasing microwave power (as a result of increasing electron density and residence time) and decreasing field frequency. Reformation of the PFC molecules form their fragments is found to be the main mechanism limiting the abatement efficiency. Reformation increases with decreasing gas temperature and increasing initial concentration of PFC molecules. Comparison between measurements and thermodynamic calculations shows good agreement. The residual PFC flow rate (or mass flow), for a given concentration of PFC in the gas mixture, is found to depend only on the specific energy, i.e. the energy deposited per PFC molecule expressed as the total microwave power divided by the PFC flow rate. This is illustrated in figure 1 for a fixed concentration of 0.75% of SF_6 in the gas mixture at three different nitrogen flow rates. It shows that a specific energy of 1.05 kJ/cm^3 is required to achieve an almost complete abatement of SF_6. We will show that the energy efficiency of this plasma process increases with increasing the concentration of PFC. A method for improving the energy efficiency of our plasma reactor will also be presented.

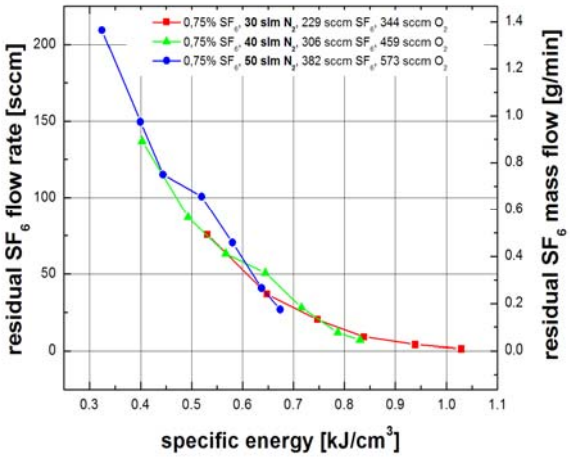

Fig 1: Residual SF_6 flow rate as a function of the specific energy, for different set of experimental conditions

Swift chemical sputtering of covalently bonded materials

K. Nordlund, E. Salonen and A. V. Krasheninnikov
Accelerator Laboratory, P.O.Box 43, 00014 University of Helsinki, Finland

When energetic atoms or ions escape from a plasma and hit a wall material, they can cause the material to erode. The erosion is well understood if the ion energy is high enough that the erosion is caused by physical sputtering, *i.e.* when the ion collides with a sample atom and directly kicks it out of the sample. Alternatively ions with thermal energies can also cause erosion if a chemical etching reaction can
take place.

In the particular case of hydrogen escaping from a fusion reactor plasma and hitting a carbon-based wall material, high carbon erosion has been observed for hydrogen ion energies which are so low (10-30 eV) that physical sputtering is impossible. On the other hand no chemical etching reaction has been able to explain the erosion either. Using classical and quantum mechanical atomistic simulations of the ion-sample collision dynamics, we have shown that the observed erosion can be explained by a chemical sputtering mechanism, where the incoming ion attacks a chemical bond between two carbon atoms, and causes the bond to break [1,2,3]. This mechanism requires an ion energy of only about 3 eV, and occurs on femtosecond time scales, whence we call it swift chemical sputtering.

In my talk I will present the swift chemical sputtering mechanism in detail, and discuss why it is neither a previously known physical or chemical sputtering mechanism, nor chemical etching. I will also present our results on how this mechanism can explain many of the observed features of carbon erosion in fusion reactors, and finally show that it can also be important in mixed materials like tungsten carbide.

Reactive deposition of ruthenium oxide by RF-assisted Ionized Physical Vapor Deposition magnetron sputtering.

D. Benzeggouta, M.C. Hugon, O. Voldoire, J. Bretagne, M. Touzeau, and B. Agius
Lab. de Physique des Gaz et des Plasmas, Université Paris-Sud, 91405 Orsay Cedex, France

Abstract
High permittivity (***k***) oxides are actively studied for highly integrated microelectonic devices in order to replace silicon oxide. In MOSFET devices, the gate electrode have to be compatible with high ***k*** oxide. In this work we chose ruthenium oxide which presents a weak resistivity (35μΩ.cm for the bulk material), a good thermal stability. To improve the RuO_2 film quality compatible with a low thermal budget on the substrate we study a new process, called Ionized Physical Vapor Deposition (IPVD).
Keywords: Reactive IPVD magnetron sputtering, High k thin film deposition

Introduction

As silicon CMOS devices are scaled below the 100 nm gate length node, advanced high-k gate dielectrics will be required to obtain equivalent oxide thickness (EOT) < 1.0 nm, EOT being the equivalent silicon oxide thickness deduced by quantum correction. New high permittivity (***k***) oxides are actively studied for highly integrated microelectonic devices in order to replace silicon oxide.
Thin films of transition conducting metal oxides such as ruthenium oxide, RuO_2, and iridium oxide, IrO_2, are attractive gate electrodes, since they have large work functions (~ 5 eV), low resistivity (35μΩ.cm for the RuO_2 bulk material), and excellent thermal stability. In this work, we evaluate the electrical and thermal stability of ruthenium oxide which presents good diffusion barrier properties to oxygen [1] and a good compatibility with the etching standard process.

Reactive magnetron sputter deposition is currently studied to deposit RuO_x from a metallic target. The composition of the deposited films is related to the oxygen/argon flow ratio. The classical transition between a "metallic" and an "oxide" regime is observed when the oxygen partial pressure is increased [2]. In classical magnetron discharges, sputtered species are emitted as neutral particles which have relatively low energy (~ 3-10 eV). The deposition regime depends on the working pressure, for a given distance between the substrate and the target: it varies from a ballistic one for which the film density is high to a thermalized one where deposited films present poor qualities in particular in terms of density and resistivity.
In order to improve the film quality compatible with a low thermal budget on the substrate, we explore the capabilities of the RF-assisted IPVD technique for the deposition of thin films mainly when working in reactive conditions. This last process is made more complex since an additional transition (inductive to capacitive [3]) is associated to the classical one (metallic to oxide) observed when the oxygen partial pressure is increased. In this process, we use a classical magnetron reactor equipped with a RF coil [4] placed in the region between the target and the substrate, coil which induces an additional plasma for vapor ionization. The goal of the present work is to study the discharge behavior versus various parameters and its correlation with deposited film properties in order to optimize the process.

Experimental procedure

RuO_x thin films were deposited using reactive magnetron IPVD with a Ru metallic target in an Ar/O_2 buffer gas discharge (Table 1). The IPVD reactor is a prototype developed by Alliance Concept. The reactor is a 45 cm diameter and 30 cm height cylinder, and contains a planar circular magnetron cathode (10 cm diameter). The process was designed to produce an additional inductively coupled plasma by using a RF coil to ionize the sputtered vapor and the buffer gas and to dissociate the reactive gas. The target to substrate distance was approximately 10 cm. In order to understand the oxygen role during the RuO_x film formation, we studied the plasma properties through the current and voltage characteristics of the discharge and by optical emission spectroscopy [5] according to the O_2 flow rate, DC target power, RF coil power and the total gas pressure.
Optical emission spectroscopy was used to detect and follow typical species emitted by the plasma. Emission spectra were recorded with a Jobin Yvon monochromator (HR 640) in the spectral range 180-850 nm with a resolution of 0.3nm.

The as-deposited thin films were characterized using profilometry for film thickness, and 4-point probe to obtain film sheet resistance. The films were analyzed by ion beam analysis (IBA) performed with a 2.5 MeV linear Van de Graff accelerator to determine the composition of thin films: Rutherford Backscattering Spectroscopy (RBS) allows the detection of the heavier elements such as ruthenium while Nuclear Reaction Analysis (NRA) allows to analyze light elements such as oxygen.

Table 1: *Deposition conditions.*

Target composition	*Ru*
Substrate to target distance	*10 cm*
DC power density	*80-130 W*
RF coil power	*0-200 W*
Coil/substrate distance	*2 cm*
Pressure	*0.5-5 Pa*
Deposition temperature	*Floating temperature*
Ar flow	*15-37 sccm*
O_2 flow	*0-15 sccm*

By analyzing simultaneously the plasma and the deposited films, it will possible to optimise the plasma conditions in order to obtain the best quality of films.

Results and interpretation.

In this IPVD concept, relatively high pressure (a few Pa) is necessary to optimize the sputtered vapor ionization fraction [5]. Indeed, sputtered neutral particles must be thermalized when they reach the RF coil discharge region in order to increase their residence time and consequently, their ionization rate. Figure 1 shows the variations of the magnetron discharge voltage (V_{Dis}) and current (I_{Dis}) versus O_2 flow rate, for 4 values of the RF coil power, P_{RF}=0W; P_{RF}=100W; P_{RF}=150W and P_{RF}=200W.

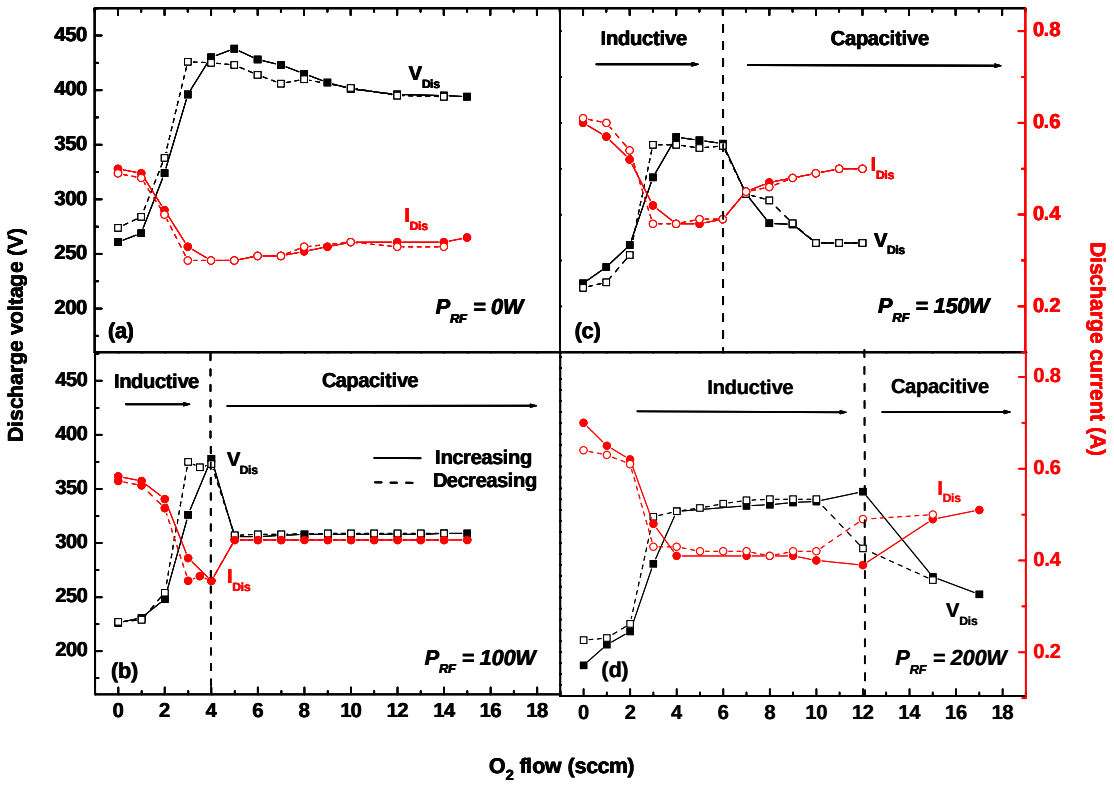

Fig. 1: *Variation of the magnetron discharge voltage and current versus O_2 flow rate for P_{DC}=130W, p=5Pa and an Ar flow rate of 37 sccm. The transition from inductive to capacitive modes is indicated by arrows for the different RF coil powers applied (P_{RF} = 100W, 150W, 200W).*

In addition to the well known metallic-oxidized target transition, another phenomenon, which consists in a transition from an inductive coupling mode to a capacitive one, is observed: this phenomenon modifies strongly the discharge and possibly the film properties. For a DC power (P_{DC}) of 130W, the first transition (V_{Dis} increases while I_{Dis} decreases) occurring around 4 sccm oxygen flow rate, corresponds to the transition from metallic to the oxide regime (fig. 1). This behavior can also be observed on the emission of the Ru I, O I and Ar I lines emitted by the magnetron plasma (fig. 2).

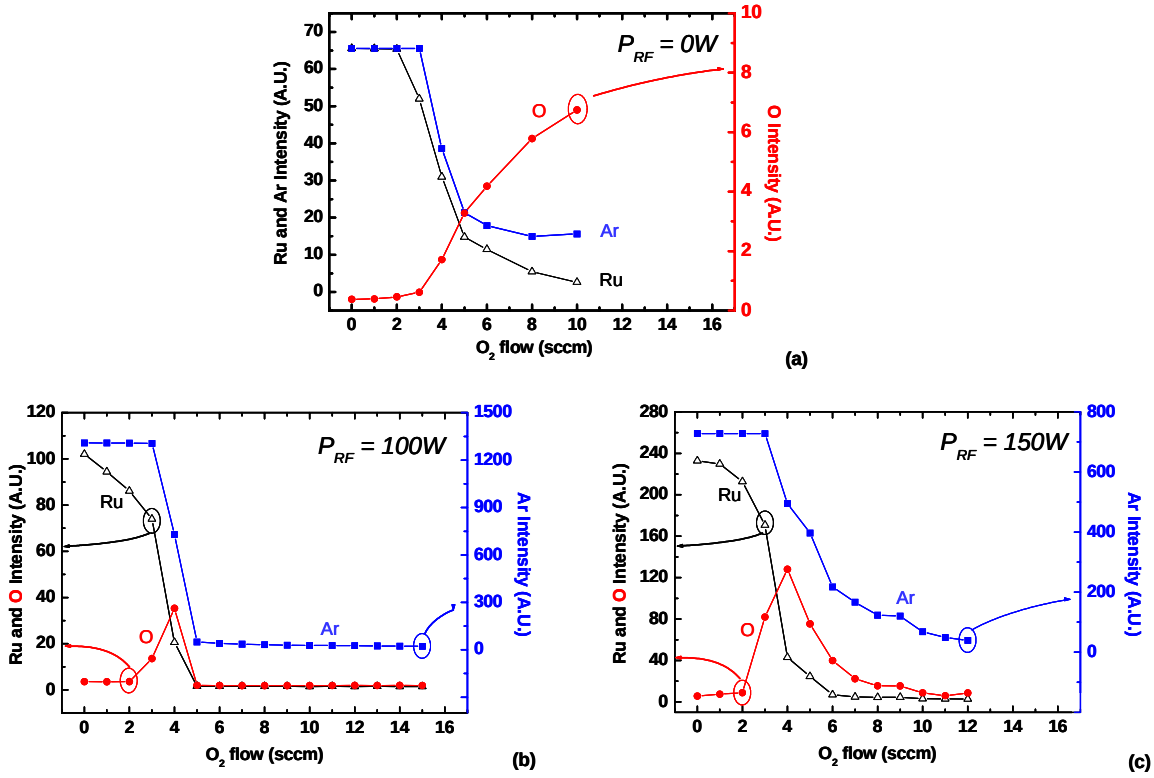

Fig. 2: *Variation of the 777 nm O I (●), 349.8 nm Ru I (Δ) and 811.4 Ar I (■) line intensity versus O_2 flow rate for conditions of fig. 1.*

The second transition (inductive to capacitive) appears in the voltage current plot (V_{Dis} decreases while I_{Dis} increases); this transition shifts to higher oxygen flow rate when the RF power applied to the coil increases (fig. 1.b.c.d). This effect is explained by the fact that the RF power is not sufficient to maintain the coupling of the coil in the inductive regime when the composition of the gas contains a larger proportion of oxygen. We can also see on OES spectra the same effect (fig. 2.b and c): in the oxide regime discharge (O_2 flow rate $\geq$ 4 sccm in our experimental conditions), the intensity of all the lines emitted in the RF plasma (Ru I but also O I and Ar I) decreases. This last result confirms a reduction of electron density and probably electron temperature in the RF plasma during the inductive-capacitive transition inducing a weak excitation of Ar, Ru and O atoms.

Figure 3 shows the variation of the magnetron discharge voltage and current versus O_2 flow rate for P_{RF} = 200W and two values of P_{DC} (80W and 130W). For larger DC power, the sputtering rate increases, consequently, oxygen target saturation occurs at large O_2 partial pressure. This effect also shifts the inductive to capacitive coupling transition (arrows of fig. 3) towards higher O_2 flows. This second transition, which is correlated to the cooling of electrons, is directly connected to the O_2 partial pressure in the plasma chamber.

In the inductive coupling regime, a high ionization of the gas is achieved in the coil centre and in the target-substrate region which produces a gas heating and a gas rarefaction. When the O_2 partial pressure is increased, due to a greater influence of e - O_2 low-threshold inelastic processes, the overall ionization efficiency decreases, producing new spatial ionization equilibrium and a transition to

capacitive regime. Effects of electron losses due to dissociative attachment on O_2 molecules can also be invoked for the reduction of the electron density. In this regime, a greater part of RF power is deposited in sheaths around the coil and near the walls. In the coil area, the gas temperature is lowered and the gas density is increased. The consequence is that the current-voltage characteristics of the DC magnetron discharge is modified: indeed, the increase of the gas density makes more efficient the ionization in the magnetized region leading to a decrease of the voltage necessary to sustain the DC magnetron discharge and then an increase of the current discharge.

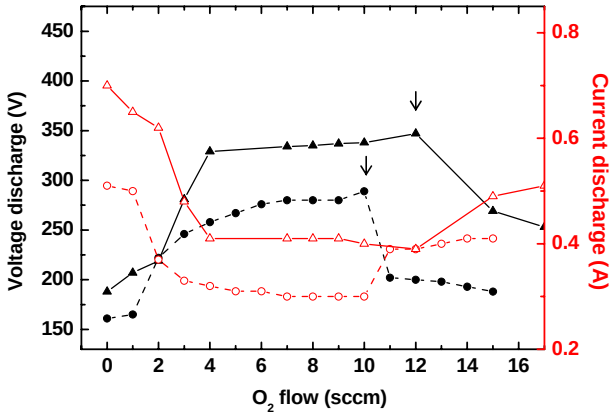

Fig. 3: *Variation of the magnetron discharge voltage and current versus O_2 flow rate for P_{RF} = 200W, two different P_{DC}, a pressure of 5 Pa and Ar flow rate of 37 sccm. The transition from inductive to capacitive modes is indicated by arrows.* ●*: V_{Dis}, P_{DC}=80W,* ○*: I_{Dis}, P_{DC}=80W,* ▲*: V_{Dis}, P_{DC}=130W,* Δ *: I_{Dis}, P_{DC}=130W.*

Film properties are reported on Figures 4 and 5, as a function of the O_2 flow rate, for two pressures (5Pa and 0.5Pa) and a RF coil power of 100W. For the two pressures, the deposition rate decreases when the RF coil power (P_{RF}) increases (fig. 4). The two parameters, pressure and RF power, do not seem to have any effect on stoichiometry (fig. 4) and density (fig. 5).

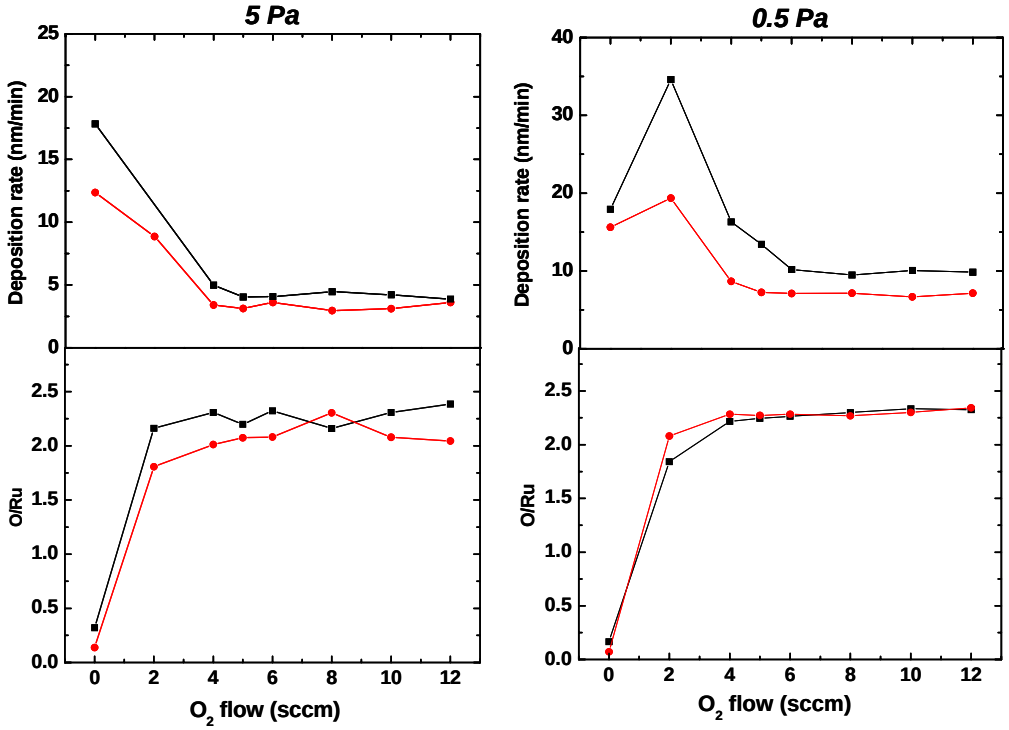

Fig. 4: *Variation of RuO_x thin film properties: deposition rate, stoichiometry* ***O/Ru****, versus O_2 flow, for two deposition pressures (0.5 and 5Pa) and two RF coil powers* ***P_{RF}*** *(■: P_{RF}=0 W,* ●*: P_{RF}=100W) - P_{DC}=80W.*

For usual PVD magnetron sputter deposition, the best quality of deposited films are usually obtained at low working pressure. In the present work we are mainly interested in dense and low resistivity oxide films, performed without any intentional heating or any post deposition annealing. The comparison of the first results reported in figs. 4 and 5 permits to draw some conclusions on the interest in using RF-assisted IPVD process when working in reactive conditions for deposition of conductive films. From these figures, we first observe that the presence of the RF plasma does not modify significantly the film density. Second, it appears, from fig. 4, that film stochiometry O/Ru reaches a value of about 2 (within the accuracy of the determination of composition by IBA) for O_2 flow rate higher than 2 sccm which corresponds to the beginning of the metal/oxide transition. But a too high O_2 flow rate produces a transition from inductive to capacitive discharge regime which is less effective for ionization, and then for the physical properties of thin film. So, for conditions of figures 4 and 5 and respective values of P_{DC}= 80W and P_{RF}=100W used here, the most interesting conditions in terms of O_2 flow rate are achieved between 2 and 4 sccm. In this range, we clearly observe an important improvement of the film resistivity when the additional RF plasma is used, particularly for a pressure of 5 Pa for which we get better results that for a pressure of 0.5 Pa.

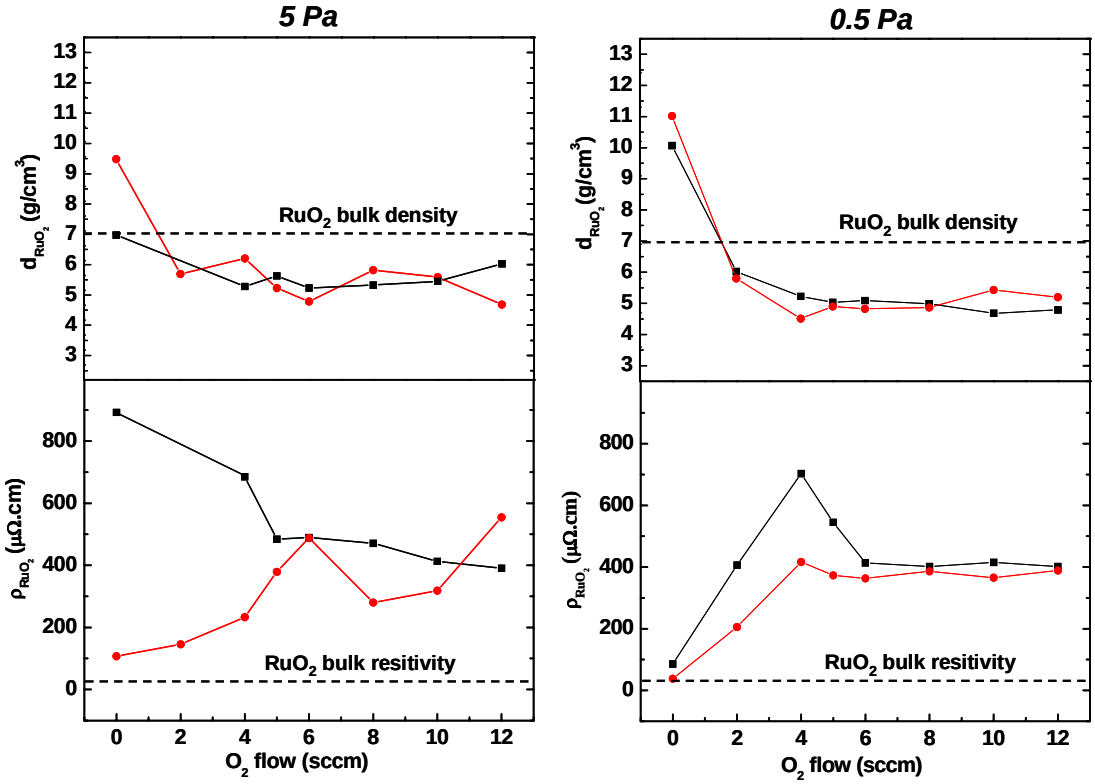

Fig. 5: *Variation of RuO_x thin film properties: density and resistivity, versus O_2 flow, for different pressures, RF coil power* $\mathbf{P_{RF}}$ *(■: P_{RF}=0 W, ●: P_{RF}=100W) - P_{DC}=80W.*

These results are very promising and can be probably improved by exploring some ways: *1)* by working with a higher ratio of P_{RF}/P_{DC} (see from fig. 1) we have the possibility to extend the range of O_2 flow rate for which we can work in simultaneous oxide and inductive regimes, *2)* the use of voltage bias on the substrate could permit to deliver a higher energy to the film, to increase the film density and to improve its morphology in term of a better crystallinity, *3)* by optimizing the geometry of the reactor, in particular for the position of the RF loop.

Conclusion

In this paper, we have studied the RF-assisted IPVD technique for the deposition of RuO_2 thin film. This technique associates a classical magnetron discharge to a RF plasma generated by a coil placed

between the magnetron and the substrate. We followed the effect of three parameters (O_2 flow rate, RF coil power and DC magnetron power) on the plasma and film properties.
We observed that in addition of the well known transition from metallic to oxide mode, in reactive PVD, it appears another phenomenon which consists of a transition from an inductive to a capacitive coupling when we apply a RF coil power. This effect depends at the same time on the oxygen presence in plasma, the RF coil power and DC magnetron power. Results clearly show an improvement of the film resistivity for conditions corresponding to simultaneous oxide and inductive regimes. Work is in progress to confirm, extend and control the potentialities of RF-assisted IPVD process for reactive conditions.

Vacuum Beam Studies of Radical Enhanced Atomic Layer Deposition of TiN Thin Films

Frank Greer

As microelectronics devices shrink and as their aspect ratios increase, it has become increasingly difficult to deposit thin films with sufficient conformality and control for many different practical applications. For example, the deposition of Cu diffusion barrier layers has been traditionally accomplished by advanced Physical Vapor Deposition (PVD) methods. However, as the step coverage required for the barrier layer approaches 100%, and as the barrier thickness required shrinks below 100A, PVD methods may not be able to meet these demands. To address these concerns, Atomic Layer Deposition (ALD) has been proposed as an alternative to PVD. In thermal ALD, a metallic precursor (*e.g.* Titanium Tetrachloride TiCl4) and a reactive species (*e.g.* NH3) are alternately introduced in isolated pulses into a deposition chamber. Repeating these pulses in a cyclical fashion, results in the growth of a film (*e.g.* TiN). Because the pulses of precursor and reactive species do not overlap, the film growth proceeds entirely through a series of surface reactions. This ensures that the film grows one layer at a time, allowing for precise thickness control, and yielding conformal step coverage in high aspect ratio features.

One problem with thermal ALD is that the deposition temperatures required to achieve practical growth rates and acceptable film properties can be relatively high (400C or greater). [1] Unfortunately, deposition temperatures in excess of 300C, may be incompatible with the temperature-sensitive films and structures in microelectronics processing. However, by using a more reactive species like a radical as the second reactant, atomic layer film deposition at much lower temperatures is possible. [2]

In this work, fundamental studies of Radical Enhanced Atomic Layer Deposition (RE-ALD) of TiN were performed in an ultra-high vacuum beam system.[3] By directing independent, calibrated beams of $TiCl_4$ precursor molecules, hydrogen radicals, and nitrogen radicals at different surfaces (inc. TiN, W, Cu, Si, and SiO_2), the individual steps of this RE-ALD process were characterized as a function of temperature (see Figures 1-3). With these data, phenomenological models were developed to calculate deposition rate parameters such as sticking and reaction rate probabilities (see Figure 4). These models were verified using modulated beam mass spectrometry to measure surface reaction products evolved during the RE-ALD process. XPS analysis and sheet resistance measurements for the deposited films will also be presented to illustrate that conductive TiN films with low residual Cl content can be grown at temperatures below 450K with the RE-ALD process.

Abstract
In this paper the processes occurred in a free burning electric arc in air between electrodes from composition materials on the base of cooper *(Cu, Cu-W, Cu-Mo, Cu-Mo-LaB$_6$)* and silver *(Ag, Ag - CdO)* were studied. By methods of optical spectroscopy radial profiles of plasma temperature are determined. The structural changes in a working layer of electrodes are investigated by metallographic techniques.
Keywords: electric arc, plasma, consumable electrodes, composition material.

1. Introduction

A problem of developing of reliable interrupting devices, where ignition of electric arc often is realised, can not be resolved without careful analysis of processes which take place in the arc and its electrodes. Furthermore, an electric arc, being generated at contact disconnection, results in considerable material erosion of contacts. We investigated plasma of the free burning electric arc in air between electrodes from composition materials. Such arc is model of arcs arising between contacts of current releases of electric circuits.

2. Experimental Set-up

The arc was ignited between the end surfaces of the non-cooled electrodes. The discharge gap l_{ak} was of 2, 4, 6 or 8 mm. The diameter of the rod electrodes was of 6 mm. To avoid the metal droplets appearing a pulsing mode was used: the current pulse up to 30 A was put on the "duty" weak-current (3.5 A) discharge. The pulse duration ranged up to 30 ms. The quasi-steady mode was investigated.

Because of the discharge spatial and temporal instability the method of the single tomographic recording of the spectral line emission was used. A 3000-pixel CCD linear image sensor (B/W) Sony ILX526A accomplished fast scanning of spatial distributions of radiation intensity. It allows the recording of the radial distributions of unsteady-state arc radiation intensity in arbitrary spatial sections simultaneously.

3. Results and Discussions

3.1 Electric arc between electrodes from composition materials on the base of cooper *(Cu, Cu-W, Cu-Mo, Cu-Mo-LaB$_6$)*

The radial profiles of temperature are determined in the average cross section of the discharge gap l_{ak} = 2, 4, 6 and 8 mm in air at arc currents 3.5 and 30 A. The temperature profiles are obtained from relative intensities of copper spectral lines 510.5 and 521.8 nm. Because of the discharge spatial and temporal instability the statistical treatment of obtained data was carried out. The spectral sensitivity of the experimental set-up was taken into account.

As recently was found the some secondary structure on a surface of electrodes can be realised during the discharge operation [1]. Therefore we studied our plasma in a two different modes. In the first mode the measurements of radial distributions of spectral line intensities were carried out as a statistical average value during the series of current pulses (30A) putted on the "duty" weak-current discharge (3.5 A). In this case the secondary structure on a surface of electrodes was realised. To avoid the influence of such secondary structure during the discharge operation in an another mode we measured the radial distribution of spectral line intensities as a statistical average value of single current pulses of an electric arc between smoothed surface of electrodes.

The radial temperature profiles of the arc between Cu-Mo-LaB_6 electrodes in two different modes are measured. In the first mode of the arc operation we investigated plasma of the discharge between smoothed surfaces of

electrodes. The next mode corresponds to the case of electrode surfaces covered by a secondary structure, which is realised under the arc activity.

From the comparison of obtained results the key role of the condition of the surface electrode follows. Really the presence of the secondary structure must decrease the erosion of the electrode material. As a result the amount of lightly ionised metal vapours in a discharge gap must be decreased. Therefore at the same arc currents the temperature in plasma column must be higher in case of secondary structure on a surface of electrodes.

It was interesting to compare the influence of composition of the electrodes on the plasma parameters. Additionally investigations of radial profiles of temperature in the arc discharge between pure copper electrodes were carried out. The plasma of an electric arc between Cu-Mo and Cu-W electrodes in the first mode of the arc operation was investigated in a similar way as well.

We can compare obtained radial temperature profiles of the arcs between Cu-Mo-LaB_6 electrode surfaces with a secondary structure and between copper electrodes. From these results follows that in arcs with discharge gaps 4, 6 and 8 mm at the arc current 30 A the axial temperatures are higher in case of Cu-Mo-LaB_6 electrodes. This phenomenon can be cased by both the additions of the Mo-LaB_6 to copper in such composition and a secondary structure of electrode surfaces. In case of discharge gap 2 mm such behaviour of axial temperatures are not observed. It is natural because the plasma of such arc probably is not in a local thermodynamic equilibrium. Such effect was observed in plasma of a short free-burning electric arc between copper electrodes [2].

The increasing of both the temperature and the efficiency of the plasma torch as a tool in the electrical erosion cutting is probably one of the factors, which determine the productivity of the dimensional treatment in the presence of the boron-containing compounds.

We compared radial temperature profiles of the arc between Cu, Cu-Mo, Cu-Mo-LaB_6 and Cu-W electrodes also. The arcs between composition electrode surfaces with a secondary structure were investigated in this case. The essential influence of the additions to the electrode materials on the arc plasma temperature is found [3].

3.2 Electric arc between electrodes from composition materials on the base of silver *(Ag, Ag-CdO)*

To realize spectroscopic techniques of plasma diagnostic of electrical arc discharges between composition electrodes on the silver base the reliable data on spectroscopic constants of silver and/or impurity atoms spectral lines are necessary.

Unfortunately, we have no information about discharge plasma investigation with usage of silver spectral lines. In the literature there are very negligible data on silver spectroscopic constants. The arrangement of energy levels of this atom does not give optimism for usage of silver lines in experiments on temperature determination by relative intensities technique with adequate accuracy. Nevertheless, we for the first time attempted to realize a spectroscopic technique of plasma diagnostic of electrical arc discharges between silver electrodes.

For this purpose, despite of a small difference of excitation energies of upper levels (~ 0.8 eV), the lines AgI 520.9, 768.7, 827.3 nm are selected.

The atomic spectroscopic data for these lines are taken from Ref. [4,5,6] and are listed in Table 1. Unfortunately, in the database NIST (National Institute of Standards and Technology, USA) the atomic spectroscopic data for lines AgI 768.7 and 827.3 nm are absent.

Table 1. Silver atomic spectroscopic data

λ,nm	E_m,eV	g_n	g_m	Ref.[4]		Ref.[5]			Ref.[6]
				g_mA*10^8	$g_mA/(g_mA)_{520.9}$	f	$A*10^8$	g_mA*10^8	$g_mA/(g_mA)_{520.9}$
827.7	5.256	4	2	2.3	0.153	0.166	0.323	0.646	0.107
768.7	5.256	2	2	1.4	0.093	0.157	0.177	0.354	0.069
520.9	6.015	2	4	15	1	0.565	0.694	2.77	1

The radial profiles of temperature are determined in the average cross section of the discharge gap l_{ak} = 6 mm in air at arc current 3.5 A. The temperature profiles are obtained from relative intensities of two pair's chosen silver spectral lines. In Fig. 1, as an example, the results of measurements are shown. The temperatures are determined with usage of atomic spectroscopic data fromRef. [4] and Ref. [5] for two independent serials of experiments (1 and 2). As the data from Ref. [4] and from Ref. [6] are practically coincide the temperatures by using data from Ref. [6] were not calculated.

The registration accuracy of spectral lines intensities does not exceed 10 % in our experiments. As the difference in upper levels energies of these lines are not significant, the final accuracy in determination of temperature is about 30%. The measurement results obtained by two pairs of spectral lines and in different serials of experiments practically coincide. We can conclude, that the chosen lines AgI 520.9, 768.7, 827.3 nm can be able to use in the temperature measurements in plasma contaminating the silver vapors with above mentioned accuracy.

One can note that we obtained the rather low temperature in the investigated plasma. Really, temperature on the arc axis in our case does not exceed 4200 K. But in plasma of free burning in air electric arc between copper electrodes in the same mode of discharge it is about 7000 K at the contents of cooper vapors of some percents in plasma [7, 8].

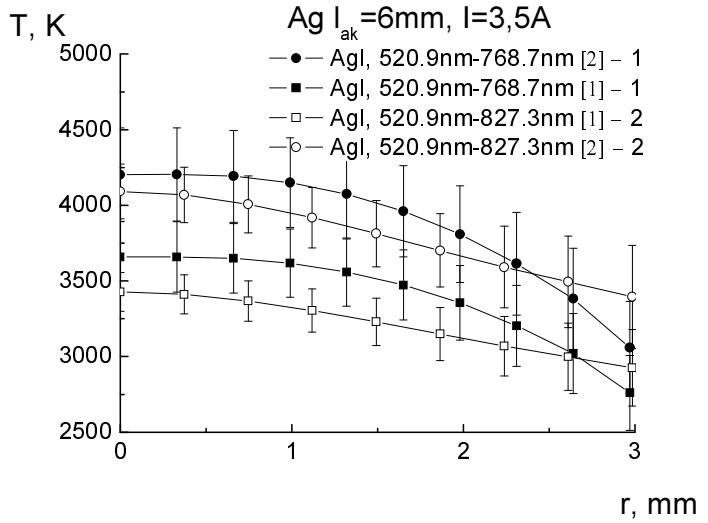

Fig 1. Radial profiles of temperature of arc plasma between silver electrodes (l_{ak} = 6 mm)

The simple estimation of equilibrium composition of a plasma mixture Ag-N_2 indicates, that at the contents of silver 1 % and temperature 4000 K the electron density is about $7*10^{13}$ $см^{-3}$. Apparently, such electron density is sufficient for maintenance of an arc current 3.5 A in a discharge.

In spectroscopy measurements of radial temperature profiles in plasma of an electric arc discharge between Ag-CdO electrodes to increase the reliability of obtained results were used both line of silver, and line CdI 479.9, 508.5 and 643.8 nm. The atomic spectroscopic data for these lines CdI are taken from Ref. [4,5,9,10] and are listed in Table 2. From the table the essential differences of these data from each other are visible.

Table 2. Cadmium atomic spectroscopic data

λ,nm	g_n	g_m	Ref.[4]		Ref.[9]		Ref.[10]		Ref.[5]		
			g_nf	$g_nf/(g_nf)_{643.8}$	g_nf	$g_nf/(g_nf)_{643.8}$	$A*10^8$	$g_nf/(g_nf)_{643.8}$	gnf	$A*10^8$	$g_nf/(g_nf)_{643.8}$
479.9	3	3	4.9	1.02	0.42	0.23	0.41	0.23	0.41	0.4	0.3
508.5	5	3	12	2.5	0.65	0.38	0.56	0.44	0.72	0.62	0.52
643.8	3	5	4.8	1	1.8	1	0.59	1	1.38	0.45	1

The temperatures at the discharge axis calculated by intensities of cadmium spectral lines with usage of spectroscopic data from Ref. [4] twice and more exceed temperatures obtained with usage of data from other references. Therefore in further these data were not taken into account.

In Fg. 2 the radial distributions of temperatures in the average cross section of the discharge gap l_{ak} = 6 mm in air at arc current 3.5 A obtained by spectral lines of silver and cadmium are shown. It is visible, that the temperatures obtained by AgI and CdI spectral lines are in close agreement.

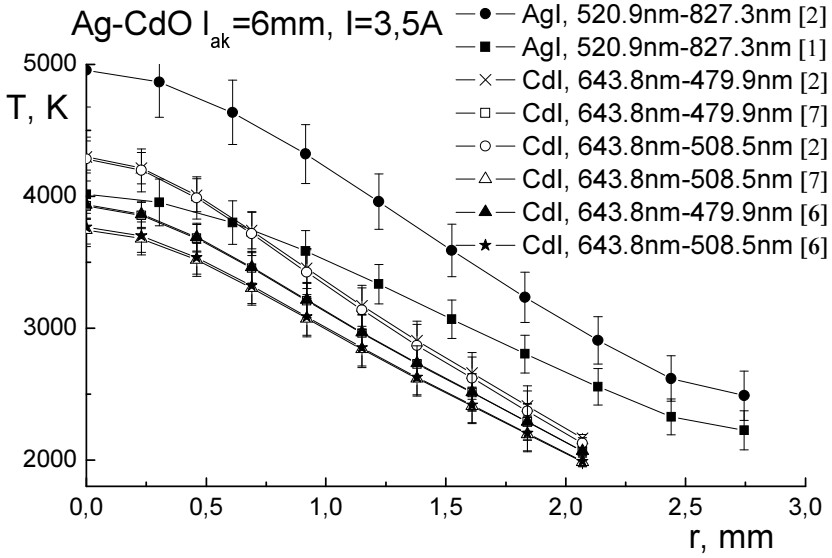

Fig 2. Radial profiles of temperature of arc plasma between composition Ag-CdO electrodes (l_{ak} = 6 mm)

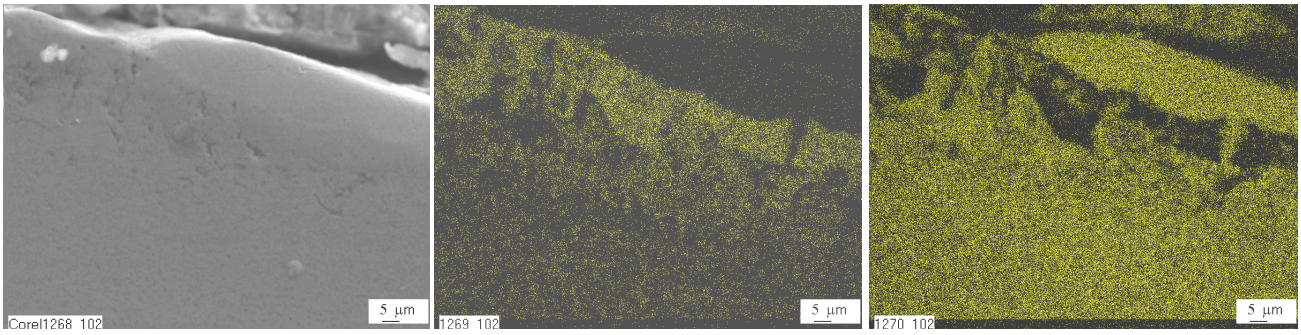
The structural changes in a working layer of electrode take place during the electric current switching. These changes were studied metallographicly (Neophot-2) by a raster microscopy and X-ray spectral analysis of microvolumes of a working layer (JSM Super Probe-733, JEOL). A surface of a working layer and its perpendicular section were investigated.

It was found, that under effect of electric discharge the relief of a surface changes first of all because of melting away of a contact material. The cracks initiation is observed in a working layer on cooling caused by the arc extinction. Some of cracks on the surface «are healed» by a melt on the basis of silver. There is upbuilding of these defects observed metallographicly in a volume of a contacts working layer as the switching cycles number increases. The temperature increasing of a working layer results in a segregation of a composition. The oxide of cadmium is stored in a near-surface layer in defects and in crack edges (see Fig. 3).

Quite often the increasing of this phase concentration is observed because of segregation phenomena near crack face. Lengthy areas of material enriched by silver structurally associated with enriched by oxide composition. At segregation, apparently, there is dissociation oxide of cadmium. It is known that the dissociation temperature of oxide is lowered with a decreasing of the contents of oxygen in a material. However, most probably, these processes are intensified during the melting of component on the silver base or at pre-melting temperatures. The segregation enrichment of crack faces by cadmium or by phase on its base takes place in the solid-phase of the composition.

The structure change of a working layer can exert influence on the mass transfer in an arc discharge gap. The decrease of electrical and thermal conductivity of areas enriched by oxide and fixation of an arc discharge on these parts of surface [11] can promote an overheating of areas of a material enriched by silver and their ejection into a discharge gap. This mechanism of erosion can promote a decrease of temperature of an arc discharge caused by the intensive silver ejection. In this case the electrical erosion of contacts accompanied also by

dissociation oxide of cadmium is increased. The probability of welding together of contacts is increased too. These results do not contradict by the authors of paper [12].



REM (second. electrones) RX Cd Kα RX Ag Rα

Fig 3. Cadmium and silver distribution in working layer of composition Ag-CdO electrodes

Conclusions made on the base of obtained results of metallographic investigations can be compared with results of spectroscopy measurements. In Fig. 4 radial distributions of silver and cadmium spectral line emissions are shown.

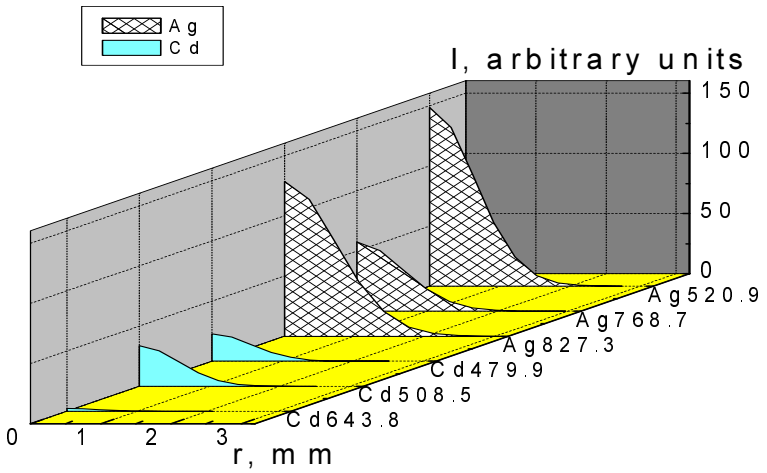


Fig 4. Radial distributions of silver and cadmium spectral line emissions

From such radial profiles the ratio of these atoms in plasma is possible to calculate on the base of obtained temperature profiles. In the assumption of the equilibrium of the energy level population we calculated radial profile of atom concentration ratio of silver and cadmium in the average cross section of the discharge gap l_{ak} = 6 mm in air at arc current 3.5 A. We used relative intensities of spectral lines AgI 768.7nm and CdI 479.9nm. Calculations carried out in such manner indicated that in plasma at the discharge axis the atom concentrations of silver and cadmium approximately equal (see Fig.5).

The next explanation of this parameter behaviour can be suggested.

The mass content of the cadmium oxide in the electrode material is about 10 percents. The approximately equal amount of the atom concentrations of silver and cadmium at the discharge axis can be formed due to the pressure of saturated vapors of cadmium above the electrode surface some orders exceeds the pressure of silver vapors (see Fig.6). The decreasing of the silver fraction at the discharge periphery can be simple explained by geometrical factor.

However, as the ionization potential of cadmium atom (8.99 eV) exceeds this potential of silver atom (7.58 eV), the ionization processes in the channel of investigated arc are determined for the most part by silver atoms.

About that indicates the temperature established in plasma of such arc discharge, which correlates with the plasma temperature of arc between silver electrodes (see Fig.1 and Fig.2). Based on the foregoing analysis of the secondary structure at the surface of the composition Ag-CdO electrodes this results can be quite expected.

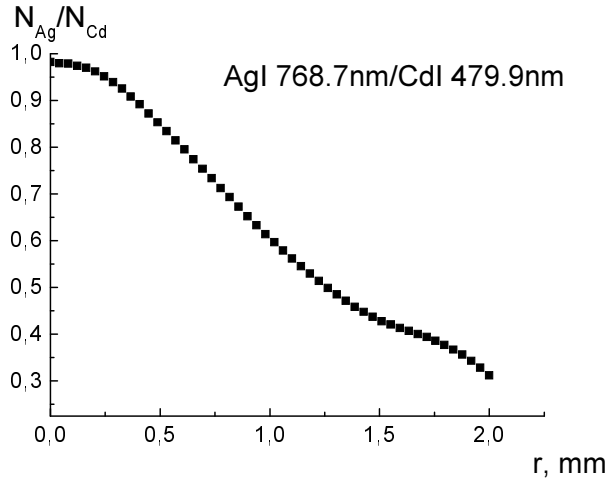

Fig 5. Radial distributions of atom concentration ratio of silver and cadmium

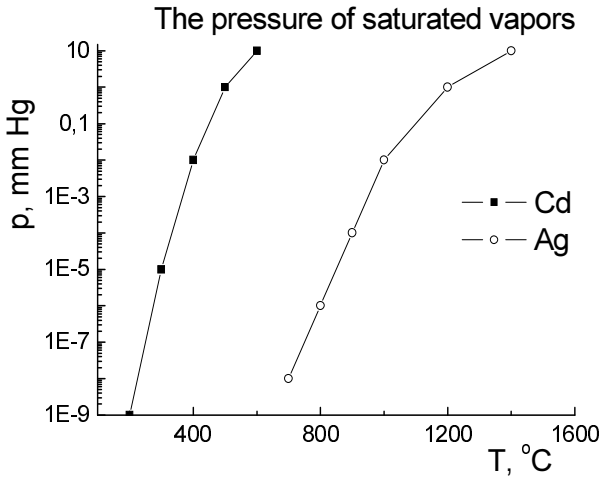

Fig 6. The temperature decencies of the saturated vapors pressure of cadmium and silver

4. Conclusions

Tthe processes occurred in the discharge gap are determined by erosion of the electrode material and condition of its surface. The obtained results allow to make some conclusions concerning of processes of the electrode material erosion in arc. The spectroscopy techniques yield results, which are not at variance with another metallographic technique results.

We for the first time attempted to realize a spectroscopic technique of plasma diagnostic of electrical arc discharges between silver electrodes and composition electrodes on the silver base.

HIGH PRESSURE NON-EQUILIBRIUM RF PLASMA REACTOR

George Paskalov

The Polymet Company, LLC, Los Angeles, California, USA

1. INTRODUCTION

Different plasma technology applications use a variety of plasma reactors and torches. A capacitive discharge has been shown to generate non-equilibrium plasma at atmospheric pressure [1]. In the present study we developed several co-axial plasma reactors with different electrode configurations in order to produce large volume, uniform, non-thermal plasma. Coaxial type reactors have been developed for pollution control applications [2]. Alternating voltages at frequencies up to 100 kHz generated electric field and gap discharges. These discharges spread widely in a fine pattern.

2. EXPERIMENTAL SET-UP

The experimental set-up shown in fig.1 includes an RF generator, plasma reactor, enthalpy probe, spectrum analyzer, gas analyzer, temperature/micro-pressure controller and a data acquisition system. The RF generator was developed with two potential outputs (push-pool schematic diagram), 160 kW RF power at 13.56 MHz working frequency and variable RF output voltage between 0 and 20 kV. Two different types of plasma reactors were tested: planar and co-axial geometry. The cross section of the co-axial plasma reactor is shown in fig.1. The parameters of the reactor are presented in the following table:

Number, i	1	2	3	4	5	6
R_i ,mm	3	9	10	18	20	25
ε_t	80	4	1	4	80	-

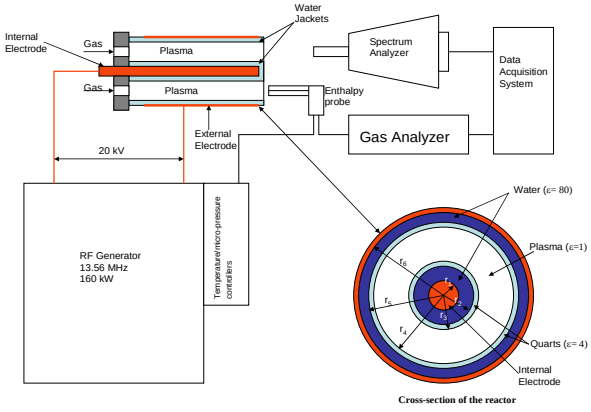

Fig. 1 Experimental Setup

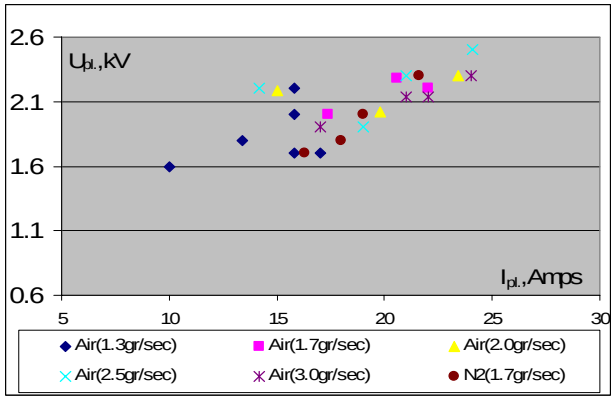

Fig.2. U-I characteristics

Argon, Helium, Nitrogen and small quantities of methane are used as the plasma gas. The gas flow rate was measured by mass-flow controllers. Plasma discharge is self-ignited. An emission spectroscope was used to study the spectrum of plasma radiation and to measure the electron and vibration temperatures. The chemical composition of the plasma gas was analyzed by a residual gas analyzer RGA-500. The gas temperature was measured using the enthalpy probe.

3. Results and Discussion

3.1 Electrical parameters. The equivalent electrical parameters were calculated based on a multi-coaxial capacitor analogy. The electrical field in each layer can be written as: $E_i = U_e/(\varepsilon_i r_i A)$, where U_e –

voltage, ε_i – dielectric penetrability for layer i; r_i – the radius for the layer i; i – is the number of layers; $A = \Sigma_i (\ln(r_{i+1}/r_i)/\varepsilon_i)$. Parameter A was constant and depended only on torch geometry. The radial distribution of the electric field intensity was non-uniform and varied from 48 V/cm to 7620 V/cm. For example, for water cooled reactor and U_e = 5000 Volts the electric field in the plasma gap ($r_3 – r_4$) is about E_3 = 7620 V/cm and E_1 = 317 V/cm. In case of air cooling: $E_1 \sim 25$ kV/cm and could cause sparking in the gap between the internal electrode and the quartz.

The loading impedance was calculated for two regimes: with and without plasma. The equivalent capacitance of the plasma reactor was calculated using the following formula: $C_{pl.} = 2\pi\varepsilon_0\lambda/\Sigma_i ((\ln(r_{i+1}/r_i)/\varepsilon_i)$. The typical reactor's capacitance without plasma is between 5 and 10 pF. After plasma ignition the the plasma reactor's total capacitance changed to approximately 75 pF. The voltage – current characteristics of the plasma reactors is shown in fig.2. As we can see, the influence of the plasma gas flow rate is negligible. U-I characteristics are different for different plasma reactors, but they always have a positive slope ($\Delta U_{pl.}/\Delta I_{pl.} > 0$). The U-I characteristics are similar to those for the positive column of a DC discharge. For non-uniform plasma discharges the U-I characteristics typically have a negative slope ($\Delta U_{pl.}/\Delta I_{pl.} < 0$). Over a wide range of plasma power ($P_{pl.}$) the discharge ($R_{pl.}$) active resistance varies from 50 to 200 Ohms. The ionization and recombination processes define the balance of electrons in the plasma gap. The current density was evaluated by following formula [3]: $j_e = E\,\mu_e\,e\,n_e$, where μ_e – is the electron mobility, n_e – electron density, e – electron charge. Typical experimental j_e were in range of 120 – 400 Amps/cm^2.

The dynamics of atmospheric pressure capacitive discharge was studied for different plasma reactor configuration and gas compositions. The stability of the plasma depends of the plasma gas flow rate and electric field profile. Electric field profile can be change by changing the geometry of the electrodes. Compared to the planar capacitive plasma reactor [1], the plasma, produced by coaxial reactor is much more stable. The stability of co-axial plasma is higher for smaller ratios of R/r, where R and r – are the radius of the external and internal electrodes respectively.

The structure of the plasma discharges depended on the power, torch geometry and plasma gas flow rate. Analysis of the electrical characteristics and visual observations showed that the discharge has a uniform structure at atmospheric pressure. The stability of plasma depended on the plasma gas flow rate and the electric field profile. The velocity and partial pressure profiles (see fig. 3) were asymmetric and depended on the plasma gas injection method: axial or tangential. The most effective condition was found at the ratio: $G_{axial}/G_{tang.} = 4 – 6$. Power losses into electrodes are high, but decrease with plasma gas flow. For example, at $G_{pl.} = 0$ gr./sec, the thermal efficiency of the reactor, $\eta_{pl.}$, is only 30 %. However, at $G_{pl.} > 1.3$ gr./sec the $\eta_{pl.}$ increases up to 60%. The maximum efficiency of the co-axial reactor was 65%.

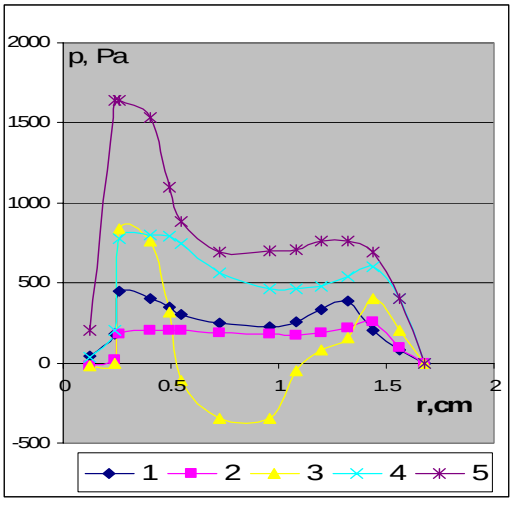

Fig.3 Radial distribution of the partial pressure

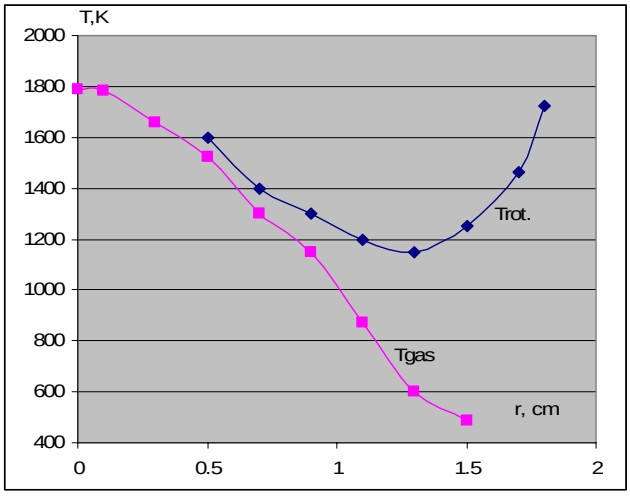

Fig.4 Radial distribution of rotational and gas temperature at plasma discharge power of 28 kW.

In Fig.3 the following curves are shown: 1 – G_{axial} =19 gr/sec + G_{tg} = 8.2 gr/sec; 2.- G_{axial}=11 gr/sec; 3.- G_{tg}=12 gr/sec; G_{axial} = 11 gr/sec + $G_{rad.}$= 8.2 gr/sec; 5. $G_{axial.}$ = 19 gr/sec + G_{tg}= 8.2 gr/sec; 1 – 3 no discharge; 4,5 – discharge.

3.2 Optical characteristics.

Visually the discharge has a volumetric form. At lower power the discharge is located only at the end of the torch. Increasing the power allowed, increased the volume of the discharge making the discharge very uniform. At the same time the sheet space (~ 1mm thickness) became much brighter. The uniformity of the discharge is very sensitive to the plasma gas flow. At higher gas flows the discharge is less uniform. By increasing the power, the stability and uniformity of the discharge can be restored. The plasma energy was 4.5 kJ/gr at the specific plasma flow rate of 0.31 gr./(cm^2 sec).

In order to investigate the influence of discharge parameters on plasma temperature we measured the rotational, vibrational and electron temperatures using spectroscopic methods. We studied the plasma spectrum in the interval of $5000A^0$ – $6700A^0$. Emission intensity was measured by monochromator SPM-2. Analysis of the emission spectra showed that the plasma spectrum content dominantly vibrational-rotational bands of Nitrogen molecules - N_2, Nitrogen Oxide -NO and the radical - OH. The most intensive spectrum is $(+2)N_2$ – second positive system for $C^3\Pi$ and $B^3\Pi$. High level $C^3\Pi$ is at the level of 11 eV compared to the base of $N_2(X'\Sigma^+)$. We did not observed the radiation spectrum of the first positive Nitrogen $(+1)N_2$ (transfer $B^3\Pi$ ---$A^3\Sigma^+$). The above spectrum was intensive for linear capacitive discharge [1]. The evaluation of the rotational temperature $T_{rot.}$ was made based on OH and $(+2)N_2$ spectrum bands. To increase the intensity of the emission spectrum of the OH A-X transition we added a small amount of water vapor to the plasma gas [2]. The radial distribution of the rotational and gas temperatures is shown on fig.4 and 6.

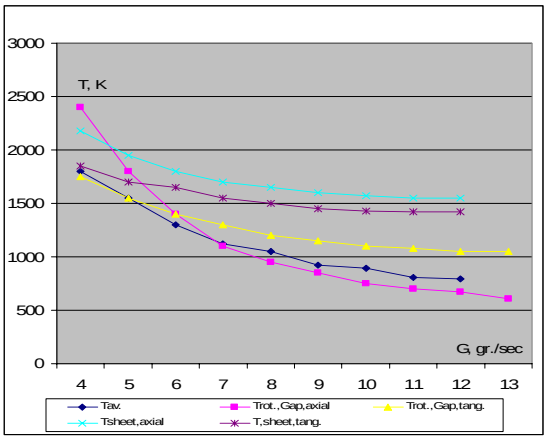

Fig. 5 Plasma temperature vs. plasma gas flow

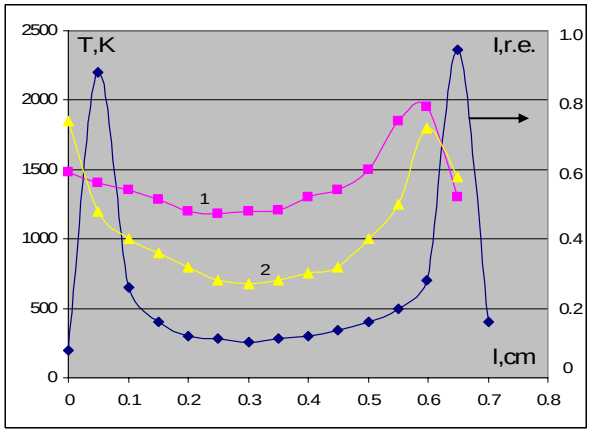

Fig.6 Radial temperature and plasma intensity distribution

The rotational temperature $T_{rot.}$ was determined by analysis of the line sequences intensities $(+2)N_2(\nu' = 0; \nu''=0)$. Rotational temperature was calculated on intensity of band $\Delta\nu = -2$ of the rotational-vibrational plasma spectrum of the system $(+2)N_2$. In the region of the middle of the plasma gap $T_{rot.}$ = 1200K at $G_{pl.}$=2.15 l/min and $P_{pl.}$ = 12 kW. $T_{rot.}$ (See fig 6, curve 1) does not depend on the power, $P_{pl.}$. Increasing $P_{pl.}$ allows a higher intensity of the rotational-vibrational spectrum. At constant plasma power, increasing the plasma gas flow rate, decreases the gas temperature in the middle of the gap up to 900K (Fig.6, curve 2), but does not change in the area under electrodes. The length of the plasma jet was 110 mm at $P_{pl.}$ = 14.3 kW and $G_{pl.}$ = 3 gr./sec. The radial distribution of the gas temperature T_{gas} at the end of the plasma torch is shown in fig. 4. In the interval of power 10 kW < $P_{pl.}$ < 14.3 kW and $G_{pl.}$ = 2.15 gr./sec, the maximum gas temperature is approximately1700 K and decreases if we increase the gas flow. The characters of the $T_{gas}(r)$ and $T_{rot.}(r)$ show that the plasma gas is well mixed at the exit of the torch and there is no significant influence of the

electrical field on the temperature profile. The very narrow high intensity layer is located near the internal electrode. The intensity of the spectrum in the positive column and close to the electrodes is very different.

The radiation profile is practically constant up to $G_{pl.}$= 18 gr/sec and does not depend on the gas plasma input method. The plasma is more uniform for the tangential plasma gas input, but $T_{rot.}$in the plasma column is much higher compared to the axial gas input because the axial velocity of plasma is much lower and residence time for the gas is higher.

Vibrational temperatures around 0.35 eV, were independent of power. In non-equilibrium plasma the spectroscopic techniques couldn't give us reliable data about gas temperature. Gas temperature was measured by an enthalpy probe. In the middle of the region between internal and external electrodes T_{gas} was about 0.1 eV at $G_{pl.}$= 1.3 gr./sec. Changing the power from 5 to 45 kW didn't affect the absolute value of T_{gas}, but significantly changed the emission intensity of the rotational spectrum. The gas temperature in the sheath region was approximately 0.15 eV and was less sensitive to plasma gas flow.

The parameters of the non-equilibrium plasma depend of the electric field, E, cyclotron frequency, ω, electron-molecule collision frequency ν_{e-m} and change of quantity, δ. The effect of the electric field on the energy of electrons is negligible, if $E << E_p$, where $E_p = 4.5x10^{-8}(\delta T_g(\omega^2+\nu_{e-m}^2)^{0.5}$, V/cm. In case of Nitrogen plasma $\delta = \sim 10^{-3}$, T_g = 4000 K, $\nu_{e-m}=\sim 10^{11}$ c^{-1} and $E_p \sim$ 180 V/cm. In our experiments $E =\sim E_p$. Thus, electric fields could have a substantial effect. In simple case δ does not depend on the average electron energy ε, and $\omega >> \nu_{e-m}$: $T_e = T_g(1+0.75E/E_p)$. At $E = E_p$, $T_e =\sim 1.75\ T_g$. Thus, the electron temperature could be very close to the gas temperature. For typical experimental conditions (Nitrogen plasma and high frequency electric field: $\Delta T = T_e - T_g = e^2E_0^2(1 + 0.2\cos\omega t+0.4\sin\omega t)$. Thus, during one period of the electric field, the ΔT is changed from $1.4A^*$ to $1.2A^*$, where $A^* = e^2E_0^2/(3m\ \delta\nu_{e-m}^2)$. Note that $A^*=0.5\Delta T_{dc}$, where ΔT_{dc} is the temperature change in constant electric field ($E = E_0$, $\omega = 0$). At $\omega = 8.5x10^7$ (sec^{-1}), $\nu_{e-m} = 2x10^{11}$ (sec^{-1}), $\delta = 10^{-3}$ and E_0 = 200 V/cm we have $\Delta T =\sim 0.8$ eV. Thus, if $T_g =\sim 0.31$ eV , the T_e will be $=\sim 1.1$ eV. In the above calculations we use the value of ν_{e-m} at $T_e \sim 1$ eV, and assume that $\omega \sim = \delta\nu_{e-m}$. In reality ω is less than $\delta\nu_{e-m}$. Also, ν_{e-m} depends of the T_e. In order to get better results we calculated the T_e using the iteration method and the following formulas:

$\nu_{e-m} = 2.9x10^{-7}[N_2]xT_e(1+T_e^{0.5})^{-0.5}$ and

$T_e = T_g + (e^2E_0^2/(3m\delta(T_e)\nu_{e-m}^2(T_e))x(1 + (1-2\omega^2/\delta\nu_{e-m}^2)\cos2\omega t/(1+4(\omega/\delta\nu_{e-m})^2 + \sin2\omega t/(2\omega/\delta\nu_{e-m} +0.5\delta\nu_{e-m}/\omega)$.

The solution of the above system for our experimental data give us $T_e =\sim 0.8$ eV.

We have tried to evaluate the electron density, n_e , by analyzing of Hydrogen lines (Balmer series), but the intensity of H_β line was very weak. In order to increase the intensity of the Hydrogen lines, we added to plasma gas a small quantity of Hydrogen (less than 0.02% vol). The n_e in the area close to the internal electrode was around 3×10^{19} (m^{-3}) and was much higher than in the area under external electrode, $n_e \sim 2x10^{18}$ It was direct correlation with the electrical field profile.

The coaxial reactor was tested for two applications, such as: laser excitation and water treatment. Plasma water treatment system was developed to decontaminate drinking water and waste water.

Conclusion

Electrical and spectroscopic measurements were conducted to understand the structure and effectiveness of the co-axial plasma reactor. The plasma was thermodynamically non-equilibrium. The difference between electron and gas temperature was around 0.8 eV. Plasma discharge was uniform and stable in the wide range of the plasma gas flow. However, it was no difference between electron, vibrational and rotational temperature at the end of the reactor in the plasma jet.

Self-trapping effect of fast electrons in pulsed non-local plasma sources

Low pressure (<1 Torr) plasma sources utilizing time-modulated power, where the plasma properties of the post-discharge phase are important [1], have recently attracted the attention of a number of researchers. It has been shown that the characteristics of the afterglow plasma, where the electron temperature, T_e, is small, greatly depend on an additional group of fast electrons with large initial energy $\varepsilon_f >> T_e$. These electrons can lead to a dramatic increase in the potential drop between plasma and wall in post-discharge plasma or similar plasmas with external sources of fast electrons [2-4].

It is well known, that the electrons escape the plasma much more faster than ions and charge the wall surface negatively. To maintain the plasma quasi-neutrality, the layer of positive space charge in the vicinity of the boundary surface is formed and it is equalizing the electron and ion fluxes ($j_e = j_i$) to the wall.

In traditional local approximation, the EDF is factorized as $f_0(w,\vec{r}) = n_e(\vec{r})\, f_0^0(w, E/p)$, so the electron distribution over the kinetic energy *w* at a fixed point *r* depends on the local values of the reduced longitudinal field *E p* and other parameters (the gas temperature, the density of excited particles, etc.). In this approach the electron density profile at retarding (negative) potentials $\varphi(\vec{r},t)$ for the Maxwellian EDF is Boltzmann distribution

$$n_e(\vec{r},t) = n_0 \exp\left(-e\varphi(\vec{r},t)/T_e\right), \qquad (1)$$

n_0 corresponds to the plasma density at $\varphi = 0$. Electron flux to the wall is equal to

$$j_{eb} = j_{eT} \exp\left(-e\Delta\Phi/T_e\right), \qquad (2)$$

where the chaotic flux at the plasma-sheath edge $j_{eT} = n_s \bar{v}_e = n_s\sqrt{T_e/2\pi m}$, n_s is the plasma density and, $\Delta\Phi = (\varphi_w - \varphi_s)$ is the potential drop in the sheath. In the surface vicinity the electrons are repelled, and the Boltzmann distribution (1) is invariant with respect to choice of the reference point, where $\varphi = 0$, $n_e = n_0$. It means that in (2) it is possible to replace n_s by n_0 and $\Delta\Phi$ by φ.

The ion flux is formed in quasi-neutral plasma with $n_e \approx n_i = n$. So, it does not depend on the negative $\Delta\Phi$ value, and is referred as the ion saturation current. This flux corresponds to the sum of the diffusion and conductivity fluxes, and at uniform partial temperatures equals to ambipolar flux:

$$j_i(\vec{r},t) = -D_i dn/dr + b_i E_a n = -D_a dn/dr \qquad (3)$$

The normal to the boundary density gradient is to be calculated in the region where plasma is quasi-neutral and collisional, but not too far from the wall in order to consider the particle fluxes as conserving.

The near-wall sheath, which width is determined by the local Debye radius r_D, is collisionless in low-pressure plasmas, i.e. thin with respect to ion mean free path λ_i. The separation into plasma and sheath is, of course, conventional and at distance order λ_i from the boundary surface the charge separation (and the field strength) smoothly increases towards the surface; this region is often referred to, as presheath. The directed ion velocity u_i continuously increases towards the wall up to the sound velocity c_s ($u_i = c_s$) in some distance from the wall. For $r_D < \lambda_i$ it means that the quasi-neutral approximation ($n_e = n_i$) becomes invalid in the vicinity of this point and in the quasi-neutral approximation the electric field diverges here. The transition to the sheath

occurs, and n_e decreases fast toward the wall. This point is adopted usually as a position of the plasma-sheath boundary, and the condition is known also as the Bohm criterion (see, f.e. [5] for details). For electron temperature $T_e >> T_i$ it has simple form

$$u_i = \sqrt{T_e / M} \qquad (4)$$

The plasma density decreases by the factor $\sqrt{e}$ over the last ion mean free path, and according to (1), the potential difference over the presheath is $\approx T_e / 2$. [5]. Therefore, sometimes they say that in a collisionless plasma only voltage of a half of T_e can be applied.

The potential drop in the near-wall sheath, which corresponds to the absence of the net current through the surface, from (2) and (4) is equal to

$$\Delta\Phi_b = \frac{T_e}{e}\ln\left(\frac{\sqrt{T_e/(2\pi m)}}{c_s}\right) = \frac{T_e}{2e}\ln\left(\frac{M}{2\pi m}\right) \approx (3-6)\frac{T_e}{e} \qquad (5)$$

Estimation (5) is widely used in practices (see, f.e. [5]). However, the EDF in the partially ionized plasma is, as a rule, non-Maxwellian. For such EDF in [6] it was proposed to use the Bohm criterion (4) the "screening" temperature

$$T_{sc} = -\left(\partial\left(\ln(f_0)/\partial\varepsilon\right)\right|_{e\varphi_b}^{-1}, \qquad (6)$$

i.e. reduction scale EDF at the energy equal to the potential drop in the sheath $e\varphi_b$. Naturally, for the Maxwellian EDF $T_{sc} = T_e$. In reality the inelastic collisions with frequency ν^* result in the EDF tail depletion with respect to the Maxwellian, so that EDF tail temperature $T_e^* = \sqrt{D_\varepsilon / \nu^*}$ is markedly less then T_e [7] (D_ε is the electron coefficient of diffusion along the energy). Therefore "screening" temperature (6) can be very small even when T_e is large.

The escape of the fast electrons to the wall enhances this EDF decrease. The EDF tail depletion due to the fast electrons escape is efficient only at the distances less than the electron energy relaxation length λ_ε. At low pressure, when the plasma scale L is less than λ_ε, the EDF is non-local (see [7] for details), and the EDF tail is depleted throughout the whole plasma volume. Appropriate "temperature", which can be estimated as $T_{ew} = \sqrt{D_\varepsilon \tau_{df}}$, is also small ($\tau_{df} = \Lambda^2 / D_{ef}$ - time of free electron diffusion to the walls). Thus, the EDF in this case is additionally depleted and "screening" temperature (6) and the potential drop (5) can be very small. That fact that due to these kinetic effects, the wall potential $\Delta\Phi_b$ is considerably reduced, and even can eventually disappear was marked in [8].

For atomic gases in the energy range $\varepsilon < \varepsilon^*$, in which most electrons are concentrated, length $\lambda_\varepsilon = \lambda\sqrt{M/m} > 100\lambda$ (ε^* is the threshold energy for inelastic processes). Therefore the inequality $\lambda_\varepsilon > L$ holds up to relatively high pressures pL<5–10 cm Torr. The electron current density j_w to the negatively biased wall surface is transported only by the high energy part of electron population. The principal distinction with the results of the fluid approach is caused by the fact, that at distances less than the EDF relaxation length λ_ε, the concept of mean directed velocity fails and we cannot represent electric current as the sum of the diffusion and conductivity fluxes like the expression (3) [7]. Electrons with total energy $\varepsilon = w + e\varphi(\vec{r})$ (kinetic plus potential in electric field) lower than eΔΦ are trapped and at these distances do not contribute to electron current. The current in the vicinity of a surface is transported in the form of free diffusive flux of fast untrapped electrons with ε >eΔΦ at constant value of ε. This mechanism can not be taken into account by fluid theory.

The ratio of density of trapped electrons (n_{et}), to density of free (n_{ew}) electrons, can be, in general, be estimated from the condition that the ambipolar flux of ions must equal the free diffusion flux of fast electrons ($n_i D_a / L \sim n_{ew} D_{ew} / L$). Therefore the number of higher energy free electrons is always small ($n_{ew} < 10^{-3} n_{et}$, so that $n_i = n_{ew} + n_{et} \approx n_{et}$). In such a situation, the addition even of a small number of fast electrons with energies $\varepsilon_f >> T_e$ can dramatically change the characteristics of plasma with non-local EDF. This statement is the main point of this paper and presented here results differ significantly from obtained in the framework fluid model with beam electrons [9] and for plasma with bi-Maxwellian EDF [10].

These additional fast electrons can be created by various plasma-chemical volume processes with participation of long-living excited states of atoms and molecules, negative ions, photoionization, etc., or externally injected. Examples of volume processes are Penning ionization of metastable atoms and molecules

$$A^* + A^* \rightarrow A^+ + A + \vec{e}\,, \qquad (7)$$

superelastic collisions of slow bulk electrons with metastable atoms and molecules

$$A^* + e \rightarrow A + \vec{e}\,, \qquad (8)$$

or associative detachment of electrons from negative ions

$$A^- + A \rightarrow A_2 + e_f\,. \qquad (9)$$

Excessive energy in reactions (7-9) is passing to fast electrons e_f and can considerably exceed average energy of electrons and the potential drop (5). For example for Ar metastables (with energy $\varepsilon^* = 11.55\ eV$), the energy of fast electrons $\varepsilon_f \approx 7.3\ eV$ for (7) and $\varepsilon_f \approx 11.55\ eV$ for (8); for O_2 molecules $\varepsilon_f \approx 3.6\ eV$ for (9).

Non-local fast electrons with $\varepsilon_f > e\varphi_b$ are produced in the volume by results from reactions (7-9) and they are lost to the walls due to their free diffusion, i.e. kinetic equation for their EDF $f_{of}(\varepsilon, \vec{r})$ is

$$\nabla D_f \nabla f_{of}(\varepsilon, \vec{r}) = \nabla \cdot j_{ef}(\varepsilon, \vec{r}) = \sum I_j(\vec{r}) R_j(\varepsilon) \qquad (10)$$

In the source terms in (10) $I_j(r)$ are the source intensities and $R_j(\varepsilon)$ are the energy spectra of the reactions (7-9). Because $R_j(\varepsilon)$ is a narrow (like δ-function) peak in energy region of their origin [2-4], then at $\varepsilon_f > e\varphi_b$ density of fast electrons is

$$n_{ef} = I_j \tau_{df} \qquad (11)$$

where $\tau_{df} = \Lambda^2 / D_{ef}$ - time of free electron diffusion to the walls. The physical meaning of these is evident: fast electrons escape on the wall faster then they can relax and loss their energy by collisions in the discharge volume.

The fast electrons flux to plasma boundary with area S can be found via their birth from (10) as

$$j_{ef} = \int_V \sum I_j dV / S\,. \qquad (12)$$

As source term I_j may be determined enough accurately, the balance equation (12) lets easy to find the flux j_{ef}. For example, for reaction (7), $I_p = \beta_p N_m^2$, where $\beta_p \approx 10^{-9}\ cm^3/s$ is the rate of (7) and N_m is density of metastable atoms.

In the presence of additional fast electrons (7-9), the zero current condition is of the form

$$j_i = j_{eb} + j_{ef} \qquad (13)$$

where j_{eb}, j_i and j_{ef} are defined according to Eqs. (2,3,12).

The Eq. (13) determines the potential drop in the sheath as a function of the fast electron flux j_{ef}

$$\Delta\Phi = \Delta\Phi_b + \frac{T_e}{e} \ln\left(\frac{j_i}{j_i - j_{ef}}\right) \qquad (14)$$

The near wall potential jump increases in comparison with the value $\Delta\Phi_b$ (5), calculated at the assumption only bulk electrons, i.e. when j_{ef} is negligible.

In stationary plasma of self-sustained glow discharges the wall potential $e\Phi > \varepsilon^*$ [5], so created in reactions (7-9) fast electrons are usually trapped in the volume and so not contribute in flux on the wall.

In contrast, in the post-discharge plasma T_e falls rapidly so the potential jump (5) decrease also rapidly and it is low with respect to the energy ε_f of additional fast electrons (7-9) . As the densities of long-lived excited states, which determine sources I_j in (10-12), are decreasing slowly, at some time afterglow the flux (12) will equal the ambipolar ion flux (3). The relation (14) become incorrect if j_{ef} is close to j_i and if $j_{ef} > j_i$, in order to maintain quasi-neutrality, part $j_{ef} - j_i$ of the flux of fast electrons must be self-trapped, i.e., the walls will acquire a potential of the order of ε_f / e [2-4]. When this occurs the wall potential, $\Delta\Phi$, will increase from $\Delta\Phi_b \approx 0.1-0.3\ V$ to anomalous large $\Delta\Phi_f = \varepsilon_f / e \approx 3-10\ V$. In this case the trapped electrons with $\varepsilon < \Delta\Phi_f$ cannot escape to the wall and are cooled in the plasma volume by collisions with atoms and bulk electrons (heating the latter) forming a step-like EDF in low energy direction (see [3] for detail). The physical meaning of these is evident: this part of appearing fast electrons trapped in the volume and can not escape to the wall. They relax by electron-electron and elastic electron-atom collisions, e.g. by processes with small energy losses, creating a continuos electron spectra in the region $\varepsilon < \varepsilon_f$.

The fast trapped electrons can lead to excitation from metastable levels and significantly increase the intensity of spectral line emission in afterglow [3,4]. These effects have been experimentally investigated in pulsed rf ICP discharge in Ar. The plasma excitation experiment has been described in detail in [4]. To show the effect of gradual increase in the wall potential, measurements of the time dependence of the plasma potential have been made for different gas pressures (see Fig.1). The transition between regimes of free-flight and partial

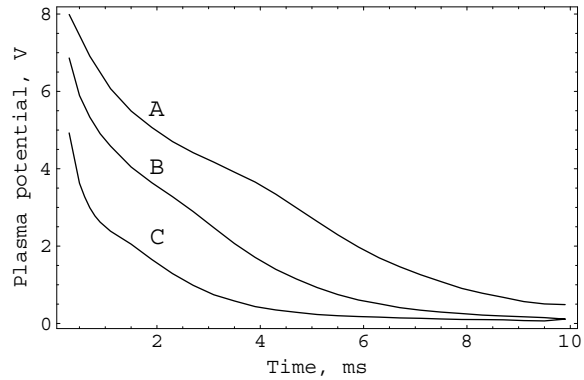

Fig. 1 Time dependence of the plasma potential for different pressure after termination of rf power. Average power is 250 W and rf pulse duration is 100 μs. A – 20 mtorr, B – 10 mtorr, and C – 5 mtorr.

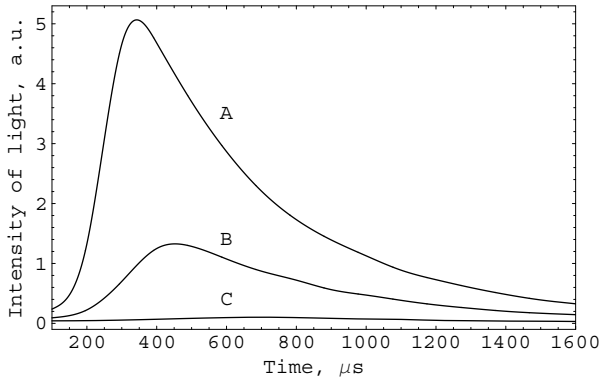

Fig. 2 Intensity of the Ar spectral line 420.1 nm in the afrerglow. Argon pressure is 20 mtorr. (100mks,500 Hz) A – 20 mtorr, B – 15 mtorr, and C – 10 mtorr.

trapping has been observed over a pressure range of 3 to 20 mTorr. During this transition, the wall potential increases from a few tenths of a volt to several volts. We also observe a significant increase in the intensity of spectral lines corresponding to transitions between the argon $3p^5 4p$ and $3p^5 4s$ levels, which is consistent with stepwise excitation (see Fig.2). These experiments demonstrate the presence of self-trapping of fast electrons and the existence of large near-wall potentials in afterglow.

ABSTRACT:

The plasma treatments of two typical volatile organic hydrocarbons (i.e., liquid ethyl acetate and toluene) taken as liquid targets were examined with a particular device consisting of two gliding arc reactors in humid air operated in series.

The strongly oxidising species generated by the discharge and present in the plasma (i.e., the radicals °OH and °ON) are responsible for the degradation of ethyl acetate and toluene with an excellent efficiency. Analysis of the out going gases show that approximately 90% of the total organic carbon disappeared from the system are converted into CO_2 and CO.

Keywords:

non thermal plasma; gliding arc electric discharge; pollution abatement; oxidation ; degradation of toluene; ethyl acetate.

1-Introduction

The occurrence of oxidation phenomena in the natural world is largely identified as it occurs in biological or industrial processes. Among the later ones, the phenomena are largely involved to solve the endemic problems of the wastes treatments [1]. The quantity of mankind provided wastes drastically increases, so that a major question now concerns national and even international authorities: how to control the pollution, and also how to favour its abatement.

Traditional techniques were improved, and new ones were proposed. Among the most promising emerging technique for pollution abatement, the use of on-thermal plasma appears as a side technique close to the Advanced Oxidation Processes. It occupies a special situation which is related to its low cost and high efficiency.

We report here on using electric discharges and in particular, a new "Duplex" system involving two coupled gliding arc discharges for the treatment of Ethyl acetate and Toluene. These organic compounds are generally used as solvents in the industry of painting, inks and varnishes, of the pickling solutions, of the plastics and pharmaceutical. Both Volatile Organic Compounds (VOCs) are hazardous for human health, so that their throwing out is strictly regulated and they must be degraded, in agreement with the local regulations.

The particular plasma technique used is known to be well adapted for removing organic solutes dispersed in aqueous solutions [2-5], because it works at atmospheric pressure and quasi-ambient temperature. It also enables us to degrade non aqueous liquid media, such as spent extraction solvents [6].

2-Experimental data

The selected plasma device retained for the degradation of Ethyl acetate and Toluene involves two closed pyrex reactors (volume: 500 mL), connected by a pipe approximately 5mm in diameter. These matching reactors are intended to degrade respectively the VOCs in aqueous solution (R_1 reactor) and the organic vapours (R_2 reactor) presents in exhaust gases from R_1. The plasma reactors were built on the basis of Czernichowski's work [7] and involved a discharge between two diverging electrodes. An arc forms at the neck between the electrodes and moves along them, as a gas flow is directed along the axis of the reactor. When the feet of the arc reach the tips of the electrodes, the breaks into a plasma plume and a new arc resumes.

The target aqueous solutions were prepared by dissolving 225.05 mgL^{-1} and 228.02 mgL^{-1} of industrial grade VOCs, respectively Ethyl acetate and Toluene.

Analysis of the plasma treated solutions were performed by Total Organic Carbon (TOC) Shimadzu VOC-VE analyser. CO and CO_2 were evidenced at the output of each reactor by means of Dräger disposable test tubes.

3-Experimental Results and discussions

3-1 Kinetics

For the treatment of aqueous VOCs solutions, a problem related to evaporation takes place. In switched off discharge conditions, the amount of organic compound dispersed in R_1 decreases rapidly as it is carried out by the feeding gas flow. Elimination by 50% of toluene and acetate respectively need 7 and 9 mins (Figs.1 and 2).

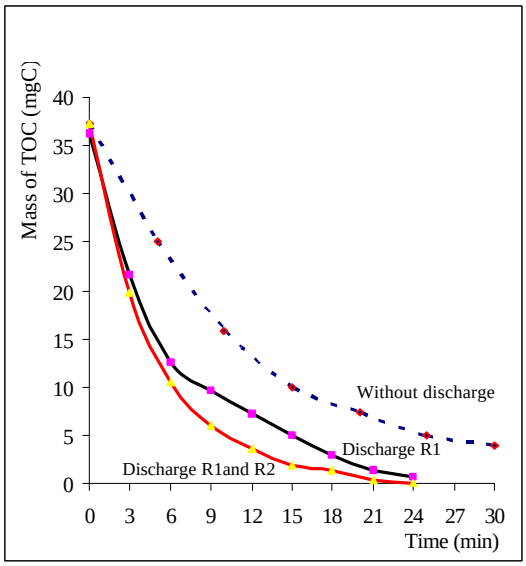

Figure 1: Decrease in the TOC with the treatment time of Toluene

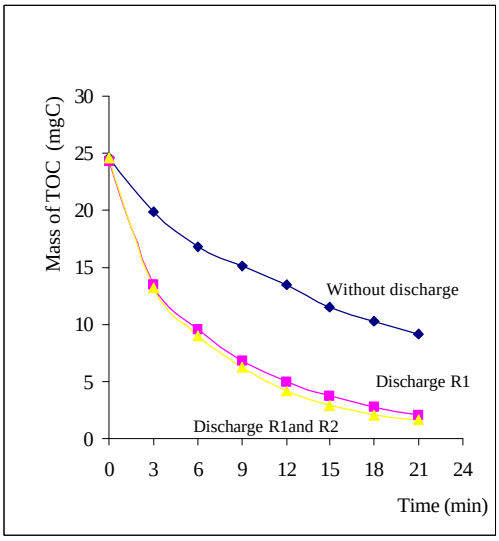

Figure 2: Decrease in the TOC with the treatment time of Ethyl acetate

However, the same pollutant abatement requires around only 3 mins for both VOCs when operating in the simplex mode with the single discharge reactor R_1 (Figs 1 and 2). This feature illustrates the fact that the interaction between the plasma species and the liquid target takes place at the liquid/gas interface. The degradation of the target probably results from the action of the oxidising OH radicals present in the plasma plume.

The exhaust gases of the system were identified by means of specific Dräger reagents. The relevant analysis show that approximately 90% of the total organic carbon disappeared from the system are converted into CO_2 and CO (Figs 3 and 4).

Operation of the reactors R_1 and R_2 in series to improves the effectiveness of the treatment. The contribution of the Duplex system is explained by the rejected CO_x rate (i.e.,90% of ethyl acetate and 80% of toluene) higher than for simplex [i.e., 60% of (Ethyl acetate) and 55% of (Toluene)], and by degradation rate which increases for simplex [i.e., V_1 = 0.1011mgC/min (ethyl acetate) and $V_{1'}$= 0.279 mgC/min (toluene)] to [i.e., V_2= 0.1241mgC/min (ethyl acetate) and $V_{2'}$ = 0.4016mgC/min (toluene)] in Duplex (tab 1). The desired effect of the second discharge is less significant, but not negligible.

Parameters of degradation	Simplex	Duplex
Kinetics constant (mgC/min) (O – 18 min)	Ethyl acetate V_1= 0.1011	Ethyl acetate V_2= 0.1241
	Toluene $V_{1'}$= 0.279	Toluene $V_{2'}$= 0.4016
Pourcentage CO_x	Ethyl acetate 60%	Ethyl Acetate 90%
	Toluene 55%	Toluene 80%

Tableau1: Comparative study enters Simplex and Duplex

Detailed measurements also show that the elimination of VOCs obeys an overall 1st order kinetics, as evidenced by the linear ln C% vs t. plots (Figs.5 and 6).

This feature agrees with diffusion phenomena of the solutes to the liquid surface.

Additionally, the plasma treatment induces a strong and rapid acid effect, so that the pH of unbuffered aqueous solutions is lowered by about 4 pH units within 1-2 minute [8]. This is related to the occurrence of NO radicals formed in the discharge.

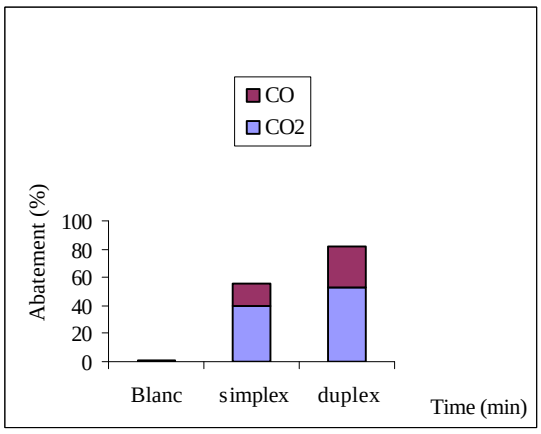

Figure 3: Conversion rate of Toluene into CO and CO_2

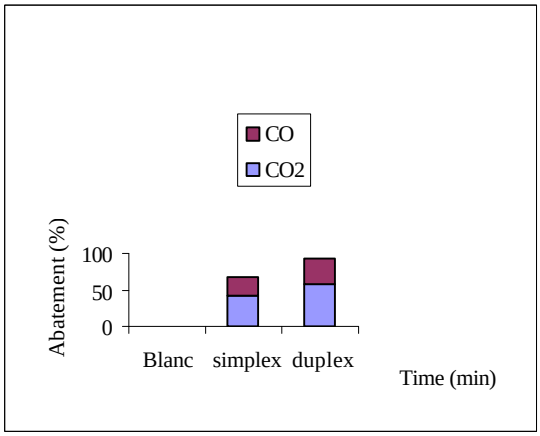

Figure 4: Conversion rate of Ethyl acetate into CO and CO_2

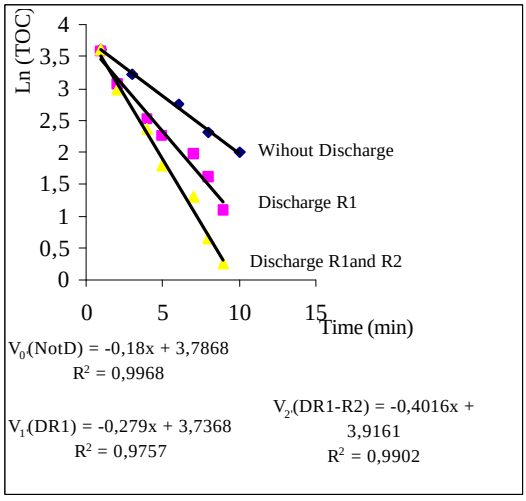

Figure 5: Kinetics of Toluene degradation

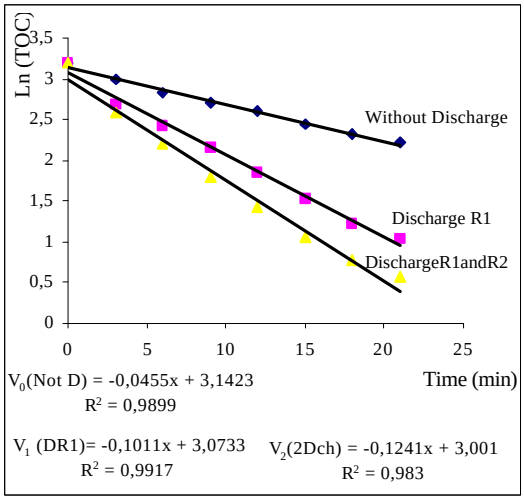

Figure 6: Kinetic of Ethyl acetate degradation

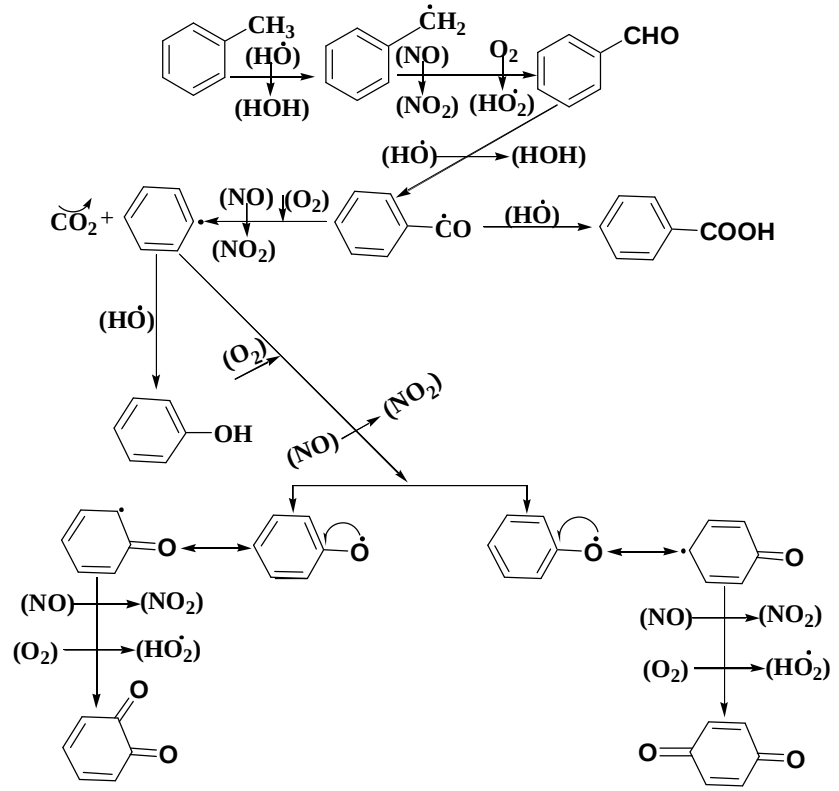
3-2 Suggested degradation mechanisms

The gas selected for this study is humid air. The electric discharge generates radicals, such as °OH, NO°, etc. which are present in the plasma and able to react at the liquid surface with the target molecules. The °OH radicals are the more suitable oxidising agents due to their high potential : E(°OH/H_2O) = 2.85V. OH reacts with the ethyl acetate or the toluene molecules by first removing an hydrogen atom from a C-H group in connection with an initiation step. This phenomenon propagates by a file of oxidation reactions which lead to the formation of intermediate acid compounds (i.e., acetic acid for ethyl acetate or benzoic acid for toluene). These acids then decarboxylate and release carbon oxides.

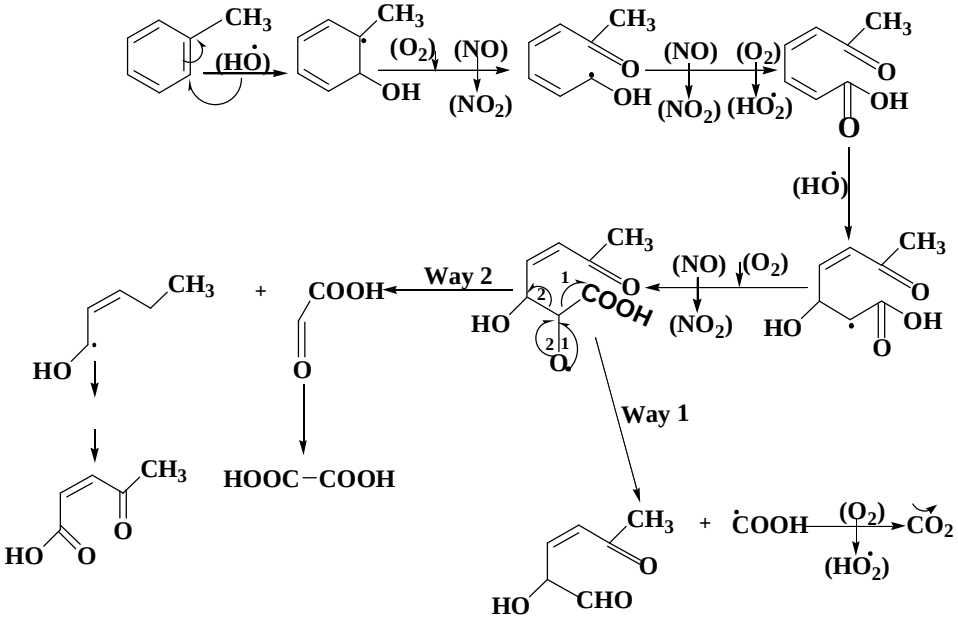
The Hydroxyl radicals will add to the aromatic ring of toluene before opening the ring and leading to intermediate species also able to decarboxylate.

Assumed degradation mechanism for toluene

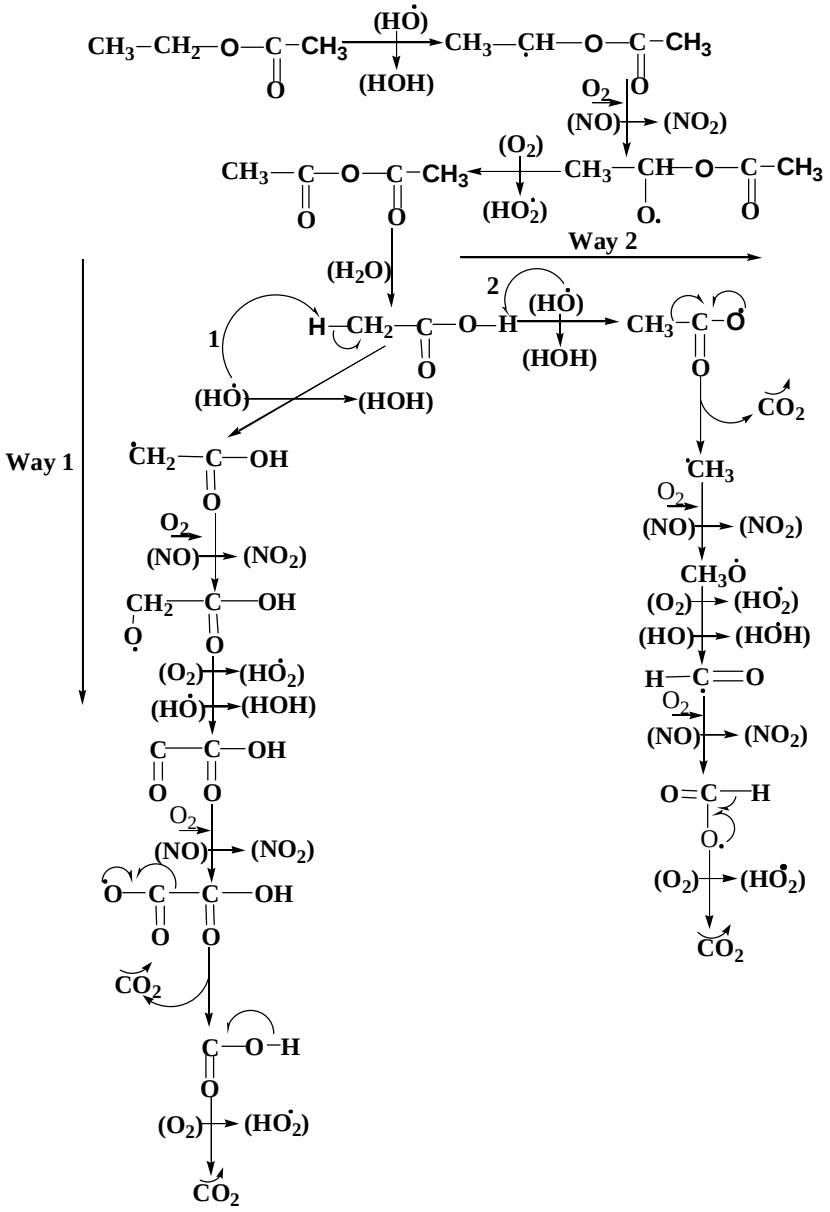
Step I



Step II



Assumed degradation mechanism for Ethyl acetate



4-CONCLUSION

The pollution abatement of aqueous solutions of dissolved VOCs exposed to non-thermal plasma treatments confirms the efficiency of this technique which is evidenced by the short time needed to remove 50% of the solutes. A mechanism involved may be related to the active species present in the plasma, (i.e., °OH and NO°).

This work was intended to limit the quantity of untreated pollutant thrown away in the open. When limited to CO_x degradation parameter, the simplex system alone allows a 60% abatement (i.e., Ethyl acetate), while it reaches 8O% with the duplex system (i.e., an increase by 25%). This increase shows that our Duplex device actually improves the effectiveness of the treatment.

Abstract

Interaction of a transferred arc with an external magnetic field is investigated experimentally. By applying an alternating magnetic field perpendicularly to the arc, the arc root oscillates on the anode in the direction of **IxB**.

The movement of the oscillating arc is observed by a stroboscopic technique. The arc responds to the time varying field up to a frequency 100Hz in the same manner as a static field. Beyond 100Hz, the oscillation amplitude of the arc reduces with the increase of the frequency.

Gas injection to the cathode region with swirling velocity results in the increase of the stiffness of the arc.

The amplitude of the arc oscillation increases proportionally with the increase of the magnetic field. It is confirmed that various pattern of heat flux on the anode can be obtained by changing the strength and the wave form of the applied magnetic field.

1. INTRODUCTION

Various types of plasma torches have been developed to generate a concentrated heat flux. Plasma arcs in a transferred mode are widely used as convenient means to weld or cut metals. However, soft and broad plasma arcs are often required for some material processing such as surface conditioning or heat treatment over a large area[1)].

By applying an alternating magnetic field perpendicular to the arc, the authors developed a system to drive an arc root on a anode back and forth at a frequency of several tens Hz. Schematic illustration for driving plasma arc is shown in Fig.1[2)]. Such an oscillating plasma arc can be regarded as a broad heat source having a width of the oscillation amplitude. By changing the field strength and the wave form, it may be easy to control the heat pattern on the anode. However few studies have been done on the distribution of the heat flux and the arc pressure.

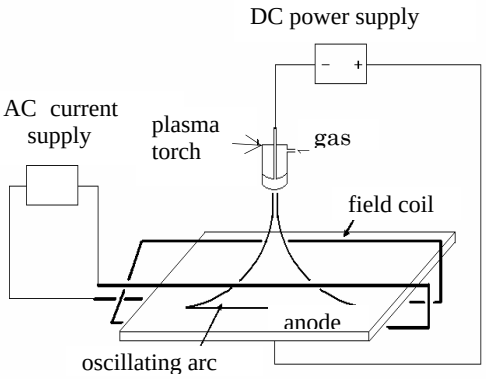

Fig.1 Schematic arrangement to generate the broad arc.

By using a simplified momentum equation, it is known that the displacement of the arc root on an anode is expressed as [1)]

$$X = (1/\beta) - \{(1/\beta)^2 - L^2\}^{1/2}, \qquad (1)$$

where L represents the distance between nozzle exit of a plasma torch and an anode, and

$$\beta = I_a B / \rho_o Q_o u. \qquad (2)$$

In Eq.(2), I_a, B, ρ, Q and u express an arc current, magnetic flux density, plasma gas density, its volumetric flow rate and plasma jet velocity at the outlet of the torch, respectively. Suffix o represents a standard state. If $(1/\beta) >> L$, the displacement of the arc root is proportional to the magnetic field as

$$X = I_a B L^2 / 2 \rho_o Q_o u. \qquad (3)$$

When the applied magnetic field varies with time as $B = B_o \sin \omega t$, it is expected for small ω that

$$X = (I_a B_o L^2 / 2 \rho_o Q_o u) \sin \omega t. \qquad (4)$$

If $(1/\beta) < L$, the second term in the right hand side of equation (1) becomes imaginary. It means that the

arc motion becomes unstable under too much strong magnetic field.

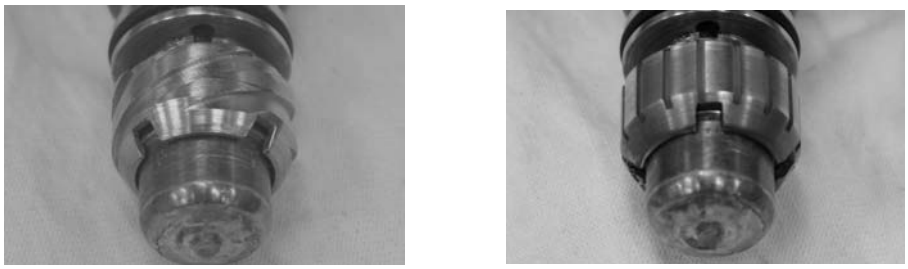
The objectives of the present work are to investigate the arc movement and the heat flow distribution on the anode under various types of alternating magnetic fields.

2. EXPERIMENT

2.1 Plasma torch and power supply for arc

A transferred arc torch with a tungsten cathode is used to generate an oscillating arc. The torch cathode is connected to a DC power supply, which is operated in a constant current mode. The arc current is adjustable up to 120A. Open circuit voltage of the power supply is 280V. Argon gas is used as a plasma forming gas in this experiment. A transferred arc is produced in the open air between the torch and a water cooled copper anode. Typical stand off distance between the torch orifice and the anode is 70mm. The arc is ignited by applying high voltage radio frequency between the cathode and orifice of the torch outlet.

The authors investigate effect of gas injection into the cathode region on the oscillating amplitude. Two types of gas feeders are used for this study. One of them shown in Fig.2 (a) produces swirling flow and the other shown in Fig 2 (b) does straight flow.



(a) **(b)**

Fig.2 Plasma gas feeding guide (a) for swirling flow and (b) for straight flow.

2.2 Magnetic field coil and current supply to the coil

As shown in Fig.3, a two-turns coil with rectangular form is designed to generate a magnetic field perpendicular to the arc.

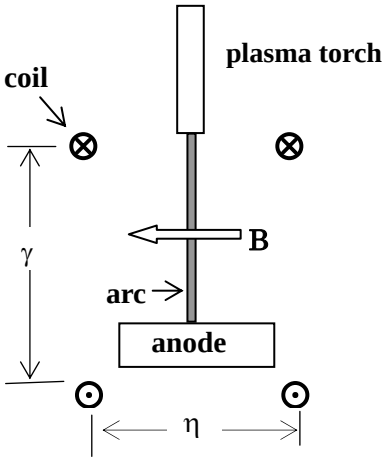


Fig.3 Arrangement of a magnetic coil.

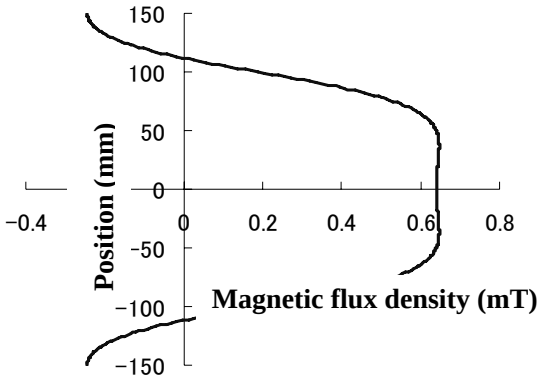

Fig.4 Magnetic flux density along vertical center line

The coil is connected to the current source, which can supply various types of alternating currents such as sinusoidal, triangular and rectangular ones with different amplitude and different frequency. The coil current and its frequency can be changed up to 300A, and up to 1kHz, respectively. One of the examples of the magnetic field strength obtained along the vertical line at the center is shown in Fig. 4 for the coil of γ=200mm and η=100mm, at an electric current of 100A.

2.3 Observation of arc motion

In order to observe the high speed oscillating movement of the plasma arc, the authors used a stroboscopic technique as shown in Fig 2. The arc is observed through the holes of the disk which rotates at a constant angular velocity. In this case, the arc is exposed at a certain time interval τ and an observation frequency, f is expressed as $f = 1/\tau$. If the frequency (f) satisfies the following relation with the frequency of the alternating magnetic field (f_o) as

$$f = f_o / N \text{ , (N; an integer)} \qquad (5)$$

the observer finds the arc in the same position. If the observation frequency is slightly different from Eq.(5) as

$$f = (1 - \alpha) f_o / N, \qquad (6)$$

the arc is observed as if it moves at a frequency of αf_o.

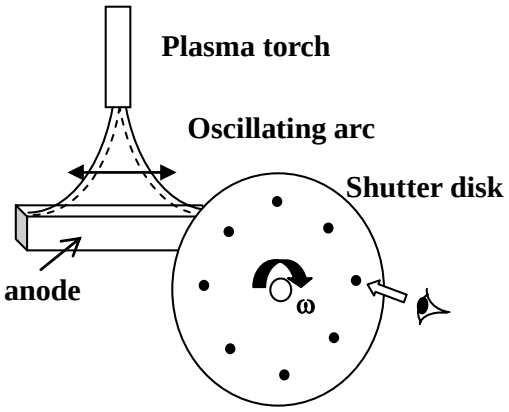

Fig.5 Schematic illustration on the stroboscopic observation of the arc.

If the observation frequency is adjusted to 1% shift from that written in Eq.(5) by controlling the disk speed, the arc movement can be observed as if it moves at a frequency a hundred times smaller than the real one.

2.4 Measurement of heat flux distribution on the anode;

The distribution of the heat flux along the arc motion is investigated by using specially designed copper anode as shown in Fig.6. Its dimension is 200mm (L) and 100mm (W). The anode is divided into several sections through which a cooling water channel passes. Thermocouples are inserted into the water channel at the inlet and the outlet of each section.

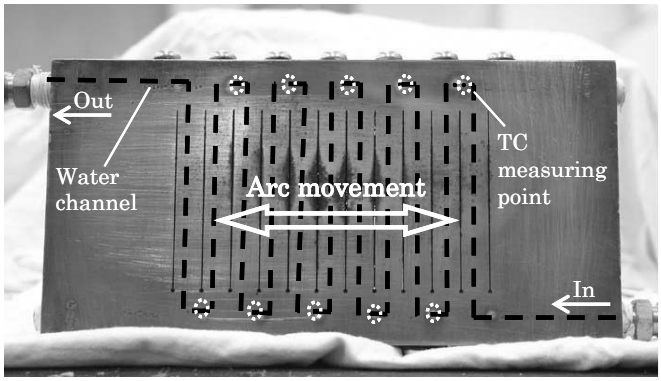

Fig. 6 Water cooled copper anode for the measurement of heat flux distribution.

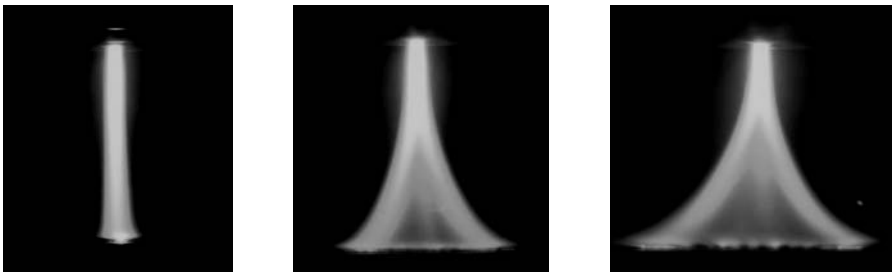
Heat flow from the arc root into each section is evaluated by measuring the temperature increase of the cooling water.

3. RESULTS

3.1 Effect of swirling flow

A stable long arc is obtained under no external magnetic field as shown in Fig. 7 (a). Under the alternating magnetic field perpendicular to the torch axis, the arc oscillates in a plane perpendicular both to the magnetic field and to the torch axis as shown in Fig.7 (b) and Fig 7 (c). The effect of the swirling velocity on the amplitude of the oscillating arc motion is studied by using two different types of the gas feeding guides as shown in Fig. 2. Fig. 7 (b) and Fig.7 (c) illustrate the arc movements with and without swirling velocity, respectively. As is evident from these figures, swirling gas injection leads to the increase of the stiffness of the arc.



(a) **(b)** **(c)**

Fig.7 Plasma arcs: (a) without magnetic field, (b) oscillating arc with swirling gas flow and (c) oscillating arc without swirling gas flow. Plasma gas flow rate is 15NL/min. Arc current is 130A. In the case of (b) and (c), the wave form of the applied magnetic field is rectangular and its amplitude Bo is $3x10^{-3}$ T. The oscillating frequency is 60Hz.

3.2 Variation of oscillation amplitude with magnetic field

Experimental observation reveals that the time response of the arc motion is considerably good. Up to 100 Hz of the magnetic field frequency, the displacement of the arc is not different from that under the static field. When the field changed with time at 200Hz, 10% reduction is observed in the arc amplitude.

The oscillating amplitude of the arc motion increases with the increase of the applied field strength, as shown in Fig. 8. The proportional relationship between the arc amplitude and the magnetic flux density is quite reasonable as the arc movement is caused by the electromagnetic force of (**I** x **B**). However, proportional relation is not obtained between the arc amplitude and arc current.

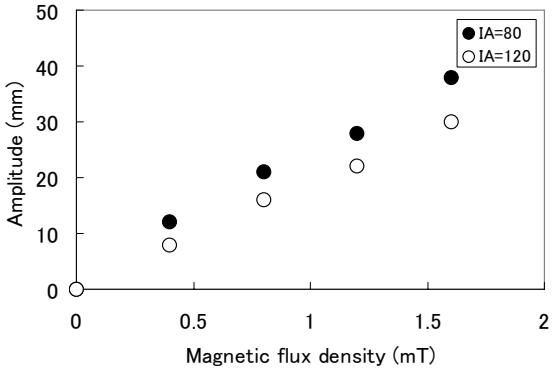


Fig.8 Variation of arc oscillation amplitude with the applied magnetic field .at a frequency of 60 Hz. The flow rate of plasma gas is 7.5 NL/min argon.

It should be noticed that, as is written in Eqs.3 and 4, the arc amplitude is not only proportional to I but also inverse proportional to u. The increase of the arc current, I surely results in the increase of the arc jet velocity, u due to the expansion of the gas volume inside the torch. Therefore the increase in arc gas velocity has negative effects on the deformation of the arc by the electro magnetic force.

3.3 Distribution of the heat flux on the anode

Heat flow patterns on the anode without and with external magnetic field are illustrated in Fig. 9 (a) and Fig. 9 (b), respectively. The flow rate of plasma gas is 15 NL/min in both cases. Applied magnetic field is in the form of triangle with the frequency of 60 Hz. The amplitude of the alternating magnetic field is 20 mT. The arc current is 120A. If the stationary arc is assumed an uniform heat source with the width of 2cm as shown by dashed line in Fig.9 (a), and the arc is driven by an alternating magnetic field with a triangle wave form , expected heat flow pattern should be as shown by dashed line in Fig.9 (b), which is similar to the experimental result.

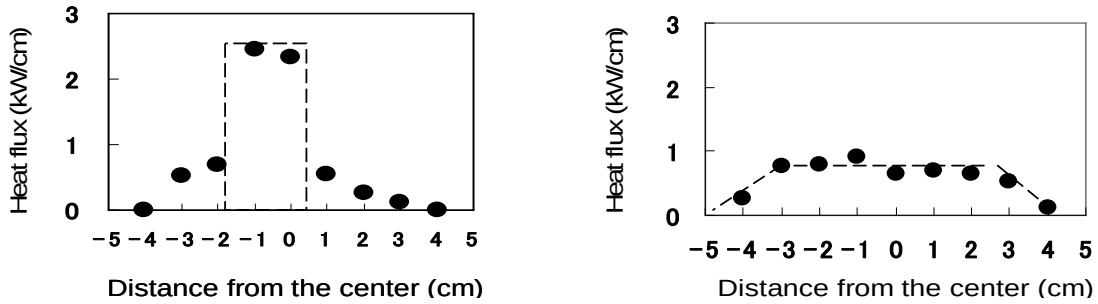

Fig.9 Heat flux distribution along the oscillating arc movement on the anode.

Heat flow pattern can be modified easily by changing the amplitude of the magnetic field and changing the wave form of the electric current supplied to the field coil.

4. Conclusions

Interaction of a transferred arc with an external magnetic field is investigated experimentally. By applying an alternating magnetic field perpendicularly to the arc, the arc root oscillates on the anode in the direction of **IxB**.

The movement of the oscillating arc is observed by a stroboscopic technique. The arc responds to the time varying field up to a frequency 100Hz in the same manner as a static field. Beyond 100Hz, the oscillation amplitude of the arc reduces with the increase of the frequency.

Gas injection to the cathode region with swirling velocity results in the increase of the stiffness of the arc.

The amplitude of the arc oscillation increases proportionally with the increase of the magnetic field. It is confirmed that various pattern of heat flux on the anode can be obtained by changing the strength and the wave form of the applied magnetic field.

QUANTIFICATION OF HYDROXYL RADICALS PRODUCED IN AQUEOUS PHASE PULSED ELECTRICAL DISCHARGE REACTORS

Mayank Sahni, Wright C. Finney, and Bruce R. Locke

Department of Chemical and Biomedical Engineering, FAMU-FSU College of Engineering, Tallahassee, U.S.A.

Abstract

High voltage aqueous phase pulsed corona discharges is an emerging technique in environmental pollutant degradation that is characterized by the production of hydroxyl radicals as the primary degradation species. This paper focuses on quantification of hydroxyl radicals using chemical probes (dimethylsulfoxide (DMSO) and disodium salt of terephthalic acid (NaTA)) that have been extensively used in several other advanced oxidation studies.

1. Introduction

High voltage pulsed electrical discharges in liquids and in gas phases over or near gas-liquid interfaces have been shown to produce highly reactive radicals ($OH\cdot$, $H\cdot$) and molecular species (H_2O_2, H_2, O_2, O_3). Through utilization of these reactive species, primarily the non-selective highly reactive hydroxyl radical and the more selective oxidant ozone, these electrical discharge reactors have been shown to also effectively degrade various organic contaminants such as phenol, nitro and chloro substituted phenol, polychlorinated biphenyls, and trichloroethylene ([1], [2], [3], [4]). The study of the physical and chemical processes that arise due to discharge initiation and investigation of how the bulk chemical reactions are affected by the discharge parameters have resulted in quantification of several reactive species (e.g., H_2O_2, H_2, O_3, O_2) and in increased knowledge of the impact of various parameters (e.g, peak voltage, solution conductivity, pH, type of salt, salt concentration, and presences of additives) on contaminant degradation ([1], [4], [5]). The presence of hydroxyl radicals in electrical discharges in water has been demonstrated by emissions spectroscopy ([6].[7]). To develop knowledge of the fundamental chemical and physical processes occurring in these electrical discharge reactors and to develop quantitative predictive mathematical models of reactor performance it is necessary to obtain accurate quantitative estimates of hydroxyl radical generation by the pulsed electrical discharge.

There have been earlier attempts to quantify hydroxyl radicals generated in water by pulsed corona discharges ([8], [9]). Joshi et al. [8] determined the rate of formation of hydroxyl radicals by using a pseudo steady-state approach utilizing a probe (phenol) and scavenger (carbonate ions) in combination. Varying concentrations of carbonate ions led to different initial conductivity of the solution and this can impact the hydroxyl radical formation. Hoeben et al. [9] tried to quantify the concentration of hydroxyl radicals using electron spin resonance (ESR) and fluorescence spectroscopy. The spin trap 5,5-dimethyl-1-pyrroline N-oxide (DMPO) was used in ESR studies but the authors didn't detect any DMPO-OH adduct due to pulsed corona discharges. Coumarin-3-carboxylic acid (CCA) was used as the probe in the fluorescence experiments but the high background signal in water compared to the fluorescent standards led to hydroxyl radical quantification problems.

In this study we use two different chemical probes to obtain independent and accurate quantitative estimates of hydroxyl radicals generated by the pulsed corona discharges. The probes selected react with hydroxyl radicals with a high rate constant of reaction to generate products that can be detected easily with techniques such as fluorescence spectroscopy and UV detection. The first method to quantify hydroxyl radical uses dimethylsulfoxide (DMSO) that reacts with hydroxyl radical to yield methanesulfinic acid and methyl radical. Several hydroxyl radical quantification techniques focus on the quantification of methane sulfinic acid or the subsequent products methane sulfonic acid and sulfate anions. Another approach is the quantification of the methyl radical or its subsequent oxidation product formaldehyde. Quantification of formaldehyde is achieved by fluorescence detection utilizing Hantzch reaction or by derivatization with 2,4

dinitrophenylhydrazine and subsequent analysis of the hydrazone by HPLC-UV detection. The later approach was followed in this study utilizing a derivatization procedure developed by Tai et al.[10] that was slightly modified for the current application. The probe selected for the fluorescence experiments is the disodium salt of terephthalic acid (NaTA). NaTA react with hydroxyl radicals to form 2-hydroxyterephthalic acid (HTA), that gives a bright stable fluorescence ($\lambda_{analyzing}$ = 425 nm, $\lambda_{excitation}$ = 315 nm)[11]. Terephthalic acid and its disodium salt are extensively used in radiation and sonochemical studies.

2. Experimental

Methods and Materials:
The compounds dimethyl sulfoxide, acetonitrile, sodium dihydrogen phosphate, acetic acid, hydrogen peroxide, potassium chloride, platinum wire (Fisher Scientific), phosphoric acid (Kodak Chemicals), reticulated vitreous carbon (RVC) disk of 1 cm thickness (Ultramet, Pomoma, CA) were used as received from the manufacturers. 2,4-dinitrophenyl hydrazine (Aldrich) was purified by a standard U.S. EPA stipulated method [12]. Desired amounts of DMSO were dissolved in the reactor (concentration = 28.16mM) and oxygen was bubbled for 30 minutes prior to the start and during the experiments. Solutions of NaTA (concentration = 0.5mM) were prepared by stirring in a flask overnight and experiments were conducted by bubbling 400 ml/min of oxygen 30 minutes prior to and during the experiment. The solution conductivity was adjusted to a desired value using potassium chloride before the experiments.

Formaldehyde quantification using HPLC:
Derivatization of formaldehyde was performed with a saturated solution of purified DNPH in acetonitrile. The derivitization procedure featured a reaction of 5 ml of the aqueous solution from the reactor, 5 ml of pH 4 buffer ($NaH_2PO_4 + H_3PO_4$) and 1 ml of saturated solution of DNPH at 40 ºC for an hour. The hydrazone thus formed was equilibrated to room temperature for 30 minutes and then analyzed on the HPLC-UV at 360 nm. The analysis was performed on a Perkin Elmer reverse phase HPLC unit with Supelcosil LC-18 column using acetonitrile and 0.5% acetic acid solution.

Quantification of 2-hydroxyterephthalic acid (HTA):
5 ml of samples from the reactor were analyzed within 8 hours of performing the experiments on a Shimadzu fluorescence spectrophotometer. The excitation wavelength was set at 315 nm and the fluoresence spectra of the sample was collected from 340 to 625 nm. The peak area was quantified for various samples.

Reactor Configuration:
Two different reactors with a volume of 1 liter were used in this work. The reactor setup has been extensively described in previous publications [1,2,13]. Cooling water at 15°C flowed through the jacket to maintain isothermal conditions in the reactor. The reactor was operated in batch mode in both reference and hybrid-series configurations.

3. Results and Discussion
The quantification of hydroxyl radicals in Advanced Oxidation Processes and biological systems using DMSO as the probe compound is popular due to its high solubility, low volatility and large rate constant of reaction with hydroxyl radicals ($k = 4.5*10^9\ M^{-1}s^{-1}$). The pathway of degradation of DMSO upon reaction with hydroxyl radicals has been extensively studied and results in the formation of methyl radical and methane sulfinic acid as the primary intermediate products. Reaction stoichiometry and experimental evidence indicate that 2 moles of hydroxyl radical yield 1 mol of formaldehyde [10].

$$(CH3)_2SO_3 + OH\cdot \longrightarrow CH_3SOOH + \cdot CH_3 \quad \ldots\ldots\ldots\

Experiments were performed to analyze the effect of oxygen gas flowing into the reactor on the production of formaldehyde at an applied voltage of 45 kV and an initial conductivity of 150μS/cm. The methyl radical formed by the reaction of DMSO and hydroxyl radical react with oxygen to form formaldehyde (Reactions 2 and 3) or can abstract a hydrogen atom from organics to yield methane (Reaction 4). It has been previously determined that the reaction 4 consumes only 0.3 to 0.5 % of the methyl radicals [10].

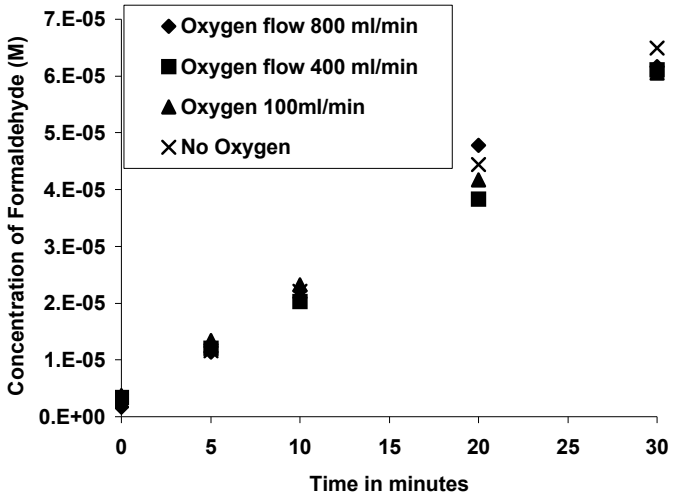

Figure 1. Formaldehyde production as a function of pulsed corona discharge time for different oxygen flow rates through the reactor. (Reference configuration, Applied voltage = 45 kV, Initial conductivity = 150 μS/cm)

Figure 1 shows that there was no change in formaldehyde production by varying oxygen flow rates. The pulsed corona discharge is a source of radical species that can recombine to give various gases (H_2 and O_2). The rate of production of oxygen at an applied voltage of 45 kV is ~$24*10^{-8}$ Ms^{-1}[5]. This result shows that the quantity of the oxygen generated by the discharge that dissolves into the solution is sufficient to quantitatively convert methyl radical into formaldehyde.

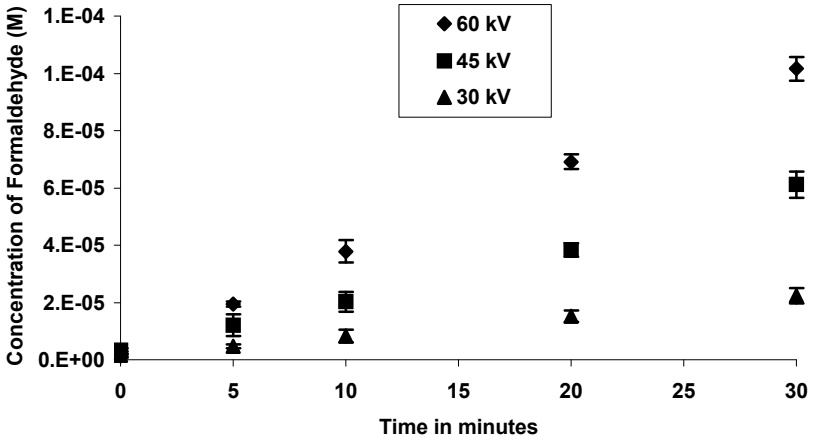

Figure 2. Formaldehyde production as a function of pulsed corona discharge time at different applied voltages (Initial conductivity = 150 μS/cm; Reference Reactor)

The applied voltage of the pulsed corona discharge was varied to test the effect of input power on the generation of hydroxyl radicals. The slope of the production of formaldehyde with time (Figure 2) is utilized to calculate the rate of production of hydroxyl radical as a function of the applied voltage. The input power into the reactor (by calculating the area under the curve obtained by multiplying the current and voltage waveforms) at an applied voltage of 45 kV is 66 J/second.. Figure 3 shows that the rate of production of hydroxyl radicals increases linearly with applied voltage and is qualitatively similar to results in literature [8]. However, the rate of production of hydroxyl radical (at 45 kV applied voltage = $6.70*10^{-8}$ Ms^{-1}) is higher than reported by Joshi et al.[8] (at 45 kV applied voltage (extrapolated from data) = $9.25*10^{-10}$ Ms^{-1}). This difference in hydroxyl radical production can be attributed to various modifications made to the reactor (reactor dimensions, electrode materials and configurations) as well as differences in methodology of measurement. The rate of production of hydrogen peroxide for similar discharge conditions without DMSO in solution is $55.6*10^{-8}$ Ms^{-1}[5]. The probe compounds should act as scavengers of hydroxyl radical thereby preventing the recombination of hydroxyl radicals to form hydrogen peroxide. However, considerable peroxide is still produced when DMSO is used as a probe compound ($42.83*10^{-8}$ Ms^{-1} (this work; data not shown)) thereby leading to the conclusion that either hydrogen peroxide is produced directly from water by the discharge or that hydroxyl radical recombination to produce hydrogen peroxide takes place inside the streamer where the non-volatile probe can't prevent it.

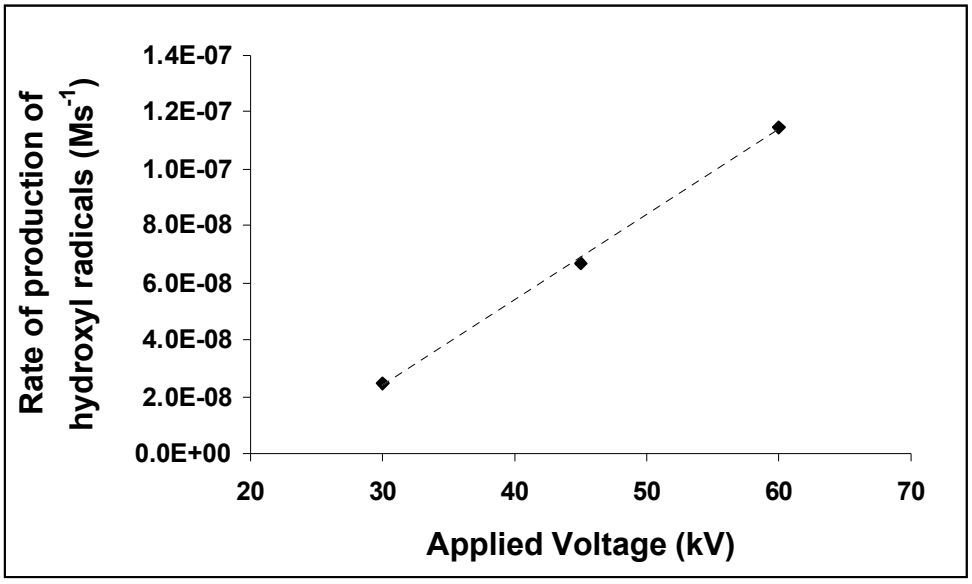

Figure 3. Rate of production of hydroxyl radical as a function of applied voltage.

Reactor modifications have also resulted in the development of hybrid reactor systems. The hybrid reactors employ an additional gas phase discharge that produces ozone and other reactive species. These species can dissolve in the liquid phase and react to produce hydroxyl radicals. Preliminary studies have shown the same amount of hydrogen peroxide generation in the hybrid and reference reactors, however, the degradation of certain organics (phenol and substituted phenols) is considerably faster in the hybrid reactors [4].

To qualitatively demonstrate the difference in hydroxyl radical production in the reference and hybrid reactors the probe compound shouldn't react with ozone. Therefore, DMSO can't be used as the probe compound. The probe compound selected for these experiments is the disodium salt of terephthalic acid that reacts selectively with hydroxyl radicals. Experiments performed in the reference and the hybrid-series reactor at the same applied voltage and initial conductivity show that a considerably higher production of the fluorescent byproduct 2-hydroxy terephthalic acid in the hybrid-series configuration (Figure 4). This implies a larger rate of production of hydroxyl radicals. The additional hydroxyl radicals in the hybrid series reactor can potentially arise from two sources; directly from the discharge at the interface of the liquid and gas surfaces and

from reactive species (such as ozone) formed in the gas phase that dissolve in the liquid phase and subsequently react to form hydroxyl radicals. However, the reaction of dissolved ozone with hydrogen peroxide to produce hydroxyl radical is pH dependent can be ruled out at the pH (~5.5) of these experiments [10].

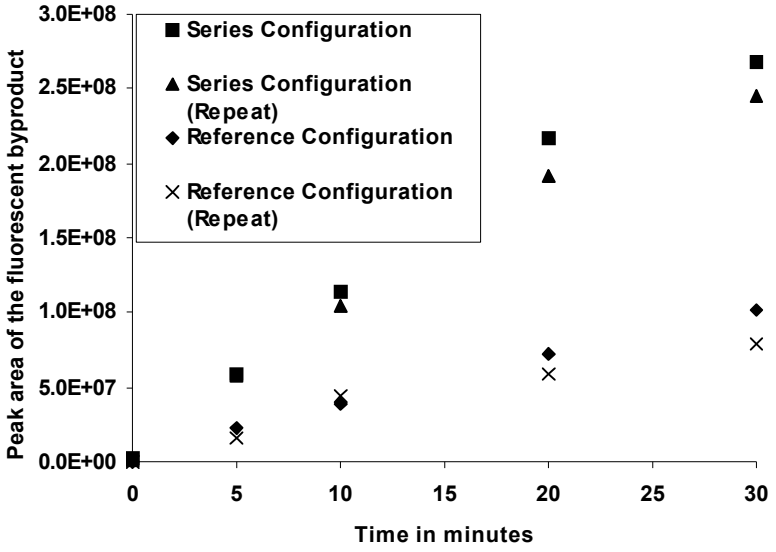

Figure 4. Fluorescent by-product formation in the hybrid-series and reference configurations (Applied voltage = 45 kV, Initial conductivity = 150 μS/cm)

4. Conclusions

The production of hydroxyl radicals by the liquid phase pulsed corona discharges has been quantified using a chemical probe compound DMSO. A linear increase in the rate of production of hydroxyl radicals is observed by increasing the applied voltage. The hybrid-series reactor results in greater production of hydroxyl radical as compared to the reference configuration as seen from the results of the NaTA experiments. This result can partly explain the greater degradation of organics seen in the hybrid reactors.

Abstract

In this work two different plasma techniques have been used to modify chemically the surface of carbon black. In some cases HOPG was used as a model material. Both, low pressure plasma as well as atmospheric plasma, have been proved to be successful to achieve this goal. To characterize the final material specific surface area, pH and acid titrations as well as XPS analysis were carried out. Although cold plasma has some advantages due to a better control of the reaction medium, atmospheric plasma has shown very good results both at oxidation and nitration of the carbonaceous surface.

1. Introduction

Plasma is a very well known technique in order to modify the surface of materials without changing the bulk properties. This is a very interesting possibility as many materials present good performance properties but should improve the interaction with the surroundings. Quite a lot of work has been done on flat surfaces both at low and atmospheric pressure, for example in the case of carbonaceous materials HOPG has been widely used [1,2]. On the other hand, concerning powder materials this technique has not been so extendedly developed.

In the present case the modification is focused on carbon black (CB). This material is known for being the most wide used reinforcement filler in the rubber industry, but it also presents other very interesting applications such as catalyst support or pigment in jet inks [3, 4]. In each of this applications CB is used in different mediums, which present a very wide range of polarity. It should be pointed out that one of the essential characteristics for a successful performance of CB in all of these cases is a good interaction with the surrounding molecules. Some attempts have already been described in literature in order to modify the surface to obtain similar compositions of the surroundings for rubber applications [5,6], oxidation reactions can also be found [7]. In most cases cold plasma was used to modify the material, which was placed on a shacking tray in a bell-jar type reactor.

Cold plasma presents some advantages such low temperatures and higher composition control; however atmospheric plasma is much more attractive to industrial processes due to the lack of vacuum and for being a continuous process. Nevertheless, the difficulty to handle powder materials through such a system does not favour the research work on this field. In the present work both a down-stream reactor as well as an atmospheric plasma torch were adapted to modify CB in O_2, N_2, NH_3 plasma environments.

2. Experimental

The modified CB was a N-134 as described by the ASTM, provided by Sid Richardson Carbon Co. Also HOPG was treated as a model for carbon black surface graphitic domains.

2.1 Treatment Description

The first step is to describe the set-up of the reactors. The cold plasma reactor is made of a glass cylindrical body which ends in two spherical vessels. The plasma is created by means of a copper coil which is coupled to the RF generator (13,56 MHz) through a capacitive impedance adaptor. In the lower vessel carbon black is placed and stirred in order to have homogeneous modification. The vacuum connection is placed at the upper part of the reactor and two cold traps are used in order to protect the vacuum pump and helping to perform a good vacuum. The pressure without modification gas was 10^{-3} mbar while during modification it was kept at 0,4 mbar. Batches of 10 grams were obtained in each experiment.

For the atmospheric treatment an Openair system from Plasmatreat Gmbh, was used. A high voltage discharge is used between two nozzles to create the plasma. A flow of gas (air or nitrogen) goes along the discharge route taking part of the plasma and transporting it to the surface of the material being treated. The plasma torch is usually active up to 20mm long and can reach a treatment width of 15mm. The torch was adapted to a reactor in which the carbon black was introduced by means of a flow of a carrier gas (nitrogen). The CB was introduced 10 mm from the torch origin, this region being described as the most active by the supplier. After the modification, the plasma gas together with the carrier gas brought the modified CB into the collection system. 95% of the powder was recovered and a treatment rate of 1 g/min was achieved. In some cases NH_3 was introduced after the plasma treatment as post-modification gas.

2.2 Specific Surface Area

Specific surface area was measured by using the BET nitrogen isotherm (N_2SA), representing the total surface area. Also the statistical thickness surface area STSA, known as external surface area measurements were carried out in order to study porosity modifications.

2.3 pH and Acidic Titration

The pH from aqueous suspensions of CB was determined as described by ASTM procedures [8]. The acidic groups were quantified and classified by using the Bohem's titration method [9] using NaOH and $NaHCO_3$.

2.5 XPS

XPS measurements were performed both at the surface of CB and HOPG. XPS experiments were performed in a PHI 5500 Multitechnique System (from Physical Electronics) with a monochromatic X-ray source (Aluminium Kalfa line of 1486.6 eV energy and 350 W), placed perpendicular to the analyzer axis and calibrated using the 3d5/2 line of Ag with a full width at half maximum (FWHM) of 0.8 eV. The analyzed area was a circle of 0.8 mm diameter, and the selected resolution for the general spectra was 187.85 of Pass Energy and 0.8 eV/step, and for the fitted (multiplex) spectra was 23.5 of Pass Energy and 0.1 eV/step. Measurements after a light surface cleaning were performed by sputtering the surface with an Ar+ ion source (4 keV energy). These measurements were made in a ultra high vacuum (UHV) chamber pressure between 4x10-8 and 1x10-8 torr.

3. Results and Discussion

Table 1 and 2 show a description of the treatments that were carried out by means of atmospheric and low pressure plasma respectively. Although many other experiments were performed only the most interesting are presented.

Table 1. Atmospheric plasma treatments

Name	Plasma gas	Post-treatment
A-N_2	N_2	No
A-Air	Air	No
A-N_2/NH_3	N_2	Yes (90 L/h NH_3, 10mm)
A-N_2/NH_3	N_2	Yes (90 L/h NH_3, 40mm)
A-HOPG	N_2	No

The post-treatment was done by introducing a flow of ammonia at the given position in table 1, after the CB inlet.

Table 2. Cold plasma treatments

Name	Plasma Gas	Power (W)	Time (min)
C-O_2	O_2	80	30
C-N_2	N_2	80	30
C-NH_3	NH_3,Ar	60	30
C-HOPG/NH_3	NH_3, Ar	60	40
C-HOPG/N_2	N2	60	40

Background reached pressure was 5·10-3 mbar, while working pressure was 0,4mbar.

One of the main concerns about the chemical modification of CB is not to alter any other parameter that may have an influence on its properties. One of the most important parameter to characterize CB is specific surface area, in other words, the amount of surface that is exposed to the surroundings. Obviously if there is a variation in this parameter the activity of CB will also probably change. Another important point is the CB porosity. The porous may have the ability to locate certain compounds or molecules, therefore a change in their size could lead to a different interaction process. Both parameters were studied and in any of the cases the changes were not large enough in order to attribute a variation in CB performance. Table 1, presents the values for the studied parameters. As it can be seen, samples treated in rich oxygen plasma environments present a larger modification of these parameters. This is due to the oxidation process which increases not only the surface area but also the porosity of the carbon black, that is the reason why the external surface area is decreased slightly. However all this parameters still fit in the N-134 ASTM classification, and therefore the effect of this variations is negligible.

Table 3. N_2SA and STSA measurements for original and treated CB

Sample	N_2SA (m^2/g)	STSA (m^2/g)
Original CB N-134	141	131,5
A-N_2	141,4	129,8
A-Air	143,4	126,7
A-NH_3	141,4	129,8
C-N_2	140,3	124,8
C-O_2	143,5	125,5
C-NH_3	141	125

When the pH was measured the presence of other groups was already likable. Table 3 presents the value for the different treatments. As it can be seen in table 3 the CB treated with O containing plasma (air or pure O_2) are highly acidic. The most acidic pH values are obtained by using atmospheric plasma, being this system highly effective for this kind of modification. For the N_2 treatment the decrease of the pH is attributed to the residual oxygen in the plasma reactor.

Table. 3 pH and acidic values for original and treated CB

Sample	pH	Total acidic groups (meq/g)	Strong acid groups
Original CB N-134	9,8	0,02	-----
A-N_2	7,8	0,146	0,02
A-Air	3,2	0,438	0,12
A-NH_3	9,2	-----	-----
C-N_2	8,5	0,051	-----
C-O_2	4,5	0,330	0,08
C-NH_3	9,8	------	------

The pH results are highly related to the acidic titration values. In this case both the total as well as only carboxylic acidic groups were determined. It should be remarked that the presence of ammonia both during the reaction in cold plasma or as post-treatment in the atmospheric system diminishes de oxidation and higher pH are found.

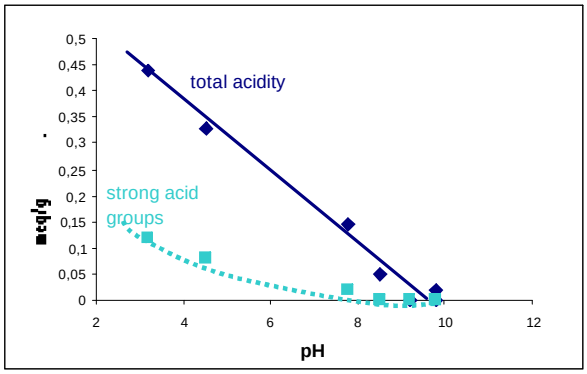

Fig. 1 pH vs. total and strong acid groups

As it can be seen in fig.1, there is a close relation between the amount of acidic groups on the surface and the measured pH. However is it also important to notice that there are not only carboxylic groups but also all other kind of weak acids, as the figure shows is the total acidity value which presents a linear relation between these two parameters.

All the previous described changes have been attributed to a variation in the chemistry composition of CB surface. To confirm this hypothesis, XPS analysis were performed on the most interesting samples. The surface atomic composition was determined (fig. 2,3), the main functionalities for O were also obtained by doing the deconvolution of the respective peaks (table 5), N signal had not enough resolution to make the corresponding deconvolution.

Fig 2,3 show the atomic composition of the CB surface before and after treatment (C,O,N,S) respectively.

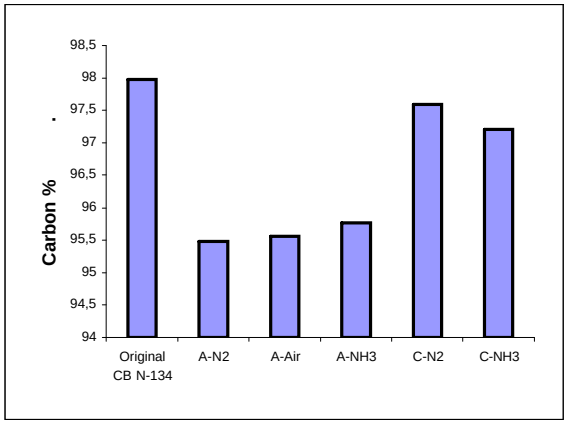

Fig. 2 % atomic C on CB

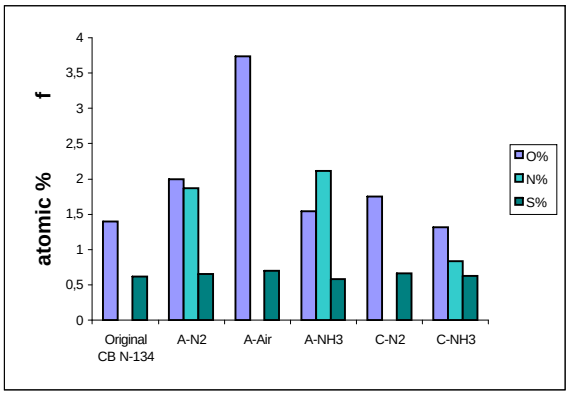

Fig. 3 % O,N,S on CB

Table 5. % of main Oxygen functionalities on the surface of CB

O groups	**N-134 orig.**	**A-N_2**	**A-AIR**	**A-NH_3**	**C-N_2**	**C-NH_3**
C=O	4	21	16	22	16	35
C-O	70	15	17	32	59	43
C-OOH, C-O-C	26	64	67	46	28	23

The peaks were assigned as following C=O 531-531,8eV C-O 532-533eV C-OOH, C-O-C 533-534eV as found in literature [10,11,12]

For this experiments also some HOPG samples were analyzed as shown in table X. When modifying HOPG with N_2 atmospheric plasma (A-HOPG/N_2), no N was detected on the surface. Probably because being in the open air oxidation is a predominant reaction. On the other hand, when modifying HOPG in the down-Stream reactor at different positions, a dramatic increase of the N functionalization was observed when using NH_3 as plasma gas. It has to be said though, that pure N_2 plasma did not modify the chemical composition of HOPG at all. The higher functionalization compared to CB is attributed to the position of the sample which was placed 2 cm below and above as well as in the cooper coil, while the CB is placed 7 cm. Different positions of HOPG did not show any relevant changes in this domain.

The result shows that it is possible using plasma treatments, not only to functionalize the edges of the crystallites, as it happens with the wet treatments, but the whole CB surface. Fig. 5 shows the surface atomic

composition for both samples while table 7 and 8 presents the major O and N functionalities for the cold plasma modified HOPG respectively.

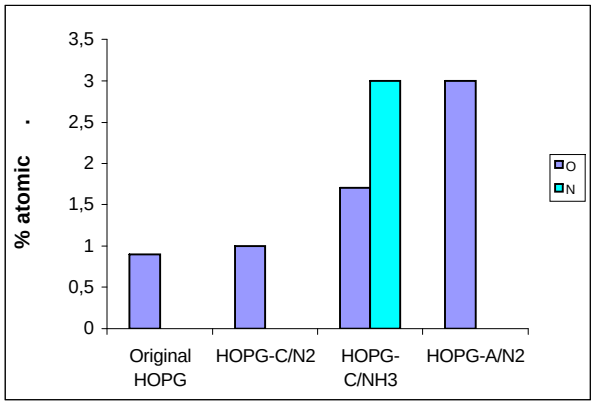

Fig. 5 HOPG atomic surface composition

Table 7. % of main Oxygen functionalities on HOPG

O groups	**HOPG**	**HOPGC/N_2**	**HOPGC/NH_3**	**HOPGA/N_2**
C=O	1,5	1,3	8,6	10
C-O	53	49,5	38	19,5
C-OOH, C-O-C	43,5	49,2	53,4	70,5

Table. 8 % of main Nitrogen functionalities after HOPG treatment with ammonia cold plasma

Sample	**Pyridine**	**Nitrile**	**Pyrrole**	**Graphitic**	**Noxide**
HOPG-NH_3	42	34	13	7	2

The peaks were assigned as following pyridine 398-399 eV, nitrile 400-4005 eV, pyrrole 400,2-400,9 eV, grphitic 4001-402, N oxyde 402-405 as found in literature [13,14,15]

4. Conclusions

CB and HOPG have been shown to be susceptible to surface chemical modification when treated both with cold plasma and atmospheric plasma. This modification has not altered other important parameters such specific surface area or porosity. The chemical modification not only concern oxidation, but also the introduction of various N functions. The treatment could be improved by modifying the position of CB in the cold plasma reactor as well as the gas composition in the case of atmospheric plasma.

Aknowledgements.

We would like to thank Dr. Michel Gerspacher and Dr. Jean-Pol Dodelet for their helpful advices and interesting discussions.

Atmospheric pressure microwave H_2O plasma source

Y. Matsuo, M. Unno, S. Ono
Department of Electrical Engineering, Musashi Institute of Technology, Tokyo, Japan

Abstract
We have developed a microwave H_2O plasma source that operates at atmospheric pressure. The basic characteristics of the plasma have been measured by the spectroscopic method. Electron temperature was about 6100K at the tip of plasma torch. The electron temperature decreases in downstream region, on the other hand, the rotational temperature increases with increasing distance from the torch exit, and these temperatures coincide at downstream region of the plasma.
Keywords:H_2O, Electron temperature, Rotational temperature, OH radical

1. Introduction

Atmospheric pressure microwave induced plasmas have been used for years as means of exciting and ionizing species for elemental analysis, plasma chemistry, plasma surface treatment and electro thermal propulsion[1]. Microwave plasma differs significantly from other plasmas, showing many interesting properties. For example, the electron density is higher in microwave plasma than in radio-frequency (RF) or direct current (DC) plasma, so its reactivity is expected to be very high. However, the pressure range of microwave plasma is very narrow, or the volume of the plasma is very small at high pressure. This is why the microwave plasma has not been utilized in the new materials synthesis in the industry [2].

In the present work in our laboratory, the study of the decomposition of the waste plastics by H_2O plasma at low pressure is carried out, and we have found that the H, O, and OH radicals play an important role in the decomposition of plastics [3]. The cost of the treatment becomes expensive because of need of a vacuum system and complex devices at low-pressure operation. Moreover these apparatus has demerit that can't treat in large enough quantities at once. Therefore we have attempted to generate big volume plasma at atmospheric pressure and to apply it to decomposition of plastics.

In this paper, an atmospheric pressure microwave plasma apparatus that was designed for H_2O plasma source is presented and the experimental results concerning the basic characteristics are shown.

2. Experimental

2.1 Experimental set-up

Microwave power generator is consisting of a magnetron, an isolator, a power monitor and three stub tuners. Microwave power (0～1.5kW) was generated by the magnetron and supplied to the coaxial type electrode through the rectangular wave guide.

A schematic diagram of plasma source we designed is shown in figure 1. The plasma source consists of a rectangular wave guide, a microwave mode converter and a coaxial waveguide. The mode converter connects the rectangular waveguide to the coaxial waveguide with a small reflected wave. The TE_{10} mode microwave which is propagated through the rectangular waveguide from the microwave power generator is converted into the TEM mode at mode converter. The diameters of the center and outer conductor of the coaxial waveguide are 6 and 16mm, the conductors taper off and play roles as electrodes for plasma generation. The microwave plasma jet is generated at atmospheric pressure at the tip of a center electrode and blown into the air by the gas pressure inside the waveguide. Argon-H_2O mixture gas was employed as plasma gas.

A schematic diagram of the spectroscopic system is shown in figure 2. The emission of the plasma is carried through an optical fiber to the multi channel spectroscope (Hamamatsu Photonics PMA-50) equipped with electrically cooled CCD detection head.

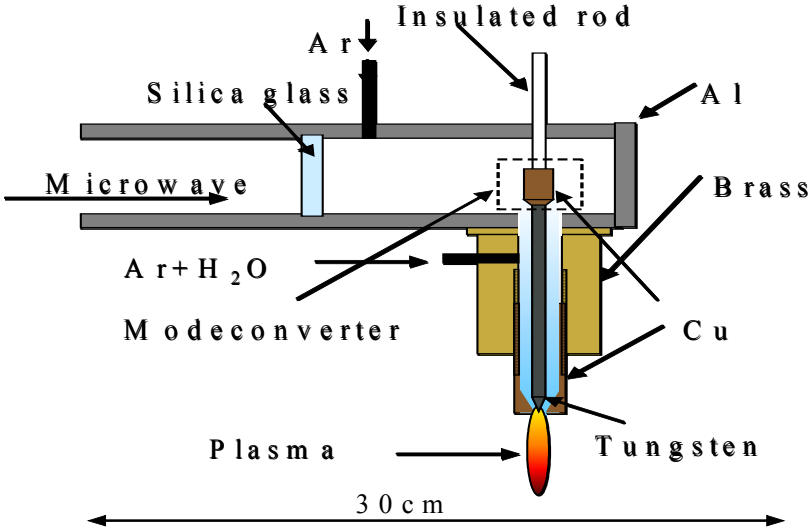

Figure 1. Atmospheric pressure microwave H_2O plasma source

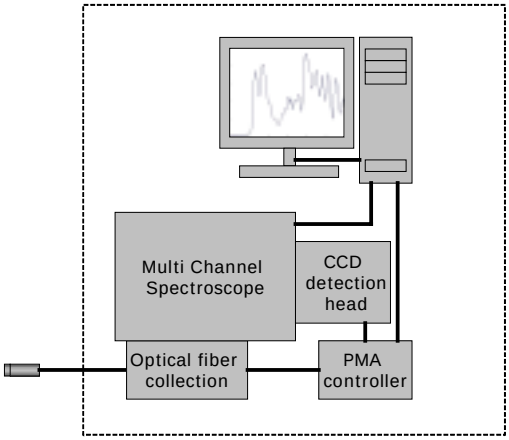

PMA-50 CCD system
Figure 2. Spectroscope system

2.2 Experimental method

2.2.1 Gas temperature measurements [4][5]

Gas temperature is generally close to the rotational temperature of a diatomic gas. Therefore we measure a rotational temperature of OH radicals by spectroscopic method. OH rotational temperature was estimated by using OH[$A^2\sum^+ - X^2\Pi^-$(v', v'') = (0, 0)] emission of the plasma. The experimental spectrum are compared with synthetic spectrum calculated from accurate experimental data of lines intensity $I_{J'J''}$(3000) of Lyman and by Dieke and Crosswhite obtained at 3000K for the rotational band OH. Using their results and equation (1), we can calculate the relative intensity of each rotational line $I_{J'J''}$ *(Trot)* through the following expression:

$$I_{J'J''}(T_{rot}) = I_{J'J''}(3000)\exp\left(-\frac{F_{v'}(J')(3000-T_{rot})}{3000T_{rot}}\right) \times \frac{Q_{rot,v'}(3000)}{Q_{rot,v'}(T_{rot})} \qquad (1)$$

Where $F_{v'}(J')$ is the energy of the upper rotational level J' and $Q_{rot,v'}(T_{rot})$ is the rotational partition function of the upper vibrational level v'. It should be noted that only the shape of different rotational spectra as a function of T_{rot} is relevant for this work. The term $Q_{rot,v'}(3000)/Q_{rot,v'}(T_{rot})$ is the same for all rotational lines issued to the upper vibrational level v'. From that point of view, this term is normalized to 1 in the evaluation of expression (1). The shape of the synthetic OH spectra varies as a function of rotational temperature due to variation of population density of concerning energy levels.

2.2.2 Electron temperature measurements [6][7]

Electron temperature was measured by LTE based measurement of high lying levels of recombining plasma because this plasma is a flowing afterglow, typical recombining plasma. Relative electron populations in excited states are generally described by the Boltzmann distribution. Therefore we can obtain the electron temperature from Boltzmann plot by using optical emission of argon (the parameters of these lines are shown in table 1).

Table 1. Argon spectrum line parameter

λ [nm]	E_k[cm^{-1}]	g_k	A_{kj} [$\times 10^8$s^{-1}]
425.9	118871	1	0.0415
426.6	117184	5	0.0033
427.2	117151	3	0.0084
430	116999	5	0.0039

3. Results and discussion

3.1 Axial position dependence of gas temperature Tg and electron temperature Te

The results for T_g and T_e are show in figure 3 at four axial locations of 1, 5, 10, 15 mm from the top of the touch. The electron temperature decreases toward downstream region, on the other hand, the rotational temperature increases with increasing distance from the torch exit, and these temperature shows coincide at downstream region of the plasma. This phenomenon can be attributed to the electron collision with heavy particles that results in energy transfer.

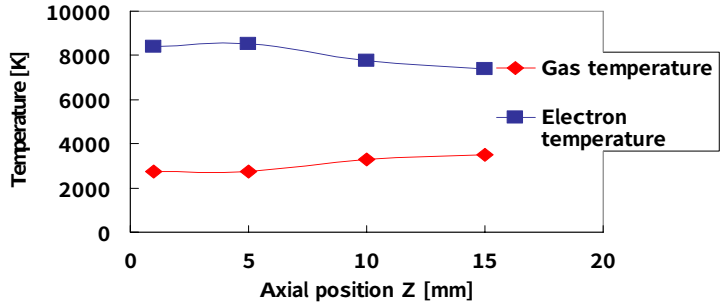

Figure 3. Axial position dependence of temperature (Ar 10 l/min, H_2O 1.2 l/min, Power 150W)

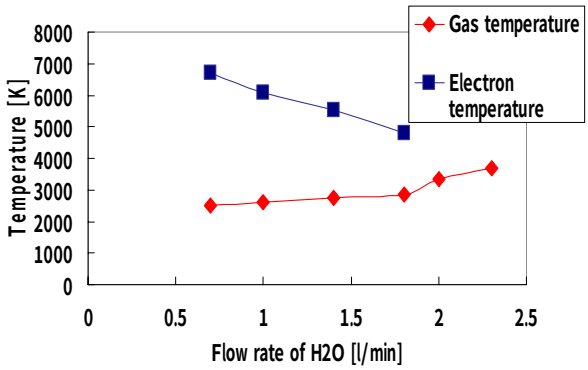

Figure 4. H_2O flow rate dependence of temperature (Ar 10 l/min, Z=10, Power 150W)

3.2 H_2O flow rate dependence

T_g and T_e dependence of H_2O flow rate are shown in figure 4. We observed, when the H_2O flow rate increases, that the electron temperature drastically decreases. It is thought that this phenomenon originates in the increase in the inelastic collision of electrons and the molecules of water. On the other hand, the gas temperature slightly increases with increasing H_2O flow rate. Since the percentage of water molecule increased, this tendency is considered to be the result from which electronic energy was efficiently transformed into the energy of translational motion of the molecule.

3.3 Microwave power dependence

T_g and T_e dependence of microwave power is shown in figure 5. We observed that gas temperature and electron temperature were not change with increasing microwave power. Dependence of the optical emission intensity of Ar, H, O, OH are shown in figure 6. These intensities increase with increasing microwave power. It is thought that the increased microwave power causes the increasing of

electron density from this result.

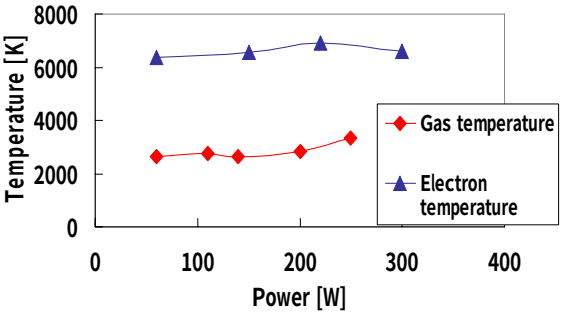

Figure 5. Power dependence of temperature (Ar 10 l/min H_2O 1.4 l/min Z=10mm)

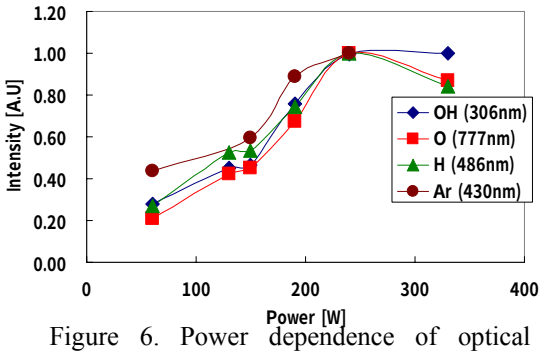

Figure 6. Power dependence of optical emission intensity of OH, O, H and Ar (Ar 10 l/min, H_2O 1.4 l/min Z=10mm)

4. Summary

Development of the source of water plasma that operates with an atmospheric pressure was performed. The fundamental characteristic of the generated plasma was clarified by the spectroscopic measurement. To use this plasma for recycling of a waste plastic is desired.

Abstract

Magnetic field of permanent magnet placed directly under the substrate can locally change the growth of hydrogenated silicon during the low deposition temperatures PECVD. A small permanent magnet with poles parallel to the substrate led to microcrystalline spot formation in otherwise amorphous film. Perpendicular placed magnet led to a microcrystalline ring formed at the magnet edges.

Keywords

plasma enhanced chemical vapor deposition - PE CVD, magnetic field, hydrogenated microcrystalline silicon (μc-Si:H), hydrogenated amorphous silicon (a-Si:H), growth, deposition process

1. Introduction

Attempts to modify silane plasma between electrodes by magnetic field to improve the quality of deposited films were reported already in 1980 [1]. Unlike the previous work [2] where the magnetic field was applied at RF powered cathode, we placed a small magnet on the opposite electrode, directly under substrates. Magnetic field influences distribution of charged particles in the silane plasma above the substrate and thus also the Si film growth. Magnetic field effects depend on the magnet orientation (parallel or perpendicular to the substrates, see insets of the Fig. 1).

2. Experimental arrangement

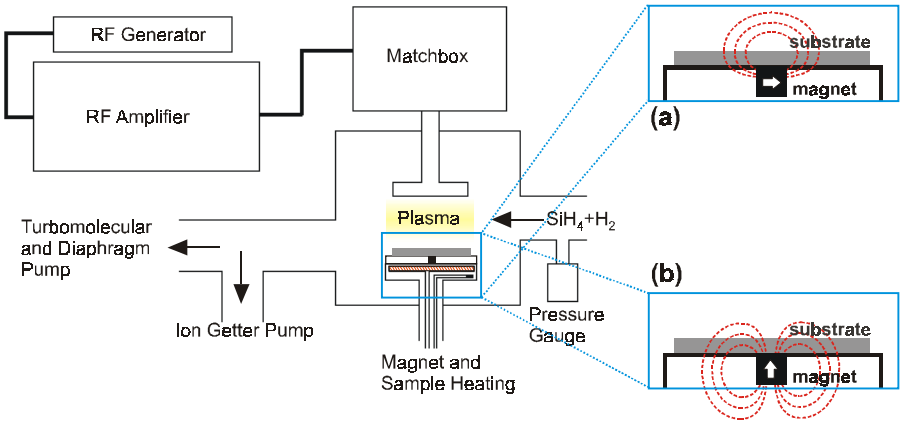

Fig. 1. PECVD deposition set-up. Insets show the detail of the magnet placement in the substrate holder.

We used standard PECVD technique of hydrogenated silicon films in an UHV chamber pumped by turbomolecular and diaphragm pumps (see Fig. 1). The glow discharge between two electrodes (diameter 80 mm, separated by 18 mm) was excited by RF generator at 13.56 MHz frequency and power 9 W. The mixture of H_2 and SiH_4 with 3 % SiH_4 and total flow rate about 52 sccm was led via the chamber at pressure 70 Pa. Films were deposited on Corning C7059 substrates with 0.9 mm thickness. Substrates were placed on the floating electrode kept at 100 °C. Magnetic field was induced by permanent magnet with dimensions 4 x 4 x 4 mm and field strength 0.4 T at the pole and 0.1 T at the side. We used an atomic force microscope (AFM – Veeco Dimension 3100) to study surface morphology of the films. Local crystallinity of the films was measured by the microscopic Raman scattering spectra excited by CW argon ion laser at 514.5 nm wavelength.

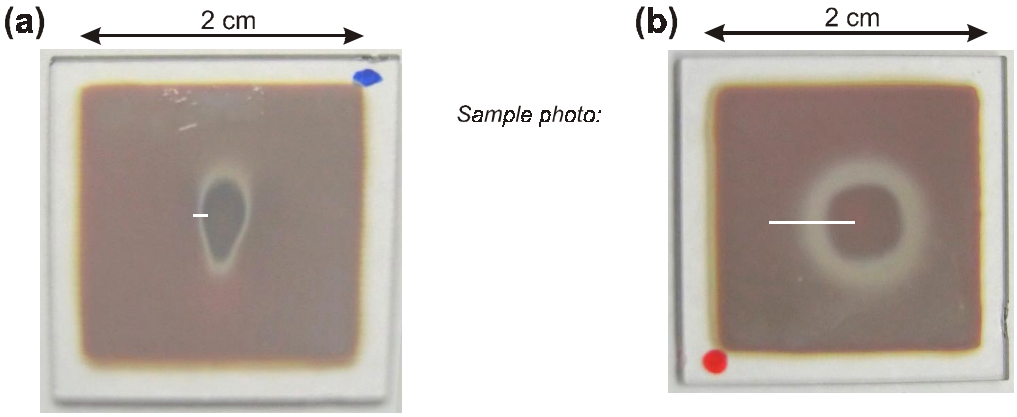

Fig. 2 Two samples of Si thin films. Films grew amorphous except in the region above the magnet. In case of magnetic field parallel with the substrate microcrystalline spot was formed (a). In case of magnetic field perpendicular to the substrate (b) microcrystalline ring with amorphous center was formed.

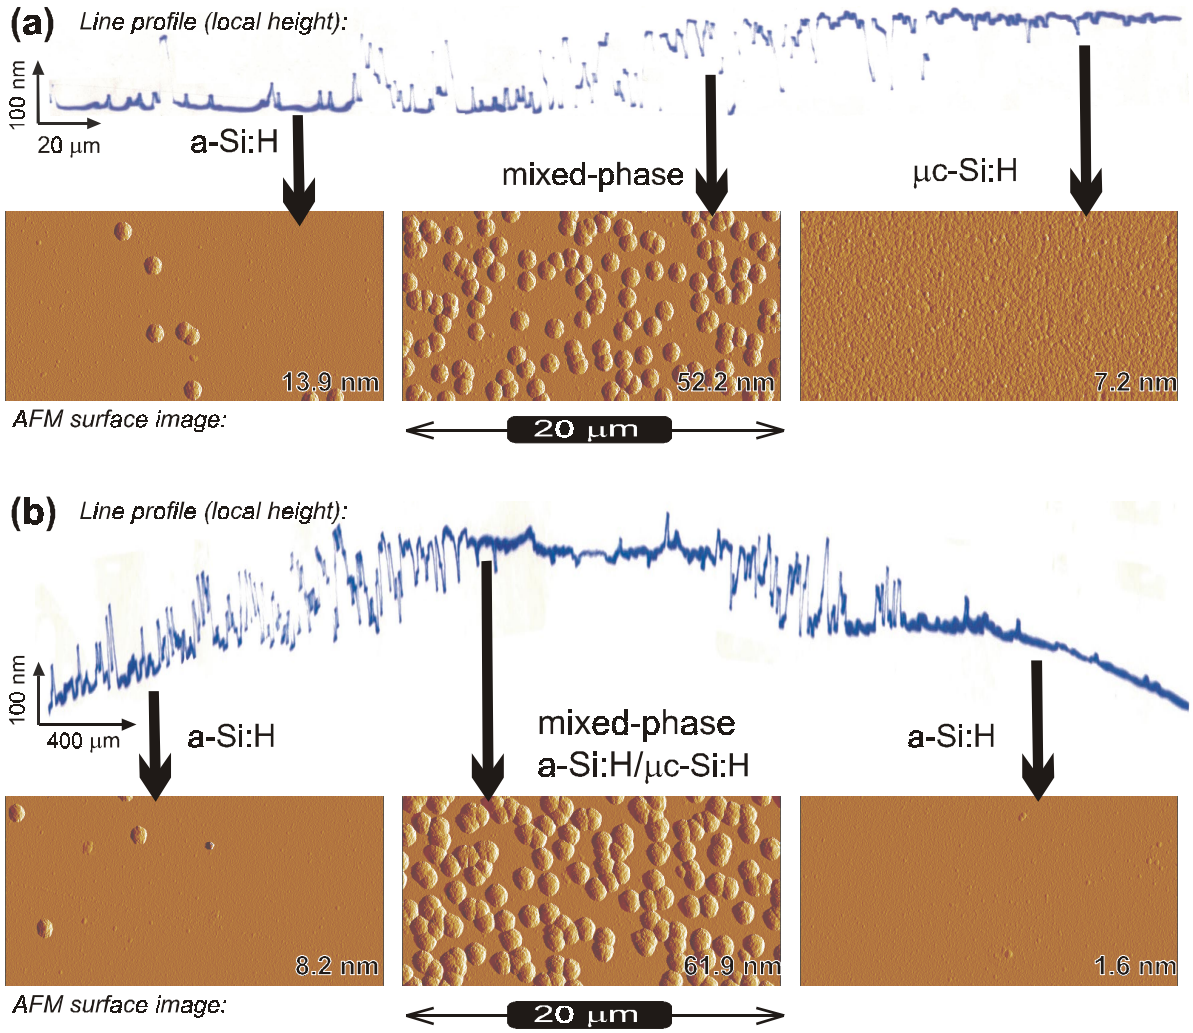

Fig. 3 Surface profiles and morphologies of the Si films. Positions of the surface profiles are shown in the Fig. 2 by white horizontal lines. The profiles show that the microcrystalline and amorphous areas of the film differ not only by their structure, but also by their thickness. AFM morphologies at selected positions of the profile show the different densities of the microcrystalline grains.

3. Experimental results

Deposition at the selected conditions normally leads to amorphous films, however, presence of the magnet locally changes the plasma and results in formation of microcrystalline regions, as evidenced by Raman spectra [3]. The changes of film structure are visible by naked eye (see also Fig. 2). The most conspicuous is the matt boundary between the area above the magnet and the rest of the film. The boundary between amorphous and microcrystalline regions scatters light due to the large surface roughness of the mixed phase film [4, 5].

Structure of the films depends on the orientation of the magnet with respect to the substrate surface. In case of magnet parallel with the substrate, the film above it grew fully microcrystalline, see Fig.2a. When the magnet was perpendicular to the substrate, the film directly above it was amorphous, but a microcrystalline ring along the edge of the magnet appeared. Transitions between the two phases are illustrated by AFM micrographs in Fig. 3.

Fig. 3 shows also the surface height profiles measured by stylus method for both cases. The thickness of the surrounding amorphous film after 2 hour of deposition was 1 μm, but the microcrystalline regions were on average 16 % thicker. About the same difference in thickness was observed between the microcrystalline and amorphous parts for both magnet orientations. Note that the amorphous center of the spot in Figs. 2b and 3b is less thick then the μc-Si:H ring around it and has approximately the same thickness as the surrounding a-Si:H.

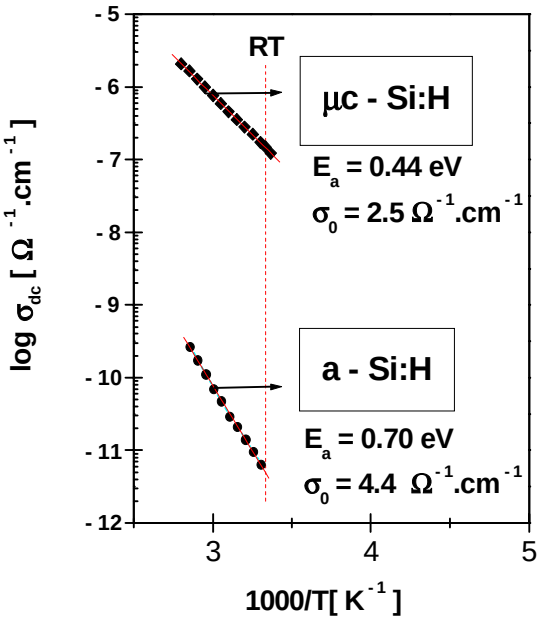

Fig. 4. Arrhenius plot of the temperature dependence of the dark conductivity for μc-Si:H spot grown above the magnet parallel to the substrate (see Fig. 2a) and for surrounding a-Si:H.

The difference in structure leads also to corresponding changes of material properties, illustrated here by the difference in the dark conductivity between the μc-Si:H spot and surrounding

a-Si:H, shown in the Arrhenius plot in Fig. 4. Conductivity of the a-Si:H at room temperature was about $7x10^{-12}$ $\Omega^{-1}cm^{-1}$ and its activation energy E_a = 0.7 eV, corresponding to standard device quality material. However, the microcrystalline spot above the magnet exhibited dark conductivity $2x10^{-7}$ $\Omega^{-1}cm^{-1}$ and activation energy E_a = 0.44 eV.

4. Discussion

The above described phenomenon may lead to important technological applications. Reduction of the deposition temperature of silicon films would enable industry to deposit microcrystalline hydrogenated silicon on flexible organic substrates such as PET. However, lowering the deposition temperature also leads to crossing the border between μc-Si:H and a-Si:H growth [5, 6]. Parallel magnetic field could make it possible to maintain the growth of μc-Si:H even at low temperatures.

Finally, our findings suggest an experimentally simple method for studying both the silane plasma and the nucleation of μc-Si:H in the early growth stages by applying a magnetic field to the substrates and using the growth of the grains as a developing process for making the nucleation density observable.

5. Conclusions

We have demonstrated new simple and effective way for influencing the growth of hydrogenated silicon thin films by magnetic field at the substrates. Magnetic field locally changes the growth conditions and at proper conditions leads to crossing of the amorphous – microcrystalline growth boundary. Properly arranged magnets could be used for reproducible deposition of microcrystalline pattern in otherwise amorphous films.

Multi-Component Modeling for Co-Condensation Systems of Silicon-Based Intermetallic Nanoparticle Synthesis Using Induction Thermal Plasmas

Masaya Shigeta and Takayuki Watanabe

Department of Environmental Chemistry and Engineering, Tokyo Institute of Technology, Yokohama, Japan

Abstract

A multi-component co-condensation model was proposed to clarify the formation mechanisms of silicide nanoparticles in induction thermal plasmas. In Cr-Si and Co-Si systems, Si nuclei are produced and they grow, subsequently the metal vapor condenses on the Si particles. In Mo-Si system, Si condenses on the Mo particles produced earlier. Their composition shows a wide range. In Ti-Si system, both vapors of Si and Ti simultaneously condense on the Si nuclei. The silicon content shows a narrow range.

1. Introduction

Induction thermal plasmas (ITPs) have been utilized for material processes such as nanoparticle synthesis since they have several advantages such as high enthalpy, high chemical reactivity, variable properties, large plasma volume, long residence/reaction time, and high quenching rate [1, 2]. Nowadays, nanoparticles of disilicides are required in industrial fields because they provide high electrical conductivity and heat/oxidation resistance. They are, therefore, expected to be applied for electromagnetic shielding, solar control windows, VLSI electrodes, and so on.

The process of the synthesis is, however, a complicated phenomenon with many controlled parameters, and it includes a co-condensation process with large or small vapor pressure differences of prepared species. Although only a few studies and researches have been conducted concerning the synthesis of silicide nanoparticles using ITPs up to the present [3], the formation mechanism of silicide nanoparticles in ITPs is still poorly understood. Therefore, investigation of the formation mechanism of silicide nanoparticles is intensively important for the precise control of the particle size distributions and stoichiometric compositions.

In the present study, numerical analysis is conducted for the synthesis of silicide nanoparticles in an induction thermal plasma to clarify the formation mechanisms especially for chromium-silicon system, cobalt-silicon system, molybdenum-silicon system, and titanium-silicon system. A multi-component co-condensation model is proposed for the co-condensation processes in silicide nanoparticle formation.

Table 1 Torch geometry and operating condition.

Torch Power	5 kW
Work Frequency	4 MHz
Reactor Pressure	101.3 kPa
Coil Radius	32 mm
Coil turn number	3
Wall thickness of quartz tube	1.5 mm
Distance to frontal end of coil (L_1)	19 mm
Distance to rear end of coil (L_3)	65 mm
Insertion length of probe (L_2)	45 mm
Torch length (L_4)	190 mm
Outer radius of inner slot (r_1)	6.5 mm
Outer radius of outer slot (r_2)	21 mm
Inner radius of injection tube (r_3)	1 mm
Inner radius of quartz tube (r_4)	22.5 mm
Outer radius of injection tube (R_t)	4.5 mm
Flow rate of carrier gas (Q_1)	0 Sl min^{-1}
Flow rate of plasma gas (Q_2)	3 Sl min^{-1}
Flow rate of plasma gas (Q_3)	10 Sl min^{-1}
Flow rate of sheath gas (Q_4)	20 Sl min^{-1}
Powder feed rate	0.1 g min^{-1}
Silicon content of feed powders	66.7 at%

2. Numerical formulation

Figure 1 shows a schematic illustration of nanoparticle synthesis systems consisting of a plasma torch and a reaction chamber. A summary of the geometry and operating conditions is given in Table 1. Powders of metals and silicon are supplied as the raw materials for silicides with the carrier gas from the central nozzle. The supplied powders are assumed to be vaporized completely due to the high enthalpy of the thermal plasma [3, 4]. The vapors of the metals and silicon are transported with the plasma flow to the reaction chamber and become supersaturated due to the rapid temperature decrease there, which leads to homogeneous nucleation. After homogeneous nucleation, the vapors of metals and silicon co-condense on the nuclei. Silicide nanoparticles are consequently synthesized from the gas phase. The silicon content of the feed powder is chosen to be 66.7 at% considered as the stoichiometric composition of disilicides.

2-1 ITP model

The calculation are based on the following assumptions to derive the governing equations: (a) steady-state laminar flow; (b) axial symmetry; (c) optically thin; (d) negligible viscous dissipation in energy equation; (e) negligible displacement current in comparison with the conductive current; (f) negligible flow-induced electric field; (g) identical temperature of heavy particles and electrons; (h) negligible effects of metals and silicon on thermofluid fields or properties of a plasma.

The fields of flow, temperature and concentration in the induction thermal plasma flow were calculated by solving the two-dimensional continuity, momentum, energy and species conservation equations coupled with the Maxwell's equations. The non-equilibrium effects by the ionization and recombination were taken into account.

Continuity:

$$\nabla \cdot (\rho \boldsymbol{u}) = 0 \tag{1}$$

Momentum:

$$\rho \boldsymbol{u} \cdot \nabla \boldsymbol{u} = -\nabla p + \nabla \tau + \boldsymbol{J} \times \boldsymbol{B} \tag{2}$$

Energy:

$$\rho \boldsymbol{u} \cdot \nabla h = \nabla \cdot \left(\frac{\lambda}{C_p} \nabla h \right) + \boldsymbol{J} \cdot \boldsymbol{E} - q_r \tag{3}$$

Species:

$$\rho \boldsymbol{u} \cdot \nabla Y = \nabla \cdot (\rho D \nabla Y) + R_r \tag{4}$$

Electromagnetic:

$$\nabla^2 \boldsymbol{E} - \xi \sigma_e \frac{\partial \boldsymbol{E}}{\partial t} = 0 \tag{5}$$

The boundary conditions along the centerline were set to insure axial symmetry. At the wall of the plasma torch, no slip conditions are maintained for the velocity, and the concentrations have zero gradient. The temperature at the inside wall of the plasma torch was calculated assuming that the outside wall was maintained at 300 K by water cooling. The injection tube was assumed to be at 500 K. The outflow boundary conditions at the torch were assumed that the gradient of the variables are zero. The sheath gas has swirl velocity component. Each gas stream has constant axial velocity with zero radial velocity having temperature at 300 K. Reaction kinetic rates of the dissociation and recombination as well as the ionization were taken into account. The transport properties were estimated using higher-order approximation of Chapman-Enskog method [5].

The governing conservation equations were solved using SIMPLER (Semi-Implicit Method for Pressure Linked Equation Revised) algorithm [6]. The governing equations and the electric field intensity equation with the associated boundary conditions were discretized into finite difference form using control-volume technique. Non-uniform grid points 30 by 30 were used for radial and axial directions, respectively. Grids were made finer close to the center and the coil region. Thermodynamic and transport properties were calculated from the temperature and compositions at each position in the calculation domain at each iteration step.

2-2 Multi-component co-condensation model

A one-dimensional multi-component model is proposed to clarify the formation mechanism of silicide nanoparticles with the following assumptions: (a) spherical particles; (b) negligible particle inertia due to the small size; (c) the same velocity of the condensing phase and the condensed phase as that of the plasma gas; (d) the same temperature of the nanoparticles as that of the plasma gas; (e) negligible heat generation caused by condensation; (f) the vapors of the metal and silicon considered as ideal gases; (g) negligible agglomeration among the nanoparticles; (h) atmospheric pressure in the systems.

Supersaturated vapor creates nuclei with the critical diameter by homogeneous nucleation [7], subsequently vapors condense heterogeneously on the nuclei [8], which results in nanoparticle growth.

Homogeneous nucleation rate of the species *i*:

$$J_i = \frac{(\beta_{11})_i n_{si}^2 S_i}{12}\sqrt{\frac{\Theta_i}{2\pi}}\exp\left(\Theta_i - \frac{4\Theta_i^3}{27(\ln S_i)^2}\right) \tag{6}$$

Critical diameter:

$$d_{pcri} = \frac{4\sigma_i v_{mi}}{k_B T \ln S_i} \tag{7}$$

Particle growth rate by heterogeneous condensation:

$$\frac{d(d_{pi})}{dt} = \sum_j \alpha_{ij}\frac{4\rho_g}{d_{pi}\rho_{cj}} D_j (X_j - X_j^s)\left\{\frac{1+Kn_i}{1+1.7Kn_i+1.333Kn_i^2}\right\} \tag{8}$$

In Eq. (6), the normalized surface tension Θ and the collision frequency function between a-mer and b-mer β_{ab} can be written as

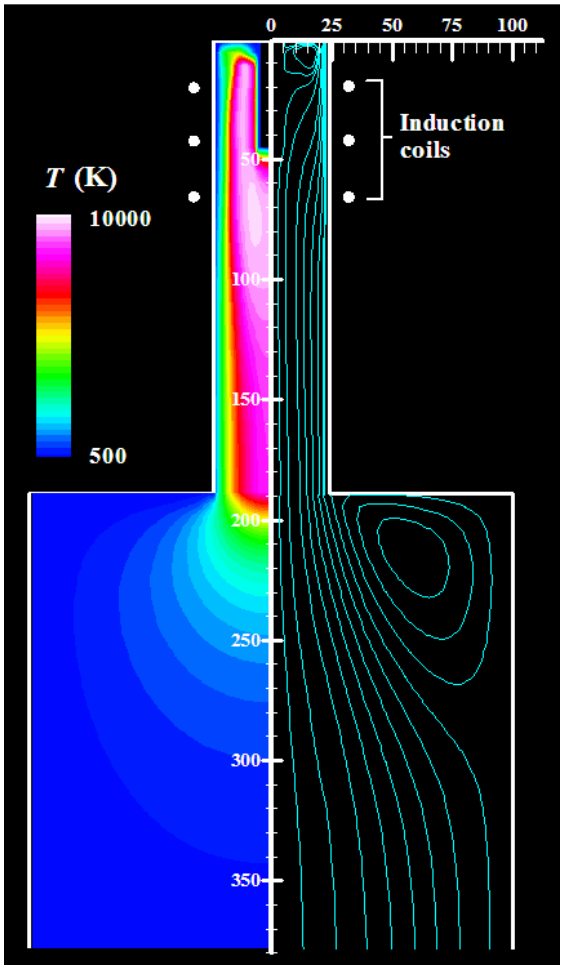

Fig. 2 Temperature (left), streamlines (right).

$$\Theta_i = \frac{\sigma_i s_{1i}}{k_B T} \tag{9}$$

$$\beta_{ab} = \left(\frac{3v_1}{4\pi}\right)^{1/6}\sqrt{\frac{6k_B T}{\rho}\left(\frac{1}{a}+\frac{1}{b}\right)}\left(a^{1/3}+b^{1/3}\right)^2 \tag{10}$$

The concentration of the metal and silicon vapors in the reaction chamber is obtained from the conservation equation written as

$$\rho u\frac{\partial c_i}{\partial z} = -G_i \tag{11}$$

The very fine computation grids are required for the nanoparticle synthesis since the nucleation and condensation processes have much smaller characteristic times than the plasma flow. Thus the grids of the reaction chamber (z=190-380 mm) are divided in 5,000 uniform grids in z-direction for the nanoparticle synthesis. The data obtained by the computation of the plasma such as the temperature and the velocity are modified for the fine grid system to calculate the rates of nucleation and condensation.

3. Results and discussion

Figure 2 shows the thermofluid fields in the plasma torch and the reaction chamber. The Joule heating by the applied electromagnetic power generates the remarkably high temperature zone (higher than 9,500 K) in and below the coil region. The high enthalpy of the plasma is

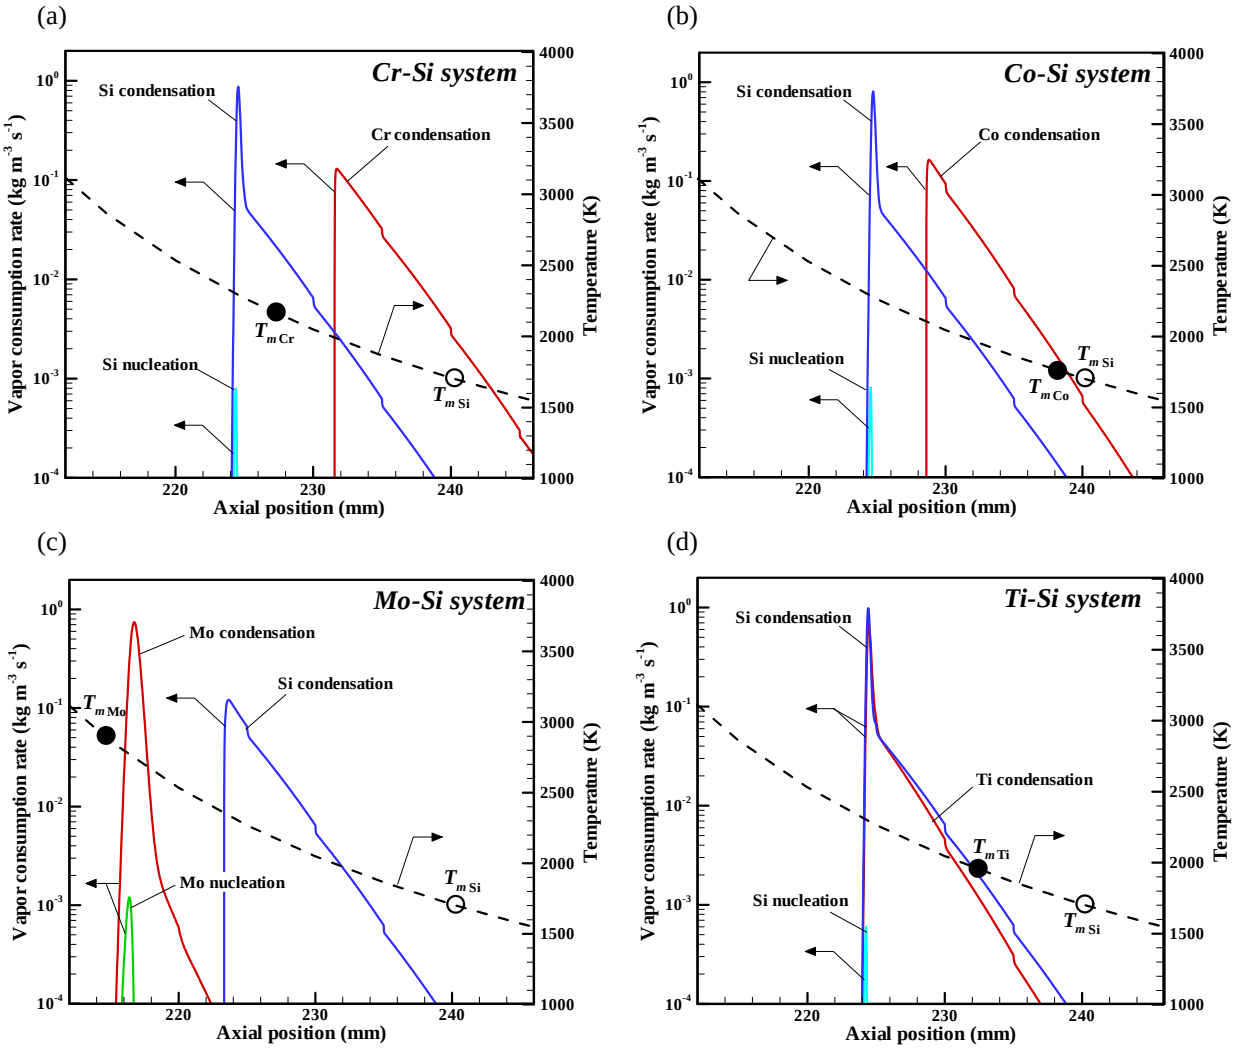

Fig. 3 Axial evolution of vapor consumption rate:
(a) Cr-Si system, (b) Co-Si system, (c) Mo-Si system, and (d) Ti-Si system

transported to the downstream region by the convection. The characteristic recirculation flow exists above the coil region since the radial Lorentz force induced in the plasma pinches the flow. In the reaction chamber, the temperature decreases drastically to below 500 K. As the result, the high quenching rate (10^4-10^5 K s^{-1}) is obtained, which leads to considerable promotion of particle nucleation.

Figures 3 (a)-(d) show the axial evolutions of the vapor consumption rate. In Cr-Si system, silicon vapor is consumed by the particle growth with homogeneous nucleation and heterogeneous condensation at the more upstream position than chromium vapor. At the downstream position, the chromium vapor consumption occurs by heterogeneous condensation on silicon particles. When chromium vapor condenses on the silicon particles, chromium is considered to be well-mixed in the liquid silicon particles with the particle growth since the temperature is higher than the melting temperature of silicon. Therefore, the nanoparticles of chromium-silicides are well-synthesized. In Co-Si system, it shows the same tendency as Cr-Si system. The cobalt vapor consumption by condensation occurs at the more upstream position compared with Cr-Si system as shown in Fig. 3 (a) since the saturation pressure of cobalt is smaller than that of chromium.

In Mo-Si system, molybdenum particles grow by homogeneous nucleation and heterogeneous condensation, subsequently silicon vapor condenses on the molybdenum particles. The temperature of the nanoparticle growth region is lower than the melting point of molybdenum. This indicates poor synthesis of silicides, because molybdenum and silicon should be well-mixed to form silicides in the condensation process. However, the stoichiometric compounds of molybdenum-silicides were observed in the experimental study [3]. The nanoparticles are, therefore, considered to grow in a super-cooled liquid state as the mixture of molybdenum and silicon even at the lower temperature than the melting point of

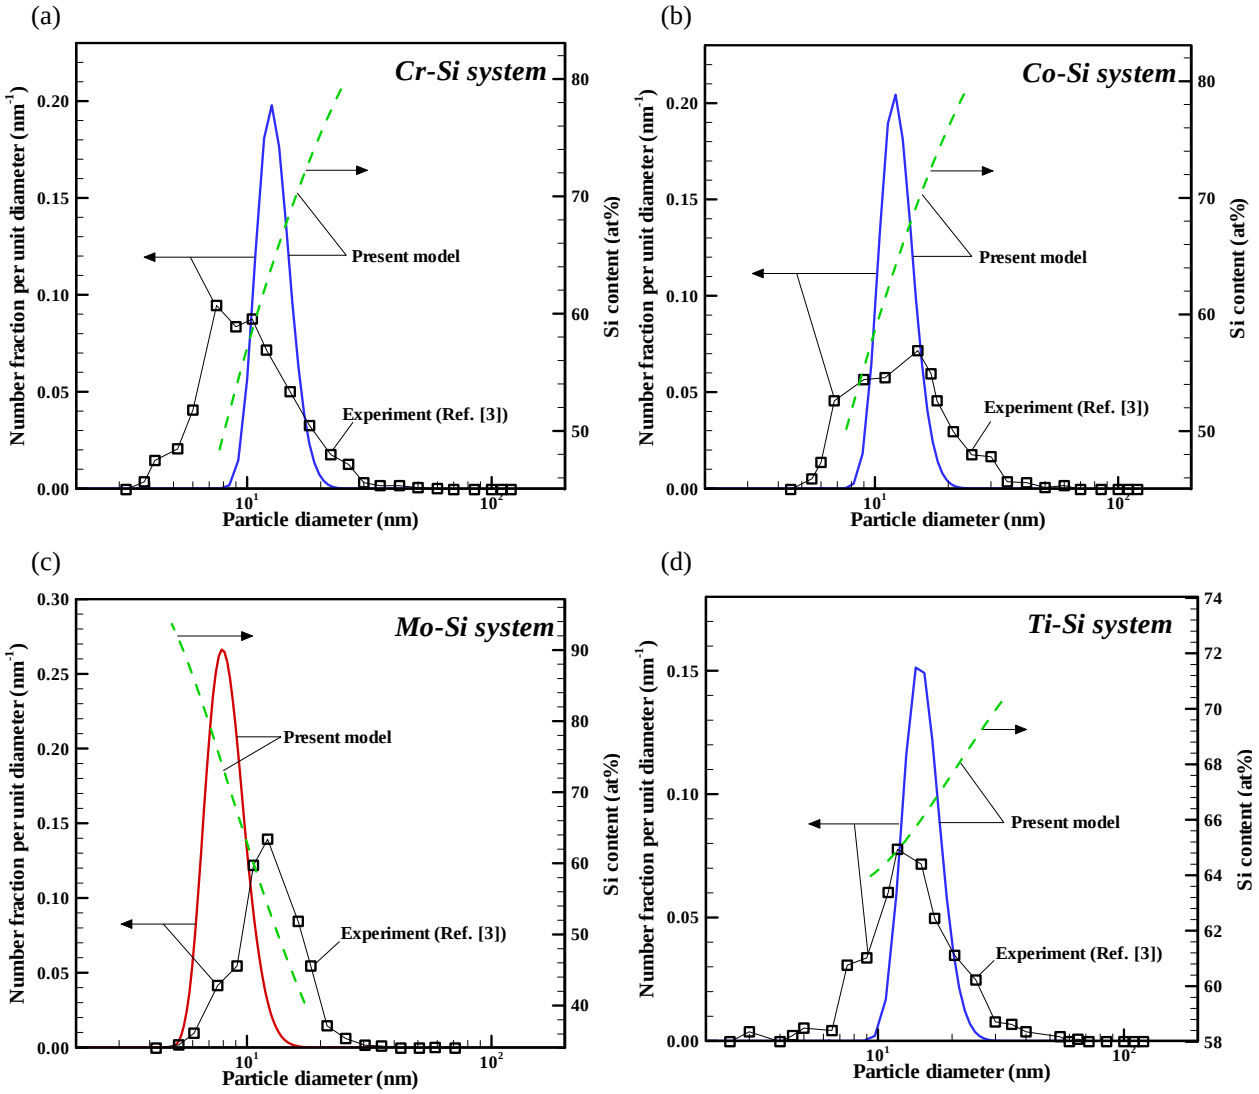

Fig. 4 Particle size distribution and silicon content:
(a) Cr-Si system, (b) Co-Si system, (c) Mo-Si system, and (d) Ti-Si system

molybdenum by the high quenching rate at the tail of the induction thermal plasma.

In Ti-Si system, silicon nucleates earlier than titanium. Immediately after the nucleation of silicon, the vapors of silicon and titanium are simultaneously consumed by heterogeneous condensation. Silicon and titanium are considered to be well-mixed in a liquid state in this co-condensation process since the particles grow at the temperature higher than the melting points of titanium and silicon, which results in the better synthesis of titanium-silicides.

Figures 4 (a)-(d) show the particle size distributions and the silicon contents finally obtained by the present model for four systems. The number mean diameters are 13.3 nm in Cr-Si system, 12.8 nm in Co-Si system, 8.5 nm in Mo-Si system, and 15.8 nm in Ti-Si system. Mo-Si system produces smaller nanoparticles than the other systems due to the difference of the nucleus size. Molybdenum nucleates with the smaller critical diameters from 0.59 to 1.94 nm, while the critical diameters of the silicon nuclei in other systems show from 0.83 to 2.65 nm. Since a larger number of the smaller nuclei are produced in Mo-Si system, a smaller amount of the vapors is consumed per one nucleus for the particle growth. As the result, the obtained particle diameters in Mo-Si system show smaller than those in the other systems. In all systems, the particle size distributions agree well with the experimental results [3].

The silicon contents show some ranges along with the particle diameters. Cr-Si system and Co-Si system have a range 48.1-79.4 at% and 49.5-79.3 at%, respectively. Mo-Si system particularly has a wide range 40-94 at%. Only Ti-Si system has a narrow range 64-70 at%, which results in the more homogeneous synthesis of the disilicide. These are determined by the balance of the contents of the formerly produced

Table 2 Compositions estimated from Ref. [9]

System	Main product	Sub-product
Cr-Si	$CrSi_2$	Cr_5Si_3, CrSi, Si
Co-Si	$CoSi_2$	CoSi, Si
Mo-Si	$MoSi_2$	Mo_5Si_3, Si
Ti-Si	$TiSi_2$	TiSi, Si

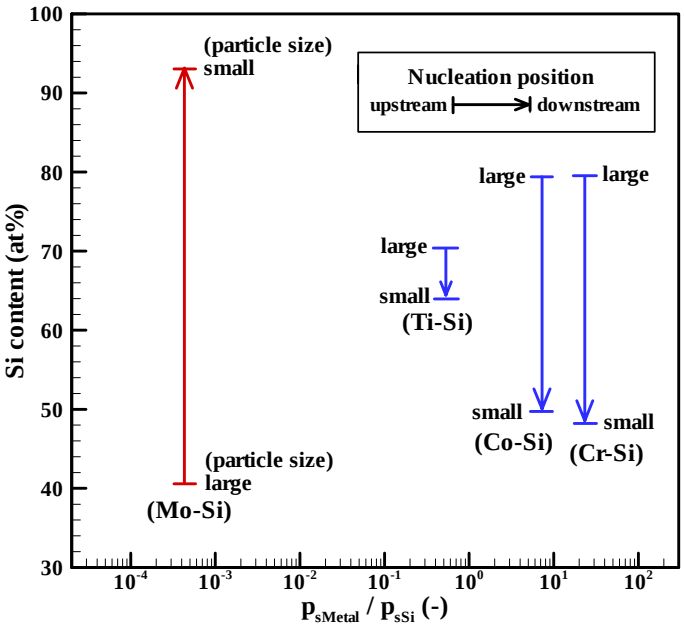

Fig. 5 Correlation chart between saturation pressure ratio and silicon content.

nuclei and the following condensing vapor. This indicates that the silicide nanoparticles synthesized in the induction thermal plasma provide diverse compositions. The compositions of the products can be estimated from the obtained silicon contents by comparing with the phase diagrams of silicides [9] and summarized in Table 2. In all systems, the required disilicides are synthesized as the main products, while the sub-products are synthesized as well, even though the powders of the raw materials are supplied with the stoichiometric compositions of the disilicides. This is because the condensation positions are different due to the different vapor pressures of the materials. However, induction thermal plasmas with the high enthalpy and the high quenching rate are notably effective even for the difficult co-condensation processes with the large vapor pressure differences. These results about the composition of the synthesized silicide nanoparticles obtained from the present model also show good agreements with the experiment [3].

Figure 5 is the correlation chart between the saturation pressure ratios and the silicon contents at the nucleation positions obtained from the present study. The larger particles with silicon nuclei generated at the upstream positions provide the larger silicon contents in Cr-Si system, Co-Si system, and Ti-Si system, while the smaller particles with molybdenum nuclei generated at the downstream positions provide the larger silicon contents in Mo-Si system. Furthermore, the silicon contents show the wide ranges when condensations of metal and silicon occur at the different positions due to the largely different vapor pressures as shown in Cr-Si system, Co-Si system, and Mo-Si system. The silicon content shows the particularly narrow range when condensations of metal and silicon occur simultaneously as shown in Ti-Si system.

This chart indicates that processes including large difference of the saturation pressures between the metal and silicon tend to produce silicide nanoparticles with wide range of composition. Conversely, the composition of the nanoparticles can be evaluated from the ratio of the saturation pressures between the metal and silicon. This chart can be used for prediction of composition in the co-condensation process.

Abstract

We have shown that it is in principle possible to make selectively specific molecules by means of an expanding thermal plasma. An NH_3 mole fraction of 6 % in the plasma is observed in a N_2/H_2 plasma. After adding O_2, the density of the formed NH_3 is decreased strongly and instead mainly H_2O and some NO is formed. The effect of adding CO_2 instead of O_2 shows the same qualitative and quantitative behavior.

Keywords: molecule formation, recombining plasma, cascaded arc, NH_3, NO

1. Introduction

Lately, the topic of molecule formation in plasmas receives a revived interest. Understanding the fundamental processes leading to the formation of molecules in plasmas used for deposition and etching, will result in the optimization of these production steps in the semiconductor industry. Also for understanding molecular abundances in the interstellar medium it is important to know how certain types of molecules are formed. We expect that we can obtain relevant information about these processes by studying the general behavior of the formation of specific molecules in recombining plasmas containing mixtures of $N_2/H_2/O_2$. Ultimately, this research could lead to a new methodology for producing selectively specific molecules by adjusting the plasma parameters.

Hempel et al. [1] studied the abundance of different types of stable molecules and radicals in a microwave plasma reactor to obtain information about the kinetics of the plasma. Only a complicated model in which all the reactions of interest take place in the gas-phase of the plasma could explain their measurements. The formation of NH_3 molecules has been observed by Vankan et al. [2] in a N_2/H_2 containing expanding thermal plasma, produced by a cascaded arc. This research pointed to the importance of molecule formation as a result of the interaction between plasma produced radicals and the walls of the plasma vessel. Also reference [3] and [4] observe the formation of NH_3 in a microwave plasma and a dielectric barrier discharge respectively. Further research on N_2/H_2 containing recombining plasmas has been conducted by van Helden et al. [5]. In this contribution we concentrate on the effect of adding O-containing species (O_2 or CO_2) to the N_2/H_2 plasma in order to investigate the tuning possibilities of the system and to find a way to predict the abundances of the molecular end products in the plasma.

By means of a dedicated tunable infrared diode laser system and mass spectrometry, we measured the mole fractions of several species in the background of the plasma vessel. We here report on the measured mole fractions of NH_3, NO and CO_2.

2. Theory

In a non-plasma environment, practically all the reactions leading to the formation of a certain type of molecule, exhibit an activation energy. This results in very specific equilibrium states of a system containing various species, strongly dependent on the exact parameters of the complete system.

By starting with a high flux of radicals, produced by plasma, radical chemistry with small or no activation energy dominates in first order the resulting equilibrium state of the system. Therefore species with the highest relative binding energies are expected to be the most abundant species. The binding energies of several species in the gas phase can be obtained from [6, 7]. A complicating factor can be that the effective binding energy of certain molecules adsorbed at a surface, is different from the binding energy in the gas phase. To get a first estimate of the end products in the gas phase, we consider only the binding energies in the gas phase.

The cascaded arc is able to produce a high flux of radicals. These active species interact with the gases injected into the background of the plasma vessel. When N_2 and H_2 are directed via the cascaded arc into the plasma

vessel, the active species N, H, N^+ and H^+ , produced in the plasma source, will interact with the molecules injected into the plasma vessel. In case molecular oxygen is injected in the plasma vessel, a fraction of the O_2 is dissociated mainly by the N^+ ions in a charge exchange reaction, followed by dissociative attachement:

$$N^+ + O_2 \rightarrow N + O_2^+ \quad (1)$$

$$O_2^+ + e \rightarrow O + O \quad (2)$$

Also the 'neutral' gas-phase reaction:

$$N + O_2 \rightarrow NO + O, \quad (3)$$

can lead to atomic oxygen radicals. These two mechanisms result in a high flux of O radicals towards the walls of the vessel.

Based on this simple consideration, the formation of H_2O compared to H_2 and O_2 is expected to be favorable, because the total binding energy of $2H_2O$ is equal to 19.0 eV and of $2H_2 + O_2$ only 14.1 eV. Therefore a high abundance of H_2O is expected compared to H_2 and O_2 in an H_2/O_2 containing plasma. The same comparison for 2NO (13.0 eV) and $N_2 + O_2$ (14.9 eV) suggests a strong tendency of a N_2/O_2 containing plasma to form mainly N_2 and O_2. It appears that in the N_2/H_2 case, dominantly N_2 and H_2 and only for 10% NH_3 is formed. This does not correspond directly to the binding energies of $N_2 + 3H_2$ versus $2NH_3$ (23.2 and 23.2 eV respectively), so apparently other factors play also a role: e.g. which species are adsorbed at the surface.

3. Setup

A sketch of the experimental setup is given in figure 1. On the left the cascaded arc plasma source is shown. The cascaded arc consists of a stack of copper plates with a central bore of 4 mm in diameter, forming a channel. PVC spacers to keep them electrically insulated. The plates stabilize the discharge, which is sustained between cathode and anode. A current of 55 - 60 A is fed through the arc channel. A substantial flow of argon and/or N2 and H2 is fed through the arc channel, producing atoms and ions. O_2 can only be directed into the background of the plasma vessel. Also N_2 and H_2 can be injected into the background of the plasma vessel.

The plasma created in the cascaded arc expands into the plasma vessel, which is kept at a pressure of 20 Pa. Also a mass spectrometer has been installed to analyze the stable species present in the background of the plasma vessel.

The laser beam from the tunable diode laser system (IRMA, [8]) is directed through the vessel. The IRMA system is composed of four different diode lasers, which can be used subsequently without changing much on the alignment of the system. So in principle four different species can be monitored relatively easy. Here we report on measurements on NO, NH_3 and CO_2.

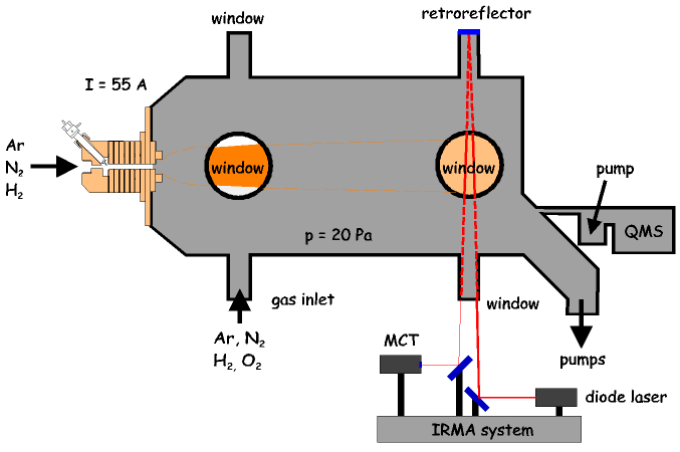

Figure 1. Sketch of the experimental setup

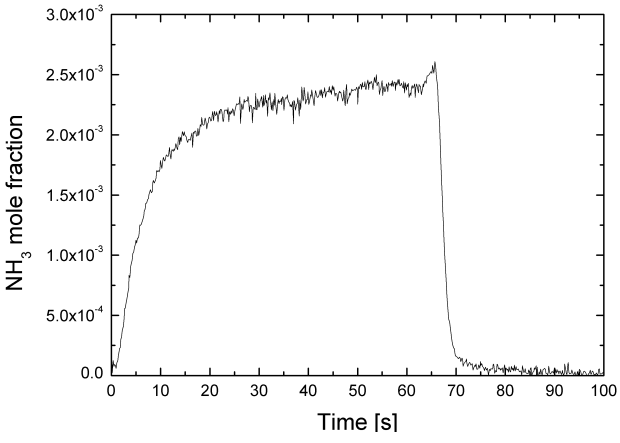

Figure 2. Time dependence of the destruction and formation of NH_3 in a $N_2/H_2/O_2$ plasma. See the text for details.

3. Results

3.1. Time dependent destruction and formation of NH_3

Figure 2 shows the time–dependence of the NH_3 concentration in an argon plasma (3.0 SLM Ar directed via the cascaded arc, operated at 60 A) with N_2 (0.28 SLM) and H_2 (0.02 SLM) added in the background of the vessel. During the admixture of 0.1 SLM O_2 in the background of the vessel, no NH_3 is observed (at time < 0 s and time > 70 s). Apparently the presence of O_2 hampers the net production of NH_3 significantly.

After closing the oxygen flow at t = 0 s, it takes 30 s for the NH_3 mole fraction to reach its maximum value of 2.3×10^{-3}. Ar^+ ions created in the cascaded arc dissociate N_2 and H_2, leading to N and H atoms, which associate at the surface to NH_3. The transit time of particles in the plasma beam is around 0.03 s and the residence time in the vessel around 0.73 s. Both these time scales are significantly shorter than the observed time constants in figure 2 of the formation of NH_3. This suggests that the formation of NH_3 is hampered by oxygen and/or oxygen containing compounds that desorb from the vessel walls. Another possibility is that the density of H atoms necessary for the formation of NH_3 takes time to build up, which is only possible when the H atoms are not bound into H_2O anymore.

3.2. N_2/H_2 plasma with O_2 in the background

In figure 3 and 4 the NH_3 and NO mole fraction in the plasma vessel are given as a function of the O_2 flow. We observe that at $\Phi(O_2) = 0$ sccm, a significant fraction of the initial gases N_2 and H_2, both directed through the cascaded arc, is converted into NH_3. Depending on the ratio of the flows of these gases, a maximum mole fraction of 6 % is obtained, as can be seen in figure 3. This implies that 7.9 % of the total N_2 flow and 15 % of the total H_2 flow is converted into NH_3. Decreasing the relative amount of H_2 results in a lower maximum observed mole fraction of 3.2 % as is shown in figure 4. The optimal ratio of $\Phi(N_2)$ / $\Phi(H_2)$ is determined to be 0.45 / 1.0 from a more detailed study on the NH_3 formation in this type of plasma.

When O_2 is added to the plasma, especially at a relatively low H_2 flow, the net production of NH_3 is stopped very efficiently, already at a low O_2 flow.

In the same experiments, we also monitored the mole fraction of NO, which is displayed in figure 3 and 4. We conclude that especially at high O_2 flows, mainly H_2O (determined by mass spectrometry) and a small fraction NO is formed. A remarkable fact is a threshold value of $\Phi(O_2) = 0.1$ SLM for the formation of NO.

3.2. N_2/H_2 plasma with CO_2 in the background

When we add another type of molecule containing O or O_2, in this case CO_2, the effect on the net production of NH_3 is qualitatively the same, which is shown in figure 5. We do observe that especially for relatively low H_2

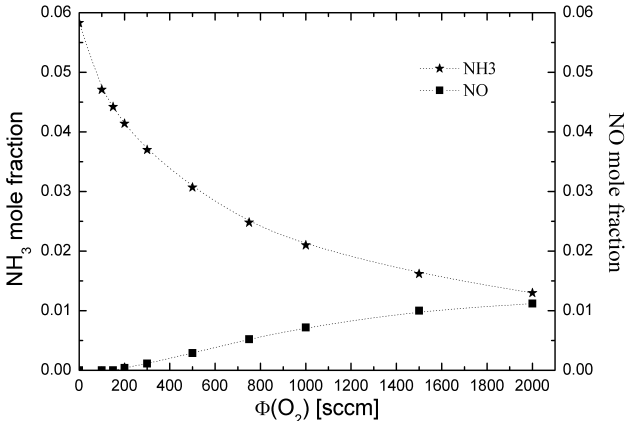

Figure 3. NH_3 and NO formation in a N_2/H_2 plasma to which O_2 is added. Gases directed through the cascaded arc: $\Phi(N_2)$ = 800 sccm, $\Phi(H_2)$ = 1200 sccm. Oxygen is injected in the background of the plasma vessel.

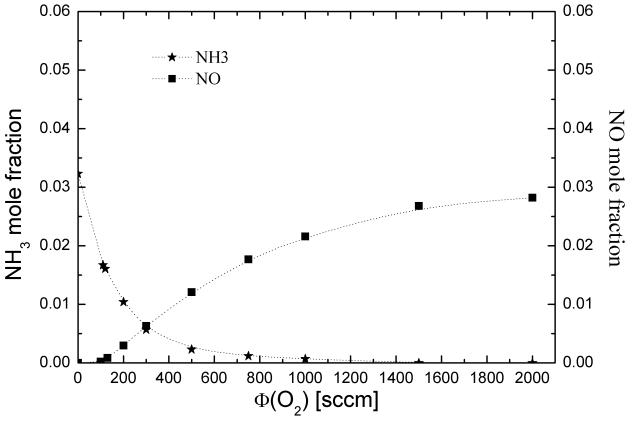

Figure 4. NH_3 and NO formation in a N_2/H_2 plasma to which O_2 is added. Gases directed through the cascaded arc: $\Phi(N_2)$ = 1700 sccm, $\Phi(H_2)$ = 300 sccm. Oxygen is injected in the background of the plasma vessel.

fractions, the effect of CO_2 is less pronounced. The depletion of CO_2 in plasmas with different N_2/H_2-ratios is displayed in figure 6 and turns out to be around 30 %. Together with the fact that dissociation of CO_2 gives only one O atom (and the stable molecule CO) and the dissociation of O_2 gives two O atoms, this suggests the competitive formation of mainly H_2O at low O_2 or CO_2 flows. The effect of adding O_2 is more pronounced because of the greater abundance of O atoms.

4. Discussion

4.1. N_2/H_2 plasma with O_2 in the background

Based on the binding energies given in section 2, we expect that in the presence of (dissociated) O_2 primarily H_2O is formed at the expense of NH_3. This is consistent with figure 3 and 4: adding O_2 to the system results in a significant decrease of the NH_3 density. Also a large fraction of H_2O was observed by mass spectrometry. A smaller abundance of NO compared to N_2 and O_2 can also be expected from the binding energies given in section 2, which is supported by figure 3 and 4 as well.

4.2. N_2/H_2 plasma with CO_2 in the background

When CO_2 is added to the plasma, instead of O_2, the same effects are observed, as is displayed in figure 5. Especially at low H_2 fractions, the effect of adding CO_2 to the plasma on the production of NH_3 is not as big as when pure O_2 is added. This is caused by the number of O atoms (the active species) that can be delivered by O_2 and CO_2. The abstraction energy of an O atom from O_2 and CO_2 is roughly the same: 5.17 eV and 5.51 eV for O_2 and CO_2 respectively. Each dissociation of O_2 delivers two O atoms for the plasma, where CO_2 only delivers one O atom.

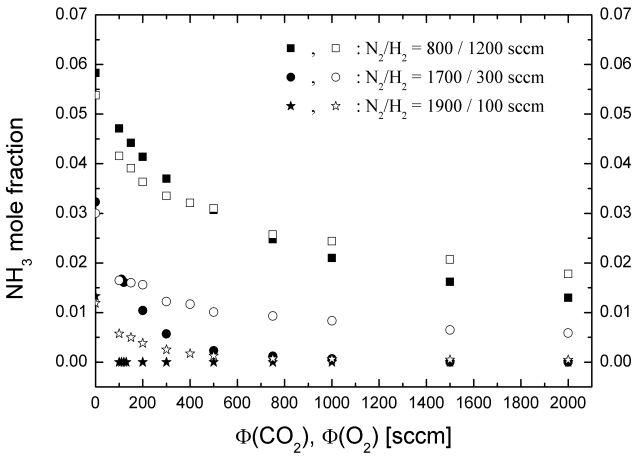

Figure 5. NH_3 mole fraction after adding O_2 (solid points) or CO_2 (open points).

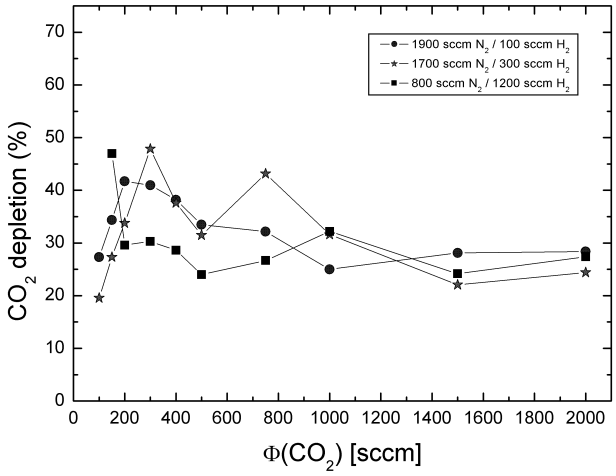

Figure 6. CO_2 depletion as a function of the CO_2 flow.

5. Conclusions

We conclude that based on an analysis of the binding energy of the species present in the plasma, an estimate of the abundance of the various species in the plasma can be obtained. Furthermore, we have shown that it is possible to selectively form specific molecules, by tuning the plasma parameters. In this case a low fraction of O_2 or CO_2 added to the plasma results in a significant mole fraction of NH_3. A high fraction of O_2 or CO_2 added results mainly in NO, H_2O and CO.

MICROWAVE PLASMA CATALYST

D. Hitchen[1], M. Houghton[1], A.I. Al-Shamma'a[1], J. Lucas[1]

[1]*Dept. of Electrical Engineering & Electronics, University of Liverpool, Liverpool, UK*

Abstract

As the internal combustion engine does not burn with 100 % efficiency, some of the, non-burnt fuel causes the release of hydrocarbons (HC) and due to inadequate mixing with the air molecules exit the engine as carbon monoxide (CO). Additionally the combustion combines nitrogen with oxygen to form oxides of nitrogen (NOx). This paper presents the microwave plasma catalyst and its effective use against vehicles against gases and particulates.

1. Introduction

The emissions from transport vehicles have dramatically increased over the last 30 years and huge sums of money are being invested in the reduction of vehicle pollution. The current method for treating these gasses is using a catalytic converter. A catalytic converter has a honeycomb of porous ceramic. This honeycomb structure is used to maximise surface area and to reduce the amounts of palladium, platinum and rhodium that are embedded in the ceramic. Once the catalyst has been heated to over 300 ^{0}C the unwanted molecules are ripped from their compounds and stick to the catalyst where they bind with other similar atoms and are then released into the atmosphere. In engines, emission control of CO, HC and NO_x is obtained by using the three-way catalyst. This is the only technique, which is presently available to the transport industry.

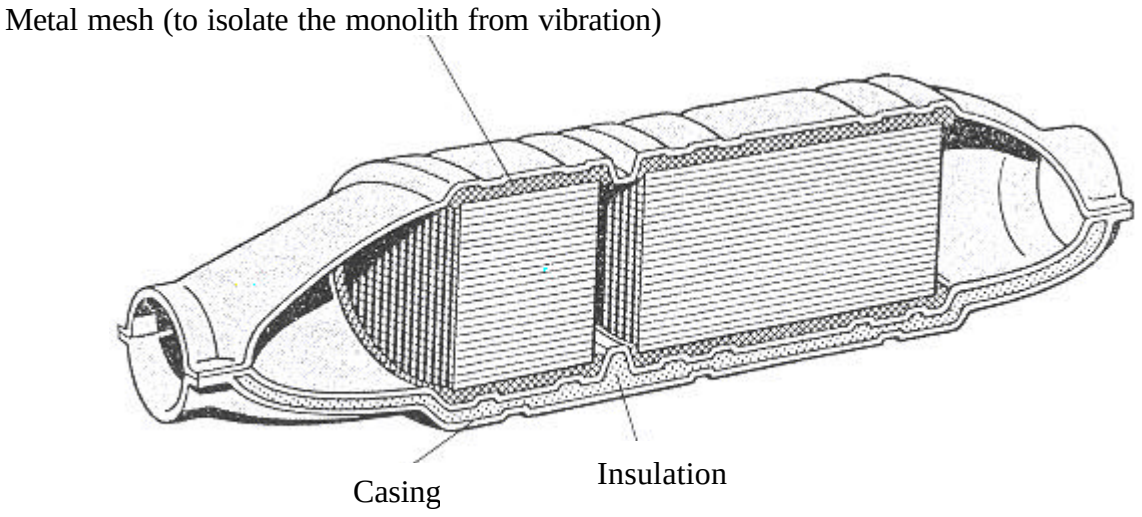

Figure 1: The three-way catalyst

The construction of the three-way catalyst is shown in figure 1. It is supported on an alumina substrate. The need to operate the air/fuel around the stoichiometric mixture means that the catalytic system reduces the fuel economy by as much as 10%. Other disadvantages are:

1. Deterioration by poisoning of the catalyst by deposits, mechanical failure of the substrate and sintering which reduces the effective interaction area giving an average lifetime of 3 years.
2. Do not start working until a minimum substrate temperature of 300^{o}C is attained.
3. The high cost of precious metals and the worldwide scarcity of sources.
4. Less efficient operation with hydrocarbon and black smoke particulate emissions.

The converter will only run at a specific air to fuel ratio, the stoichiometric ratio, of 14.7:1 [1]. The ratio is maintained by fuel injection. If there is an increase in the fuel level for example from a misfiring spark plug, overly rich fuel mixture, a leaky exhaust valve or head gasket, the temperature of the catalyst can rise dramatically causing it to melt and block up. In addition the catalytic converters have become a cause of pollution in their own right with pollution studies of the icecaps in central Greenland show that palladium

and rhodium levels have risen by 40 to 80 times since 1976 [2]. The ratio of platinum/palladium to rhodium in the snow compares closely to the ratio of use in the exhaust systems from another study [3,4]. The use of a combined catalyst and engine management system adds considerably to the cost of the engine. Present catalyst costs are €1800 for a three-litre engine reducing to €600 for a 1-litre engine.

2. Microwave Plasma Catalyst

A new form of catalyst, which has the same attributes as the three-way catalyst, has been researched, which uses plasma chemistry to clean up the exhaust gas. It has shown that microwave plasma readily satisfies the EURO IV standards for emissions but has the added advantages as follows:

1. It does not obstruct the exhaust gas flow, hence gives 10% fuel saving.
2. Only uses 2% of engine power to provide microwave power.
3. Lower cost than the three-way catalyst, it could be as low as 50%.
4. Able to efficiently oxidise HC and carbon particles especially the micro-particles that are giving the main health concern.
5. Microwave catalyst works immediately the engine is started and does not require a warm up period.
6. It does not use expensive rare earth materials (platinum, rhodium and palladium).

In plasma chemistry, the reactions that occur can differ vastly from the reactions expected at the temperatures involved. For example, even in low temperature plasma, the noble gasses become reactive and will readily oxidise in the presence of oxygen. Additionally the oxidisation of CO to CO_2 in an electric discharge, at relatively low current densities, the concentration ratios at room temperature can be shown to correspond to the ratios of reactants and products obtained in a purely thermal reactor at 3000 °K. The reason for this is that if an electron collides with a neutral atom it can throw a tightly bound local electron into an unpopulated shell; the atom is then no longer in such a strongly localised bound state and is free to form chemical bonds with other atoms.

Table 1. Ions Produced by Electron Induced Reactions in Plasmas [5].

Plasma	Ions
H_2	H^+, H_2^+
He	He^+, He_2^+
O_2	O^+, O^-, O^{2+}, O_2^{2+}
N_2	N^+, N_2^+
Cl_2	Cl^-, Cl_2^-
Br_2	Br^-, Br_2^-
I_2	I^+, I^-, I_2^-
CO	C^+, O^+, O^-, CO^+

In a microwave discharge, electrons gain energy from the applied microwave field and lose energy by elastic and inelastic collisions. The constant ionisation of the gas molecules creates new electrons, which flow to the walls due to density and space charge potential gradients. To produce free radicals at the relatively low temperatures involved, the electron temperature to gas temperature must be at least 10:1. For a microwave discharge to occur the electric field strength, which is proportional to the square root of the input power, must be increased until at some point the field will reach a strength at which a breakdown of the gas can occur. The average power transferred to a unit of gas in a microwave discharge can be given [6]: -

$$\overline{P} = \frac{e^2 e^2 n}{2m} \frac{V_c}{V_c + w^2} \qquad (1)$$

Where: (e) the maximum field strength, (n) electron concentration, (m) the electron mass, (V_c) elastic collision frequency and (?) angular frequency of the applied field.

Due to their higher electron temperatures ranging from 5 to 15eV compared to 1 or 2eV for D.C., low frequency or R.F. discharges, a higher degree of ionisation is possible using a microwave discharge.

3. System Setup

The microwave plasma laboratory systems consists of a power supply, magnetron, operating at powers up to 1000W at 2.45GHz, circulator, E-H tuner and the interaction cavity as shown in figure 1 [7,8]. However, the industrial prototype system will only contain the magnetron and the plasma cavity. The microwave power can be coupled effectively to the plasma cavity by either a flexible cable of a waveguide based up on the vehicle type and requirements.

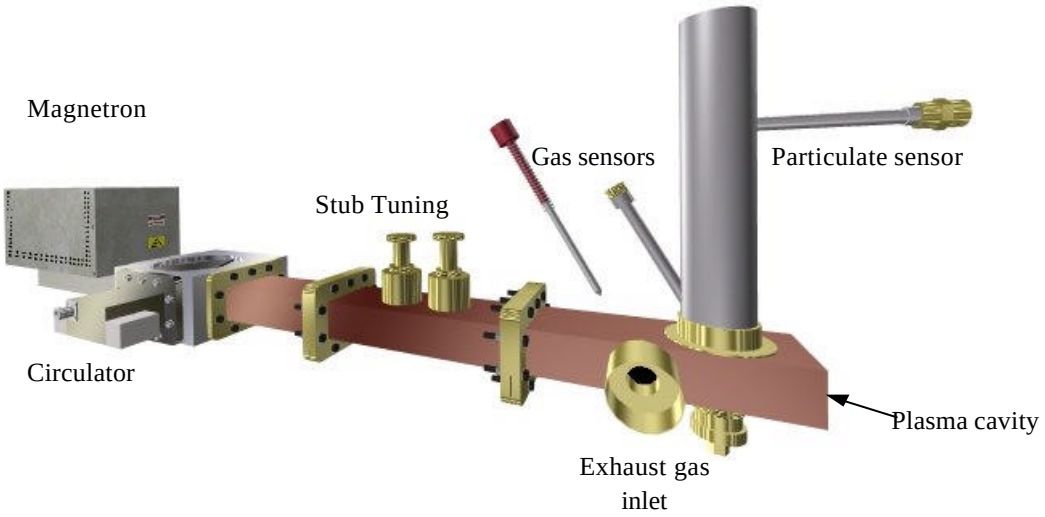

Figure 1: Microwave plasma catalyst laboratory arrangements

The microwave plasma is generated between two electrodes within the plasma cavity as shown in figures 2 and 3.This arrangement provides a uniform microwave plasma between the electrodes of the top and bottom plates. The top electrode is covered by a fine mesh, which acts as the first particulate trap. It also requires an operating power of at least 500W for a duration of at least 10 microseconds. To maintain a good plasma at reduced power, it is necessary to modulate the input microwave power so that it is alternatively turned on and off. In order to avoid any problems of re-striking the arc then the off time must be no longer than 1 millisecond. Typical powers, which will be required to keep the mesh carbon free, are expected to be of the order of 200W average. So far only two course metallic meshes have been used having 75µm holes and 25µm.

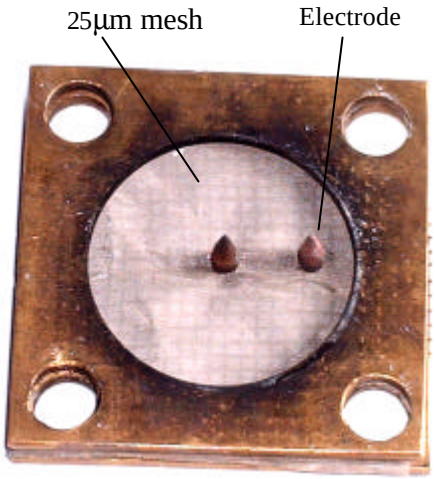

Figure 2: The Electrodes Plus 25µm Mesh

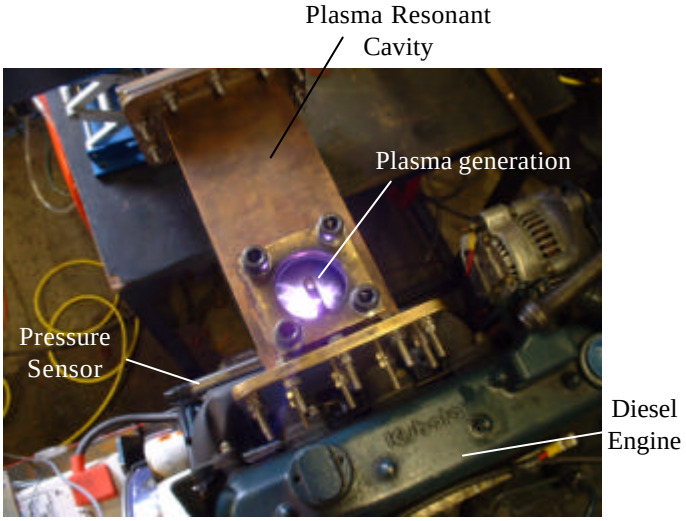

Figure 3: The Microwave Plasma – Top View

In order to maximise the electrical field within the plasma cavity resonator, various shapes of electrodes have been simulated, designed and constructed using the High Frequency Structure Simulator (HFSS). Figure 4 shows a sample of one type of electrode with strong e-field being generated to breakdown the gases and reduce particulates. When the field strength reaches a value of about 20kV/cm then automatic breakdown occurs. This has been designed to occur when the microwave power is in excess of 500W, however a pulsed power modulator is used to operate at lower average powers.

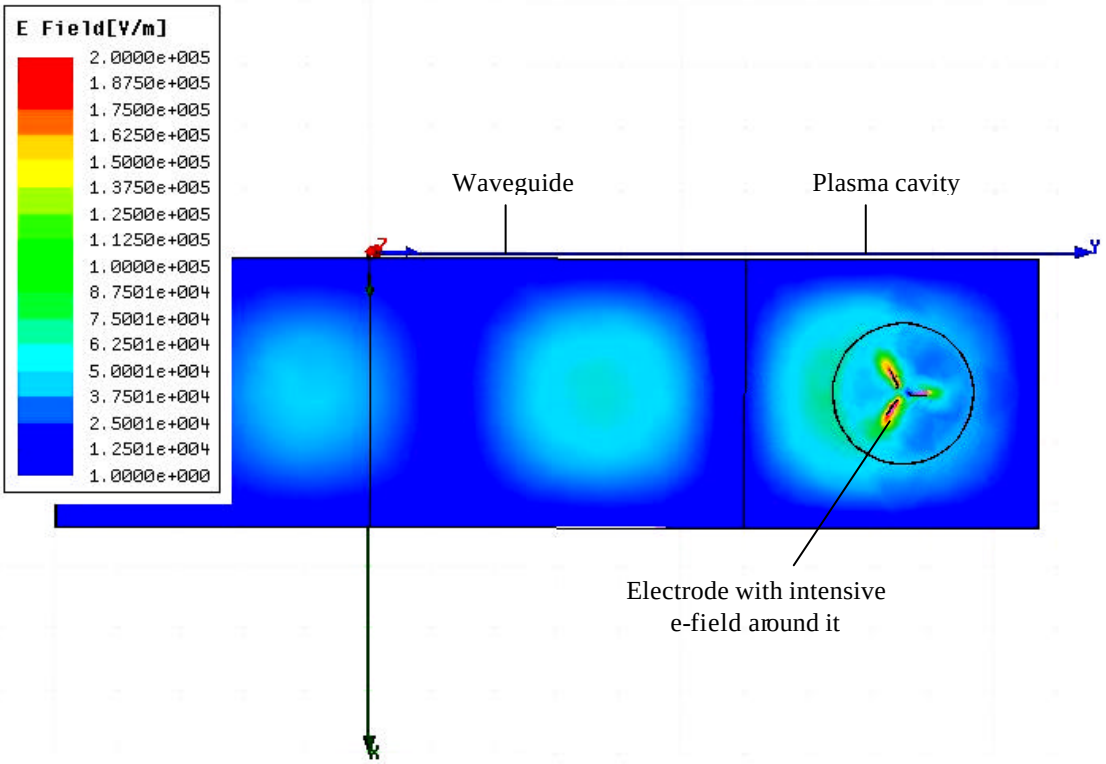

Figure 4: Top view of the microwave plasma cavity, e-field analysis using HFSS, including a trio-structure of electrodes

4. Cleaning Action of Microwave Plasma

The carbon particulates collected at the first filter having 25µm holes is shown in figures 5 and 6 with and without the plasma. The results show the effect of running the engine for 10 minutes both with and without the microwave plasma respectively. During this 10 minute period the plasma was only operated for about 2 minutes and this was sufficient to keep the mesh totally clean. Figure 7, shows the effects of the plasma on HC when the system power varied between 0 to 1kW. A reduction of 60% is achieved with this configuration, however further 30% reduction was obtained with alternative setup, the details are subject to patent pending.

Figure 5: 25µm mesh without plasma

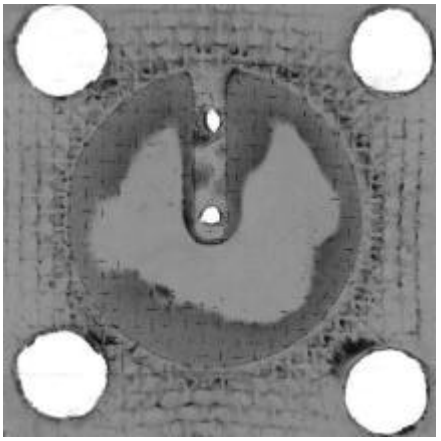

Figure 6: 5µm mesh with plasma

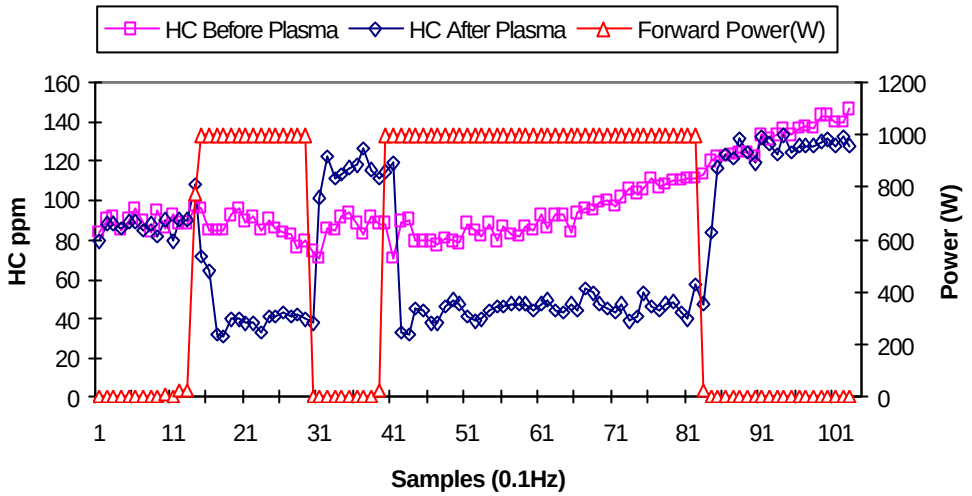

Figure 7. Hydrocarbon levels before and after plasma

Figure 8 shows the results when the exhaust emissions from a 1.8 litre petrol engine. The engine was periodically revved and on alternate accelerations, the plasma was switched on. It can be seen that the CO output peaked at 2% without the plasma on yet whilst the plasma was active, the maximum-recorded level was around 0.3%. The data were logged at 10sec using Quintox gas analyser [9].

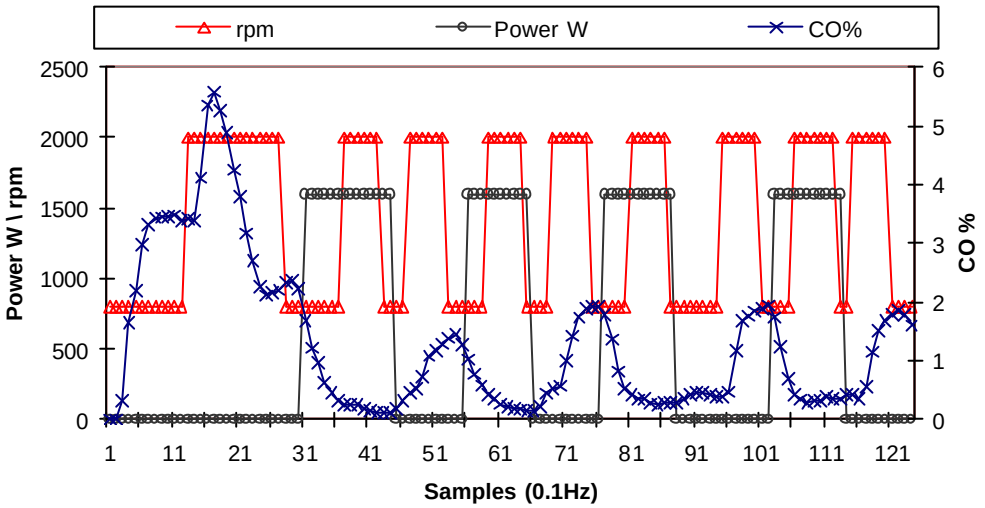

Figure 8: Carbon monoxide levels with and without plasma

It is also worth mentioning that with the plasma having an extremely high temperature, >600^{o}C any ultra fine particles passing through it will be incinerated. It has been found that the larger carbon particulates do not remain in the plasma for longer time. Comprehensive investigations have been carried out using meshes to hold up the particles long enough for the plasma to burn them proved unsuccessful as meshes with a small enough apertures, below 5 microns, and with a sufficient transmission were not available. However, initial trials conducted using a ceramic filter to remove the larger solids from vehicle exhaust have proved successful, see figure 9, and future work will be carried out to asses the effect of the plasma on the ultra fine particulates. Although earlier tests had shown that it was possible to reduce NOx with a plasma these tests where done without an abundance of oxygen. Unfortunately the intense heat of the plasma and the availability of nitrogen and oxygen ions the plasma also generates NO and NO_2 in quantities greater than that of the disassociation. Future work will also involve investigation into the reduction of the NO emissions and the possibilities of using the NO_2 as an oxidising agent to reduce particulate levels.

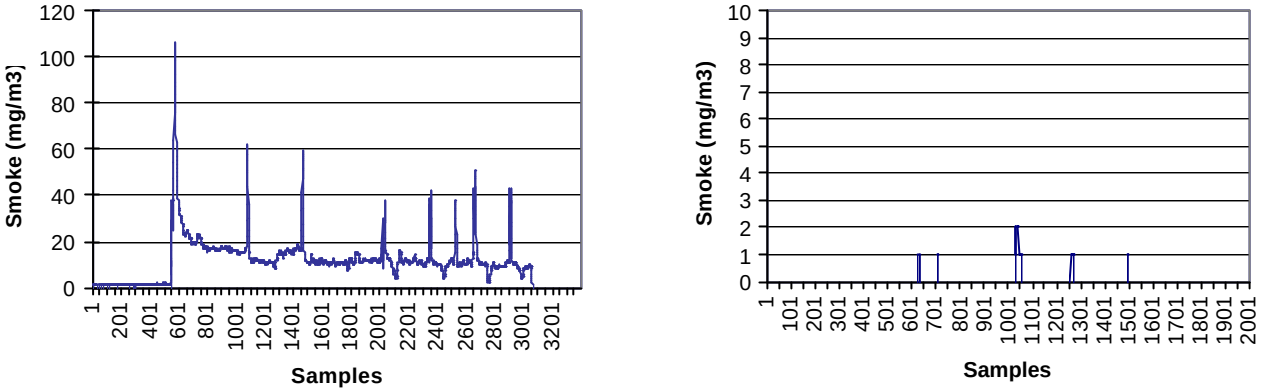

Figure 9: Smoke levels with and without filtration treatment

5. Conclusions

The microwave plasma device has been adapted for use in reducing harmful exhaust emissions from petrol, diesel and LPG engines. This system uses an electromagnetic field to cause an electrical discharge in the exhaust gasses. This breakdown causes the carbon monoxide, hydrocarbons and particulates to oxidise. The system is currently under vigorous industrial trials on diesel and LPG engines.

MICROWAVE PLASMA SOURCE AS AN OZONE GENERATOR

I. Panditha s[1], A.I. Al-Shamma'a[1], A. Shaw[1], J. Lucas[1]

[1]*Dept. of Electrical Engineering & Electronics, University of Liverpool, Liverpool, UK*

Abstract

Ozone is one of the strongest oxidising agents known. Its germicidal action having been recognised for nearly a century and it is used in drinking water sterilisation and wastewater management and more recently for killing bacteria during food packaging and cleaning food preparation areas. With the development of such applications in these industries, the efficiency and cost of ozone production has become more and more important and industry is interested in having very efficient with high ozone yield system operating at 10kWs of power.

1. Introduction

Presently, two methods are used for generating ozone namely corona discharge and ultraviolet radiation [1,2]. The Corona Discharge (CD) system is produced by passing air through a strong electric field, which is close to the ignition voltage required for electrical breakdown. Typical operating conditions range from 5000 volts for a high frequency of 1000Hz to 16000 volts for a low frequency of 50Hz (mains frequency). Air (containing approximately 21% oxygen) or concentrated oxygen (up to 95% pure oxygen) dried to a minimum of –60°C dew point passes through the corona which contains free electrons (e) which causes the oxygen (O2) bond to split allowing two atomic (O) atoms to collide with other O2 molecules to create ozone (O3):

$$O_2 + e = 2O + e, \qquad O_2 + O = O_3 \qquad (1)$$

This method suffers from the presence of moisture in the feed-gas, which causes two serious problems. First, moistures (humidity) will cause a significant drop in ozone production and a waste of applied electrical energy. Second, a small amount of nitrogen in the air converts to oxides, which then dissolve in moisture to form nitric acid, which is corrosive to the CD system construction materials causing increased maintenance. As indicated in figure 1, the production of ozone with un-dried air (-10°C) is less than half of that at the dew point of –60°C. The figure alone shows the increase in the production of nitrogen oxides increases exponentially above –40°C dew point. The overall efficiency of the CD and associated silence discharges is 1-2%.

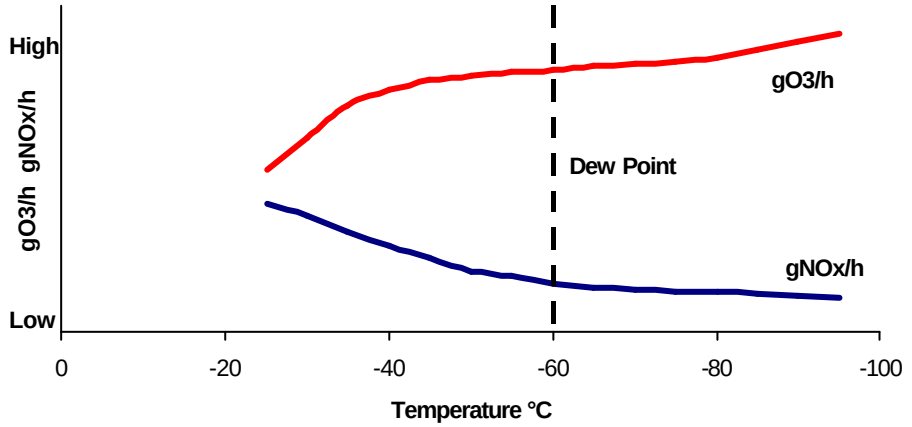

Figure 1: Corona Discharge Ozone Production

In conventional UV generation of Ozone, Ozone is produced by irradiating ambient air with UV, using low-pressure mercury vapour lamps, having wavelengths below 200nm. Longer wavelengths, around 250nm, are more efficient at destroying ozone rather than producing it. The energy of the UV splits some of the O2 molecules into two O atoms, which collide, with other O2 molecules to produce ozone (O3). Because UV light sources are not monochromatic both long and short wavelengths are generated therefore in UV systems ozone is simultaneously produced and destroyed. The concentration of ozone from the UV generator depends on the UV energy output of the lamp used, the enclosure surrounding the lamp, the

temperature, humidity and oxygen content of the air and the volume of air flowing through the generator. The UV excited ozone has an efficiency of 0.5-1.5%. UV process designers are therefore looking to develop lamps with constant improvements in the lamp characteristics including the increased power per lamp, increased UVC output per lamp (efficiency), longer lamp life, instant start and stop and no efficiency losses due to temperature.

2. Microwave Plasma Lamp

Microwaves are high frequency electromagnetic waves, generated by magnetrons, which can be stored in a resonance cavity made of metal or dielectric material. The principle is illustrated in figure 2 in which microwaves are launched into the lamp via a metal cavity resonator [3,4]. The electric field ionises the mercury vapour in the lamp to produce the UV emission, see figure 3. The design specification for the resonant cavity are summarised in table 1. The microwave frequency is 2.45GHz and is the same as that used in a microwave oven. This allows low cost magnetrons to be used. The lamps differ significantly from conventional UV lamps because they have no warm up time, do not deteriorate with age, do not have electrodes, have adaptable shapes and can be used in pulsed mode. Also the lamp does not suffer from nitric acid or moisture and does not use the expensive oxygen-enriched air as the corona discharge systems.

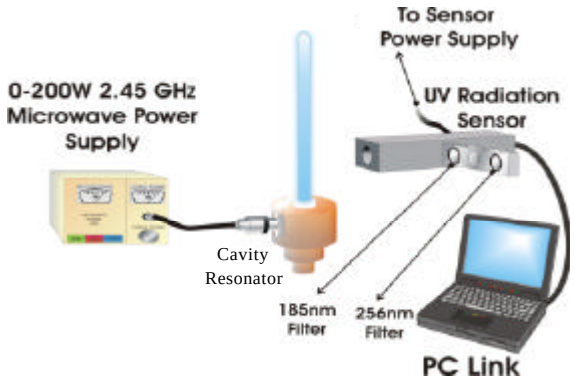

Figure 2: The Microwave UV lamp set up

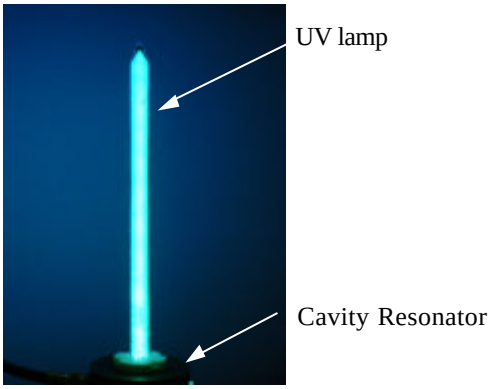

Figure 3: Microwave UV lamp in operation

Table 1: Calculation Characteristics for the resonant cavity [5]

Resonator	Mode	Resonance Wavelength (?)	Q × d	Shunt Resistance R (ohm)
	TE_{010}	$2\pi a\left(\frac{l}{2d}\log_e\frac{b}{a}\right)^{1/2}$	$\left\{\frac{1}{l}+\frac{1}{2\log_e(b/a)}\left(\frac{1}{a}+\frac{1}{b}\right)\right\}^{-1}$	$120\pi Q\frac{l}{l}\log_e\frac{b}{a}$

The lamp tube material is usually in fused silica (quartz). The choice of the suitable glass type is entirely dependent upon the emission range achievable and the application. In order to produce radiation at 185nm and 254nm, there is a limited choice of glass materials where General Electric and Heraeus usually classify this as “GE214” or “214”. Silica has the advantage of being quite transparent to a very wide spectrum of UV light and the transmittance characteristic is fairly high. For deep-UV emissions however, it is preferred to use synthetic fused silica [6]. Figure 4 shows the transmission characteristics for such quartz tubing. It has to be noted that the choice of the envelope material is important, as well as the choice of the tube wall thickness and finally, the lamp diameter.

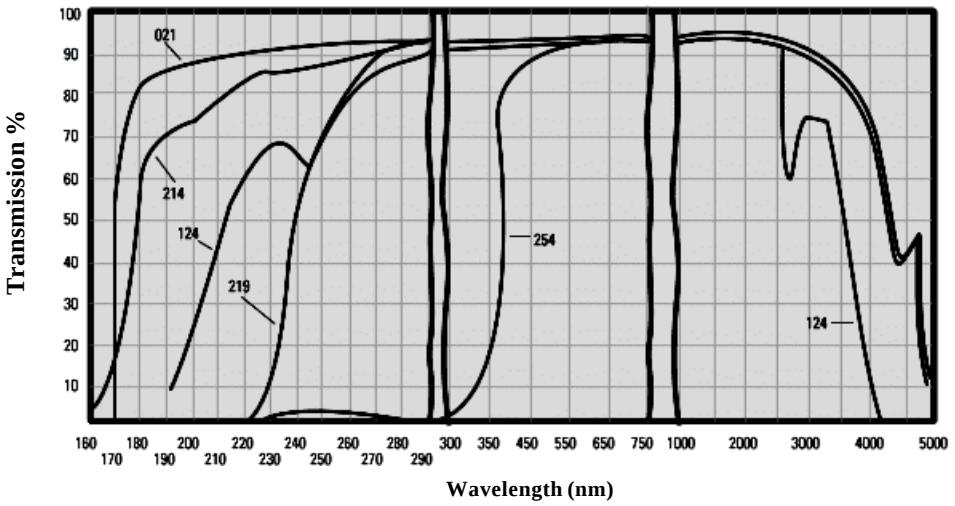

Figure 4: Transmission characteristics for different quartz tubing types [6].

3. Microwave Ozone Generator

The microwave plasma system has the benefit of being converted to an ozone generator by mounting a specially designed cylinder on top of the resonant cavity. The material used for the ozone chamber fitting was machineable grade nylon, which is a cost effective material and needs few man-hours to derive its desirable form. The PTFE ring positioning screws, allow for fine positioning and tuning of the lamp, whilst being converted to an ozone generator. The Ozone generation setup is illustrated in figure 5.

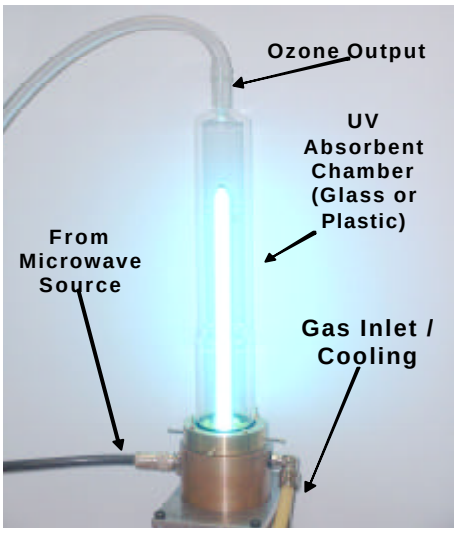

Figure 5: Schematic representation of the microwave Ozone generator

The main concept behind the ozone generator setup takes advantage of the fact that the resonant cavity allows gas flow which can be directed longitudinal to the lamp. As the gas flows alongside the lamp it gets irradiated by the 185nm line emitted and the oxygen content of the gas is converted to Ozone. Because this process is not static, the 254nm lines emitted do not severely interact with the ozone. Furthermore, whilst the gas flows through the ozone generator setup, it has already cooled the lamp and consequently resulting a high productivity rate. The inlet gas has no needs to be specially prepared for the process, i.e. a compressed air and not enriched oxygen as in the case of the conventional ozone production systems [7]. The concept of the ozone generator is shown schematically in figure 6. Ozone measurements were carried out using electrochemical transducers. The rated ambient temperatures are between -25^{o}C to $+50^{o}$C. The ranges can vary between 0 and 10ppm with a sensitivity of 0.1ppm up to a range between 0 and 100ppm. The output signal can be transmitted on a 4 – 20 mA current loop to remote displays or data logger. The device normally operates off mains power but hand held sets operating off 12V dc batteries are also used [8]. Various

experimental measurements were carried out in order to optimise the performance of the system. Figure 7, shows results of ozone concentration in ppm at various gas flow rates and microwave power ranging from 70-150W. Whilst figure 8 shows the overall ozone production rate using microwave power of only 70W .

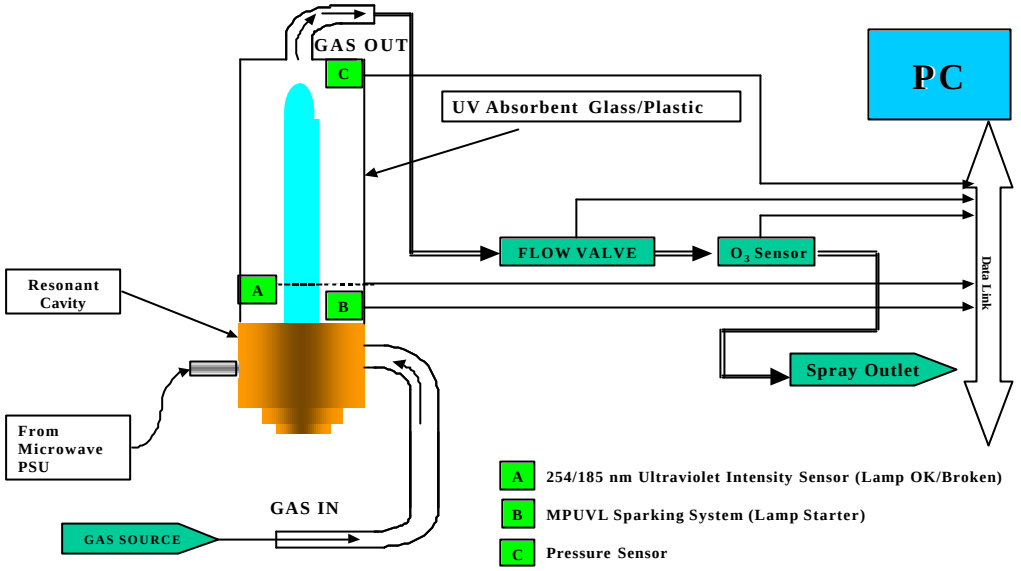

Figure 6: Experimental setup for Ozone production measurements

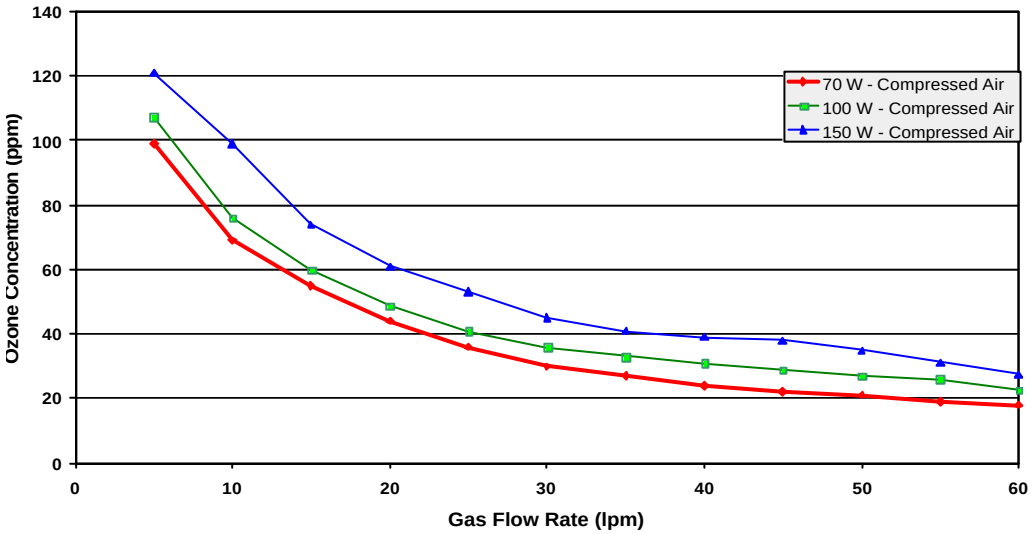

Figure 7: The performance of the ozone generator for compressed air for different net microwave power settings and different gas flow rates

This figure shows that when a fast gas flow is established, the ozone production rate is higher whilst the absolute ozone concentration is low and vice versa. Other investigations were conducted to study the effects of the microwave ozone source on various bacteria in comparison with the corona system. The both system parameters were similar in order to achieve a fair conclusions. The testing medium were varied from Petri dish to stainless metal surface. Figure 9a shows the effects of ozone on Pseudomonas Aeruginosa. The right-hand side Petri dish with agar cultivated bacteria shows the untreated Pseudomonas Aeruginosa stain and the left-hand side Petri dish shows the effect of ozone, where almost no bacteria colonies are visible. The results of the test are shown in figure 9b. As can be seen that in using agar Petri dish a reduction of more than 5 logs has been achieved within 10min operation with microwave ozone production of 70ppm. Similar results were achieved on reduction of Staphylococcus Aureus bacteria species.

4. High Frequency Simulations Using Mote Carlo Algorithm

The simulation obtains certain information concerning the number of gasses or (gaseous elements) involved, and their cross-sections for all their elastic, inelastic and ionisation collisions. The cross-sections are inserted into a special text file with a specified index, so that all processes and entries are accounted for. The software obtains information about the microwave field frequency and strength and the gas pressure. Having obtained all the necessary data, the electron trajectory can be calculated. Let Q be the collision between the electron and the gas atoms, N the number of these atoms and n the number of the collision processes. The mean free path of the electron (L) is then given by [9,10]:

$$L = \frac{1}{\sum_{j=1}^{n} NQ_j} \qquad (2)$$

The type of collision, K, is decided upon the comparison with a random number, with $RN \in \{1, n\}$:

$$K = \frac{\sum_{j=1}^{k} NQ_k}{\sum_{j=1}^{n} NQ_j} \succeq RN \qquad (3)$$

Where, n is the process with the highest electron energy demands. For the majority of the ionised gasses, process one is considered the elastic collisions and process n, the ionisation collisions. Between one and n reside the inelastic collisions in terms of energy requirements. RN is the pseudo-random number that the process is correlated and the compared with. The simulation requires some input from the user, such as, the frequency of the microwaves (GHz), the strength of the electric field (V/m), the gas pressure (torr) and finally, the number of collisions. The outputs of such a simulation include the time the electron expended after the simulation alongside with its energy. Figure 10 shows the simulation run for the Hg plasma as a function of the power fraction and the strength of the microwave field, for a frequency of 2.45GHz.

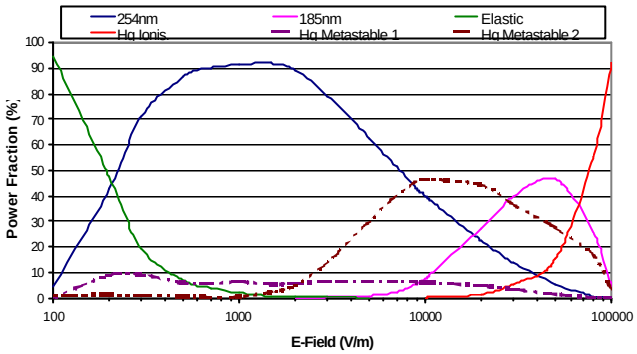

Figure 10: Monte Carlo Simulation of microwave plasma at 2.45GHz

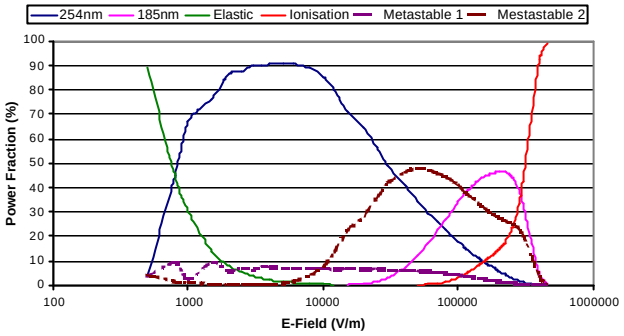

Figure 11: Monte Carlo simulation of microwave plasma at 10GHz

As the field strength increases, the 254nm line emission rises, along with some metastable processes, which is then followed by the 185nm line. At the depletion of this line, the energy the microwave field is high enough to cause ionisation. This is the highest limit reachable that can cause an effect to the gas. Figure 11 shows the simulation results for 10GHz microwave plasma. Even though the efficiencies of 254nm and the 185nm wavelengths are not severely affected, but it can be observed that the E-field required to drive the plasma has to be higher as the frequency increases. This observation is very important in the microwave plasma system development to operates at very high microwave power conditions, and produce high absolute UV/Ozone intensity.

6. Conclusions

The results have shown that a controlled low-pressure microwave discharge is able to produce higher yields of ozone than by the corona discharge for the same input energy. Currently a low power lamp (200W per meter) has been developed using a low-pressure mercury microwave discharge lamp. This system is able to develop ozone at the rate of 38 gm/kWh compared with the corona system which produces ozone at the rate of 15 gm/kWh. Furthermore a Monte Carlo theoretical model on gaseous simulation has indicated that the microwave lamp can be scaled up to produce an output of 1kW/m by using higher frequency >2.45GHz and operating under pulse mode. This level of efficiency cannot be achieved by other technologies.

THERMAL SPRAY TECHNOLOGY USING MICROWAVES

P. Mavromatidis[1], M. Houghton[1], A.I. Al-Shamma'a[1], J. Lucas[1], H. Al-Badiary[2]

Abstract

Thermal spraying is a generic name for the process of projecting molten particles at high velocity to form a surface coating on a component to give a superb mechanical bond. In this way the surface of a component can be rebuilt, if worn or damaged, or given a wide range of attributes. This paper describes the key advances using microwave thermal spray compared with current techniques including plasma spraying and high velocity oxy-fuel (HVOF). Furthermore, the system setup, electromagnetic wave simulations using High frequency Structure Simulator (HFSS) package and calculation of gas velocity is also presented.

1. Introduction

Thermal spraying is a continuous, directed melt spray process in which particles (10 to 50μm diameter) of virtually any material are simultaneously melted and accelerated to high velocities through either a combustion flame or a non-transferred thermal-plasma arc [1-3]. Combustion flame spraying uses compressed air or oxygen mixed with a fuel (e.g. acetylene, propylene, propane, hydrogen). The process yields low performance coatings due to the low flame velocity (~50m/s) and low temperature achieved within the combustion flame. In addition the combustion products, which include HC, CO, NOx, are both dangerous and contribute to air pollution, whose standards are becoming more stringent. HVOF spraying is a novel variation on combustion spraying. The compressed flame undergoes free expansion upon exiting the torch nozzle thereby experiencing high gas acceleration generating high velocities up to 800m/s. Figure 1 shows the main principal of this process. The powder particles, injected at the rear of the torch, attain these high velocities so that upon impact on to the substrate, the particles spread out very thinly and bonds tenaciously to the substrate and to all other splats in its vicinity. This yields a well-bonded, dense deposit. Alternatively high velocity methods alone can be used.

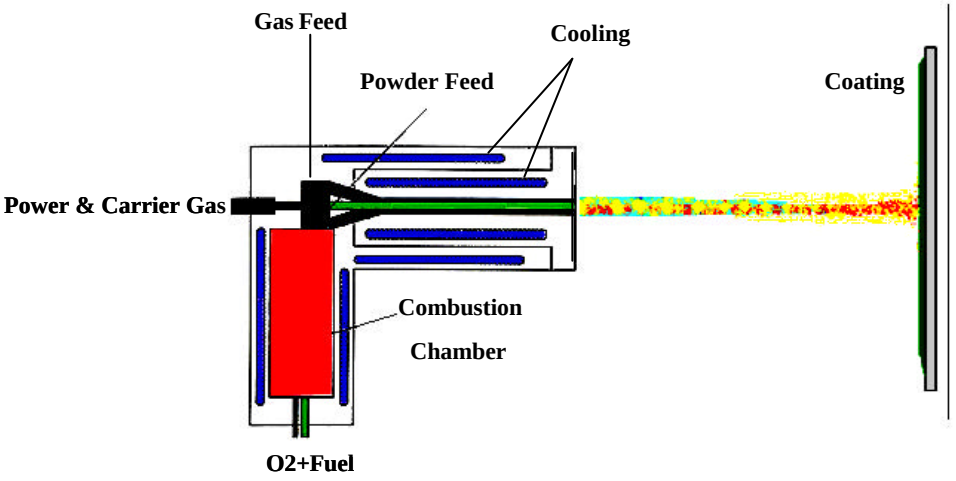

Figure 1: High Velocity Oxy -Fuel process

In plasma spraying [4], as shown in figure 2, the plasma is created by an electric arc burning within the nozzle of a plasma gun and the argon arc gas is formed into a plasma jet as it emerges from the nozzle. Powder particles are injected into the jet where they melt and the strike the surface at high velocity to produce a strongly adherent coating. Almost any material can be sprayed including metals, ceramics and plastics. The workpiece remains cool because the plasma is localised in the gun. Antolli Papyrin and colleagues at the Russian Academy of Sciences were the first to demonstrate the cold spray process in the mid-1980s [5]. The basis of the cold spray, as shown in figure 3, process is the gas-dynamic acceleration of

particulates to supersonic velocities (300-1000 m/sec), and hence high kinetic energies, so that solid-state plastic deformation and fusion occur on impact to produce dense coatings without the powder material being significantly heated. This is achieved using convergent-divergent, de Laval nozzles, high pressures (up to 500 psi [3.5 MPa]) and flow rates (up to 90 m^3/hr) of gases such as helium. The spray pattern is roughly 20 to 60 mm^2; spray rates - 3-5 kg/hr, with build-ups of about 250 µm (10 mils) per pass. Powder particle sizes are typically of the order of 1-50 µm. Obvious disadvantages to the cold spray process include the use of high gas flows, increased gas costs, especially in the case of helium. Also, this spraying process is only suitable for low temperature melting powders (e.g. copper and plastic). Furthermore, solid materials travelling at high velocities are abrasive, so the lifetime and dimensional stability of key components such as nozzle lifetimes should meet the industrial requirements in excess of 200 hours.

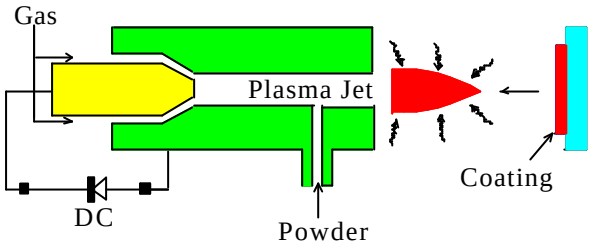

Figure 2: Plasma spraying process

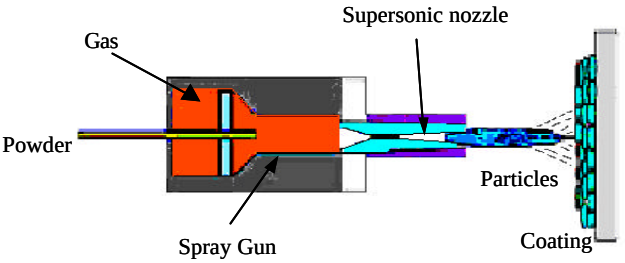

Figure 3: Cold spraying process

Thermally sprayed coatings have, in recent years, gained wide spread acceptance for a variety of industrial applications - the global market for thermal sprayed coatings is currently about £1.35 billion. This growth has been primarily technology led, and high value plasma coatings hold the lion's share of the market. A vast majority of these applications involve wear resistance, although the use of thermal sprayed coatings in combating high temperature corrosion also continues to receive considerable industrial and academic interest. These sprayed coatings are applied in order to achieve predeterminable life periods under severe operating conditions. Table 1, shows the automotive coating applications according to industry served.

Table 1: Automotive coating applications

	Wear							**Electrical**
Industry	Abrasive	Adhesive	Fretting	Erosion	Impact	Restoration	Corrosion Oxidation.	Resistance
Automotive engines	X	X	X	X	X	X	X	X
Diesel engines	X	X		X	X	X	X	
Automotive parts (non engines)	X	X				X	X	X
Rubber and plastic parts	X			X	X	X	X	
Electrical parts	X	X		X	X	X	X	

2. Key Advances

Presently the role of plasma coating within automobiles is relatively small at about £335M p.a. Such activities are concerned with engines and transmission, which represent about 10 to 20% of the car cost. Coatings are presently only 6% of this cost but are expected to rise to 8% by 2005 due to the expected increase in the use of 16 valve engines and catalytic converters for clean air emission. This low uptake of coating technology is because the two most popular commercial spray techniques, namely plasma spraying and HVOF have limitations when used with automotive applications. Plasma spraying uses expensive inert gases and has an inefficient heating process (<5%) whilst HVOF produces heating of the substrate and oxygen contamination. In addition, recently developed Cold spray technique requires high-pressure helium to give the powders sufficient kinetic energy, which is converted into thermal energy on impact with the

substrate. Cold spraying is only suitable for low temperature melting powders (e.g. copper and plastic). The spraying technique used in this research, is a continuous melting spray using a different approach on performing the bond between the injected particle and the surface. It uses a long and high thermal interaction path to gradually and uniformly heat the particles above melting temperature and only then use the extra kinetic energy to project them onto the substrate surface creating a weld-bonded coat. It uses microwave thermal heating (60% efficient) to preheat the nitrogen gas/powder so that the energy producing the forging actions is a combination of kinetic and thermal energy. This technique can be used with all coating powders including high temperature ceramics (e.g. silica, alumina). The fine control obtainable with this technique, which is a combination of cold and thermal spraying, will now open up a much wider range of coating activities within automotive manufacture.

3. Methodology

The background technology to this project is to demonstrate the use of "cold" microwave thermal heating by using to preheat the mixture of high-pressure gas and powder to produce a new arrangement for surface coating of substrates. The microwave thermal spraying system consists of a standard microwave waveguide cavity resonators operating at 2.45GHz, with the magnetron (2-6 kW) as a power source, circulator, matched load, stub tuner and the interaction cavity as shown in figure 4 (a and b). This microwave process heats up dielectric materials within the interactive cavity in a uniform distribution and then transfers the heat by convection/conduction to the carrier gas. Industrial heating in general remains one of the most difficult processes to control, due to the slow and imprecise nature of the convection, conduction and radiation process. Even when a uniform distribution of temperature is achieved, the heating time is limited by the physical properties of the heating material, such as specific heat, heat capacity and thermal conductivity. Thus in conventional heating all the heat energy is generated externally and transferred through the surface of the heating material. The microwave heating is a volumetric process and is generated internally within a dielectric material. The microwave energy is applied with a special mode distribution of the electrical (E) and magnetic field (M) profile inside the interaction cavity. The optimum arrangement has been modelled and realised by using Agilent HFSS "High Frequency Structure Simulator" software package. The electromagnetic field is distributed along and around the helix tube and throughout the silicon carbide (SiC) rod within the cavity resonator as shown in figure 5 (a and b). Thus to insure, that the rate of heating is relatively faster and accurately controlled. Once the microwaves are converted into heat in the dielectric material consisting of a SiC rod, the heat is then transferred through a helix stainless steel tube to the nitrogen carrier gas, as shown in figure 4b. Nitrogen is selected as the carrier gas, as it will prevent oxidation of the powder particles and at the same time provide a cost effective solution.

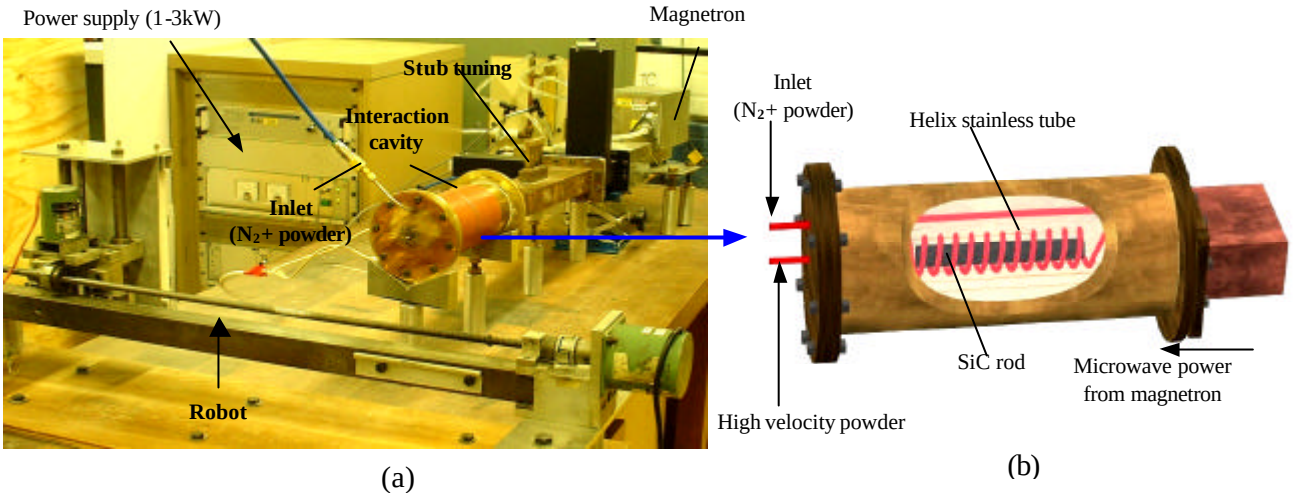

Figure 4: (a) The completed microwave system, (b) The interaction cavity

The nitrogen gas is passed longitudinally through the interactive cavity via an inner helix tube so that it has a long path interaction with the walls of the tubes. The microwaves are able to directly or indirectly heat the silicon carbide at all temperatures because it has an electrical resistance.

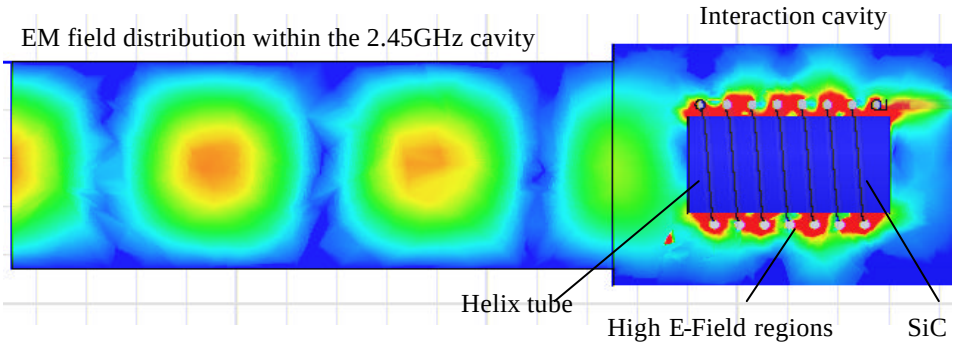

Figure 5: (a) HFSS modelling of the microwave thermal spray system

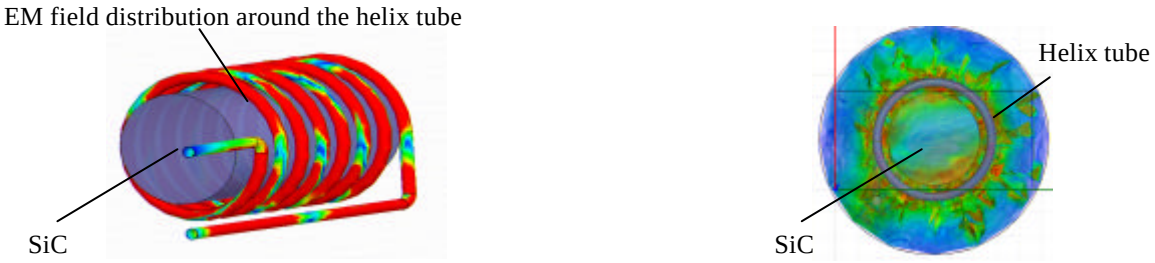

(b) (c)

Figure 5: (b) close look up into the interaction cavity resonator, (c) End view: E-field distribution within the interaction cavity

Thus the gas heating has been achieved by combining the direct and conduction heating of the silicon carbide rod and the helix tube. The hot gas and metal powder leave the helix tube via an accelerating nozzle of various designs. For each technique a model of the flow field, full 3D CFD analysis, computational temperature analysis and multiple phase supersonic flow was modelled [6]. This analysis has been carried out using a specialist CFD software package. Based upon these analyses, the optimum technique has been chosen to allow the microwaves to interface efficiently inside the interactive cavity. As the SiC warm up, the microwaves are able to use direct dielectric heating of the SiC because their electrical resistance dramatically reduces with increasing temperature (>200^{o}C). This allows the pre-heating of the nitrogen gas to be controlled by varying the cavity length (L) and microwave power (W). The calculations have shown that the nitrogen gas pressure varies between 15 and 25 bars with 76 to 152gm/min of coating powder. The input power (W_H) to pre-heat to $T_1{}^{o}$C from T_o is related to the mass flow rates of the gas (F_{gas}) and powder (F_{powder}) and their specific heats (C_g and C_p).

$$W_H = (F_{gas}\, C_g + F_{powder}\, C_p)\,(T_1 - T_o) + \text{Thermal Losses} \qquad (1)$$

Specifically for the powder we have, $W_H = R_{powder}\, C_p\, (T_1 - T_o)$

To attain the cold process supersonic flow conditions, it is necessary to either taper the helix tube or design a special nozzle to meet this requirements for various materials including copper and aluminium. Upon impact with the substrate the kinetic energy is converted into thermal energy and at the substrate surface, the temperature of the coating momentarily rises to $T_2{}^{o}$C. The relationship is given below,

$$W = C_p\,(T_1 - T_0) + \nu_p^2/2 = C_p\,(T_2 - T_0) + L \quad . \qquad (2)$$

Where L is the latent heat and ν_p is the powders velocity.

Table 2, shows how the powder temperature and velocity are related for soda glass. When T=1400 ^{o}C the powder is at its melting point. At 600^{o}C, the powder velocity has to be 1022m/s, which is the maximum nitrogen gas velocity (Mach 1.33) achievable without the need of excessive gas pressure (less than 10 bar) in order to achieve the melting condition. Hence a coating of glass ceramic is achievable within our experimental range of temperature of 800 to 1000^{o}C. The long microwave-heating path ensures efficient transfer of energy to the powder and up to 60% thermal efficiency was achieved. This independent control of

the thermal energy will allow the powder to be pre-heated to a fixed temperature below the melting temperature so that the 'cold forging' coating techniques can be used upon impact.

Table 2: Deposition of ceramic (soda glass)

T_o °C	T_1-T_o °C	$W_H = C_p (T_1 - T_o)$ Watts	ν m/sec	W_{KE} Watts	$(W_H + W_{KE})$ Watts
20	600	401	1022	522	923
20	800	535	880	388	923
20	1000	669	712	254	923
20	1380	923	-	-	923

The advantage of microwave thermal heating is that the temperature of the dielectric material continues to rise as long as power is applied. Furthermore the relationship of gas temperature with microwave power is proven to be linear, as shown in figure 7. This allows us to use a wide range of industrial relevant metals as summarised in table 3.

Table 3: Thermal and velocity spray parameters

Material	T (°C)	L (J/gm)	Sp ht (J/gm °C)	Mach 1.33 Velocity (m/s)
Tin	232	59	0.226	597
Lead	327	25	0.127	650
Zinc	420	117	0.389	699
Aluminium	660	393	0.907	811
Copper	1083	175	0.389	978
Glass	1400	0	0.669	1086

4. Coatings

The quality of coatings produced from the microwave thermal spraying system can be varied within a fully controlled environment to achieve the industrial desired conditions. In general, when coating a material, it is important that the powder is spherical and has uniformly sized particles thus easing the melting and deposition of the powder particles. The structure and phase of each coat depends on the cooling and solidification rates experienced during solidification [7]. The cooling rate, in turn, depends on material properties such as the melting point, density and specific heat. In addition, the gas conditions also affect the particle size that can be sprayed and processed economically. The substrate surface has to be adhered to the industrial standard practice of grid blasted then cleaned to remove grids, oil or other impurities. It is important that the right amount of powder is mixed in the gas at a uniform rate to ensure the melting of the deposit and create a smooth surface. The combination of the above parameters will ensure a strong bond between the surface and the particles with the minimum amount of impurities and contamination. Figure 8 shows the industrial Praxair powder spray unit used in this project. Microstructures of coatings are shown in figures 9 (a and b) and 10 (a and b) using scanning electron microscope (SEM) imaging for aluminium and copper respectively. On microscopic observation of cross section of the coating, such "splash like" morphology can be observed. The presence of entrapped gases as well as unmelted particles, determines the coating properties because they create points of stress concentration during in service loading. Larger particles do not melt down to their core, and thus do not spread on impact, which lead into a porous coating with irregular signs of cracks running through it especially for brittle materials. The porosity adversely affects the wear property, higher porosity coating resulting in a failure by oxidation whilst a low porosity level reduces the ability of coating to accommodate stress. However, for the case of the aluminium and copper powders, the particles are non-uniformly shaped with sharp edges and variable particle sizes. Pre-treatment of the surface was limited only to its cleaning with ethanol. These powders are fed in a nitrogen gas stream with velocity of only 70 m/s at various temperatures and the SEM magnifications of 1:500, which clearly shows that particles have fully melted and adhered onto one another as shown in figures 9b and 10b. The coating process applied with this microwave thermal spray system is for a range of materials including tin, aluminium, copper, zinc, lead and ceramic (soda glass) powder on steel surface and plastics. Using this technique will allow a new concept of wiring harness, where the electrical conductors are integrated into the

vehicle body shell by using a spray technique. This reduces the weight and eliminates the expensive manual fabrication and installation of the wiring harness. Thus leading towards fully automated vehicle manufacture.

6. Conclusions

The microwave thermal spray technique will provide a low cost, energy efficient system having superior control facilities. By the use of nitrogen gas, the operating costs are low and as well as higher temperature ceramics can now be sprayed. It is expected that these properties will allow new application areas to be undertaken. As a specific result of this research, the automotive industry will be provided with a more flexible mode of BIW production which will allow vehicles to be produced more cheaply and with a lighter weight, higher fuel efficiency and better protection during collisions. The choice of manufacturing materials will be increased so that designs using aluminium and composites can be used. The results of this project will allow a higher degree of robotic automation to be used in the manufacture of the vehicle and will lead to better quality control.

Abstract

There is increasing interest in the use of microwave power for industrial applications. A pulsed tuneable microwave source is beneficial as it allows the high electromagnetic field of a high power to be applied to a target without excessive heating. The Free Electron Maser (FEM) is the tuneable source with ability to operate across a wide range of frequencies from 8 to 20 GHz. Using higher frequencies than the common 2.45 magnetron, increases the fields obtained and also beneficial scaling effects on some applications, such as microwave induced plasmas. The paper presents the basic principles of the FEM system as well as the applications of UV, Ozone and chemistry.

1. Introduction

A research project assessing the use of microwave radiation for industrial applications at higher frequencies than the standard 2.45GHz produced by most magnetrons is being undertaken as part of the European Community Competitive and Sustainable Growth programme. The basic principals of the FEM system is that as electrons passing through the Industrial Free Electron Maser (IFEM) resonant cavity oscillate from side to side due to the static magnetic field produced by the wiggler magnet array [1-3]. These oscillating electrons emit electromagnetic energy, which forms what is referred to as a radiation field. The radiation field combines with the wiggler field to produce a pondermotive or beat wave. This pondermotive wave then promotes axial bunching of the electrons in the electron beam allowing a more coherent radiation output from the electrons. To allow such an interaction to take place, and energy to be extracted from electrons in the electron beam, the electron velocity must be matched to the phase velocity of the electromagnetic field in the cavity. This condition is often referred to as beam wave synchronism. For the synchronism case, equation 1 shows one form of the basic FEL resonance equation. This equation describes the wavelength output from a FEL, and has been reported previously many times.

$$\lambda_r = \lambda_w \frac{(1-\beta_e)}{\beta_e} \qquad (1)$$

where, λ_r : Electron output radiation wavelength, λ_w : is the wiggler magnet period, $\beta_e = v_e/c$, which is the ratio of the electron beam velocity, v_e to the speed of light, c. Apart from the electron velocity, another factor which is used to describe the energy of an electron in an electron beam is the relativistic mass factor γ. This quantity relates an electrons rest mass to the effective mass of the electron when it has been accelerated to a particular energy, $\gamma=1+E/511$, where, γ : is the electron relativistic mass factor; E: is the electron energy in kilovolts and 511 : is a factor relating to the rest mass of an electron (mc^2). As the relativistic mass factor may also be defined as $\gamma = (1-\beta_e^2)^{-1/2}$ then for highly relativistic electrons with a large value of γ, then $\beta_e \approx 1$. For this case equation 1 may be approximated as:

$$\lambda_r \approx \frac{\lambda_w}{2\gamma^2} \qquad (2)$$

What is significant about equation (2) is that the radiation output wavelength from an FEM varies in proportion to the wiggler period, and inversely with the electron energy. Although equation (2) is the standard relation in most FEMs work, equation 1 is more suitable for FEM, where $\beta_e << 1$.

The FEM is operated in an oscillator configuration. The FEM interaction region is a rectangular waveguide resonant cavity terminated by copper irises. It has a frequency tuneability between 8-12.4GHz. This cavity is placed in the centre of an NdFeB permanent magnet undulator with 33 periods [4]. The electron beam source is a travelling wave tube (TWT) type dispenser cathode electron gun. After passing through the interaction region the electron beam is recovered using a single-stage depressed collector. The FEM system set up is shown in figure 1.

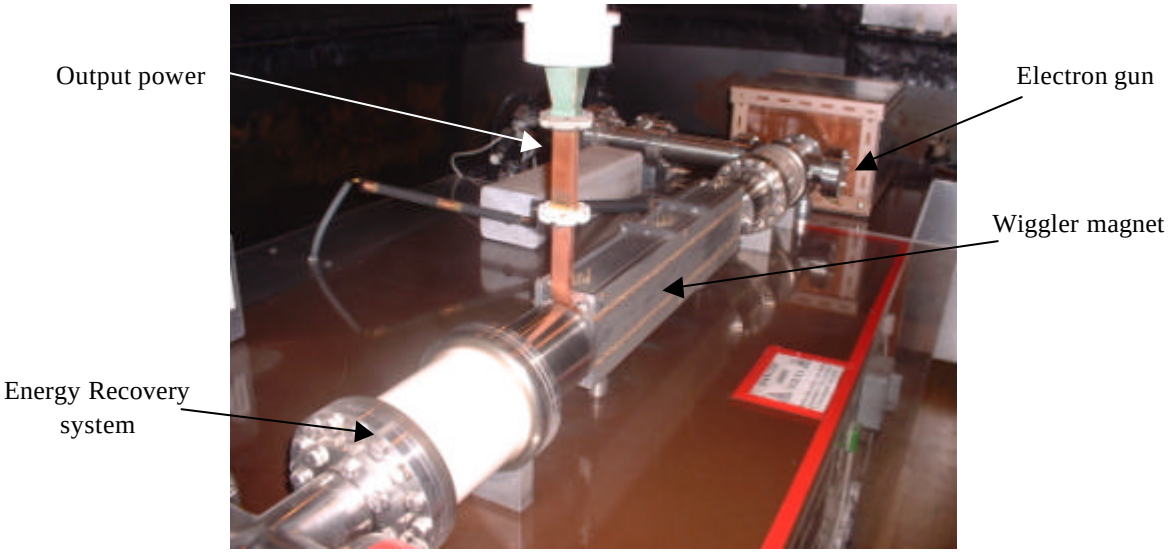

Figure 1: X-band FEM System setup seen from the collector end

The FEM characteristics is governed by the behaviour and capabilities of various components. The pulse length is limited to about 200µs by droop of the cathode supply voltage. The output power is limited to 1kW by the beam current. The pulse repetition frequency (PRF) is limited to 2kHz by the pulse generator. Average power is limited to 50W by vacuum degradation considerations because the electron beam trip level on the vacuum gauge has been set at a conservative $1x10^{-6}$ mbar to avoid any risk of poisoning the gun cathode. Various experiments in the following areas have been performed including Microwave UV/ozone chemistry, Focussed microwave heating, Microwave thermal chemistry, Microwave plasma chemistry and Microwave plasma material processing.

2. Microwave UV/ozone chemistry

The purpose of this experiment was to assess whether there is any benefit to be gained using higher frequency microwave radiation as the power source for UV fluorescent tubes [5,6]. Microwave driven fluorescent tubes can operate at much higher power per unit length than conventional mains driven tubes because there is no need for electrodes, which wear out at high currents. For the initial experiments, commercially available 16mm diameter UV tubes were used. The waveguide used at the workstation is WR90 (22.86mm x 10.16mm). This is 23mm across, so it was possible to simply drill a 16mm hole through the centre of the broad faces of the waveguide and push the tube through. Unfortunately the measured reflected power was as highest 60% of the forward power. Widening the waveguide around the tube to give the 8GHz microwaves a more "square" field distribution increased the efficiency, but reflected power was 30%. For this reason we changed to a waveguide surfatron [7], to launch surface waves along the inner surface of the quartz tube. Using the surfatron, see figure 2, it was possible to achieve almost 100% transmission of microwave power into the UV tube. The waveguide surfatron is a microwave structure for launching surface waves within a plasma column. Microwave power is supplied via a rectangular waveguide the coaxial section with tuning short circuit enables optimised the microwave power launching.

Figure 2: The 8-12GHz waveguide Surfatron

For 2.45GHz operation, the variable power magnetron was coupled to a WG9A (86mm x 43mm) waveguide. A small antenna coupling on the next wave-guide section enabled forward power to be monitored via crystal

microwave detector diode [HP423B]. The microwaves next pass through a circulator onto the tuning section. This section consists of a waveguide surfatron mounted on the wide section of the waveguide, this part of the waveguide is tuned by a stub tuner and movable short circuit, see figures 3 and 4. Any reflected power from this section goes back into the circulator and is dissipated in a dummy load mounted on the circulator's third port. A small antenna coupling mounted on this port provides reverse power measurement via crystal detector. The waveguide surfatron is it's self tuned for minimum reflected power and maximum plasma column length by correct positioning of the coaxial short circuit plunger.

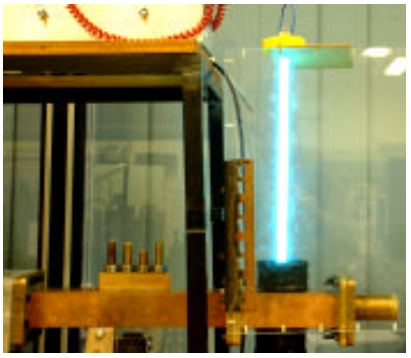

Figure 3: The 2.45GHz Microwave UV lamp demonstrator system

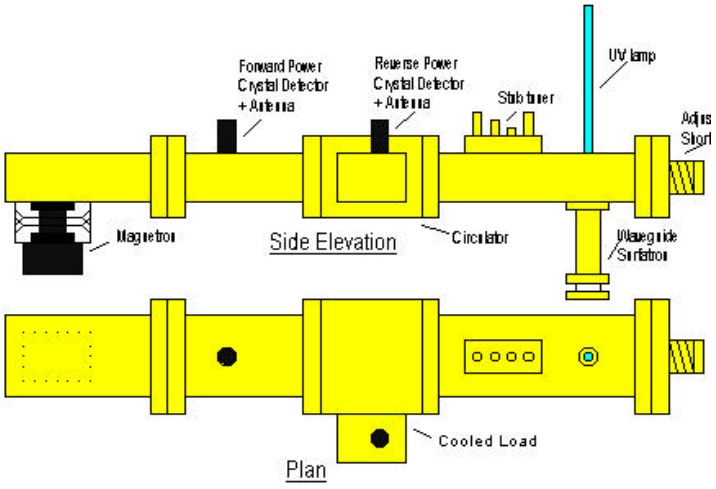

Figure 4: A Block diagram of the 2.45GHz microwave UV lamp

3. Theoretical and Experimental Considerations

A Monte Carlo algorithms [8] have been used to simulate the effect of microwaves on gases discharges at frequencies ranging from 2-10GHz. Figure 5 shows simulation results for the 2.45GHz using conventional microwave oven (magnetron) system. It can be clearly seen that as the microwave electric field increases, at 10kV/cm region that the 185nm radiation increases as the 254nm line decreases. This theoretical result is confirmed in the experimental measurements shown in figure 6 which indicated that as the microwave power increases, i.e. the electric field, so does the 185nm to 254nm radiation ratio. The FEM system was set up to generate a 100µs pulse required for the plasma column to reach the ends of a 30cm UV tube, as in figure 7. Figure 8 confirms the trend shown by this theoretical model. High power (high E field), narrow pulses yield more ozone than low power, wide pulses.

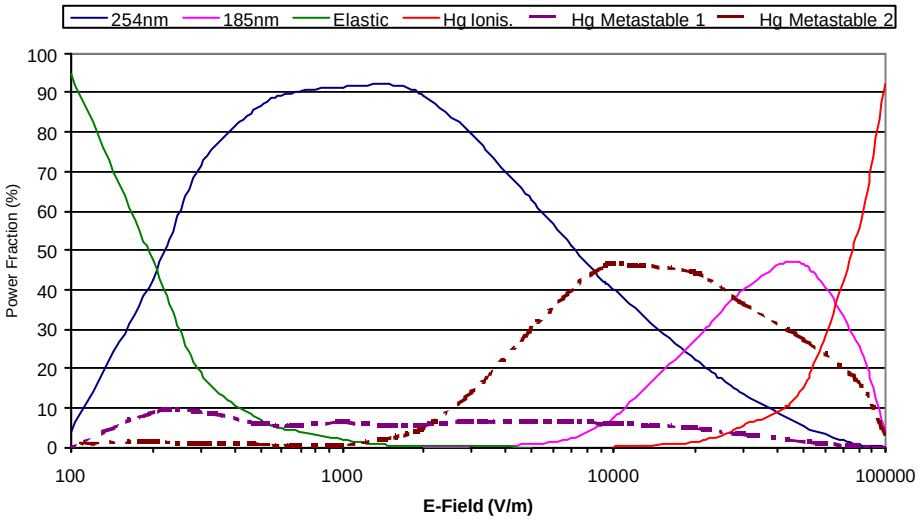

Figure 6: The 2.45GHz microwave discharge simulation

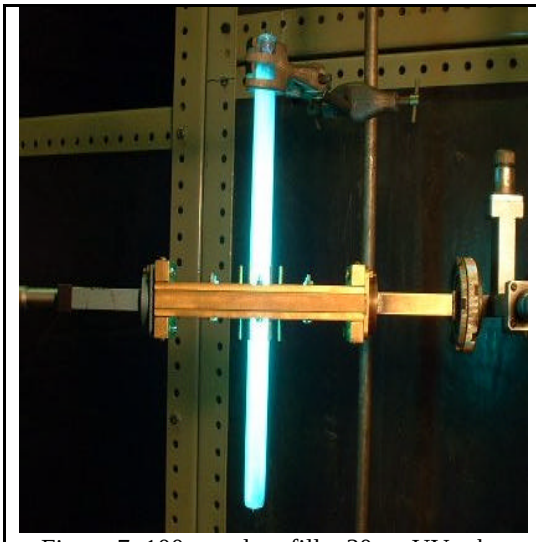

Figure 7: 100µs pulses fill a 30cm UV tube (shown with the waveguide surfatron assembly removed).

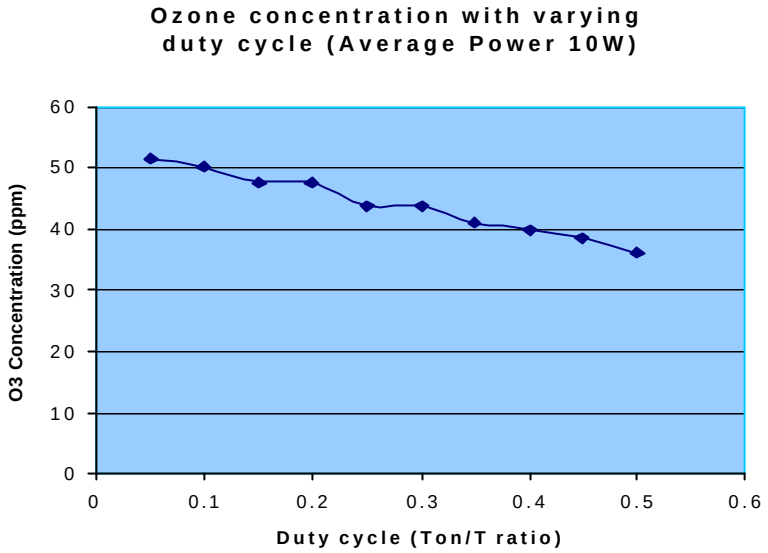

Figure 8: Experimental measurements to investigate the effect of duty – cycle on Ozone production

If high UV power density required, for example at 254nm, one can increase the microwave power but a point is reached where the power fraction, at 254nm, decreases as shown in figure 6. The theoretical model indicates the solution to obtain high power densities is to increase microwave frequency [8]. Figure 9 shows the Monte Carlo simulation for microwaves at 10GHz. It can be seen the fractional power curves have shifted right. The maximum 254nm radiation curve has now moved from 1000 v/m to approximately 10,000 v/m. This is a very important point in order to maintain the germicidal efficiency at high power densities, i.e. higher output power per unit length.

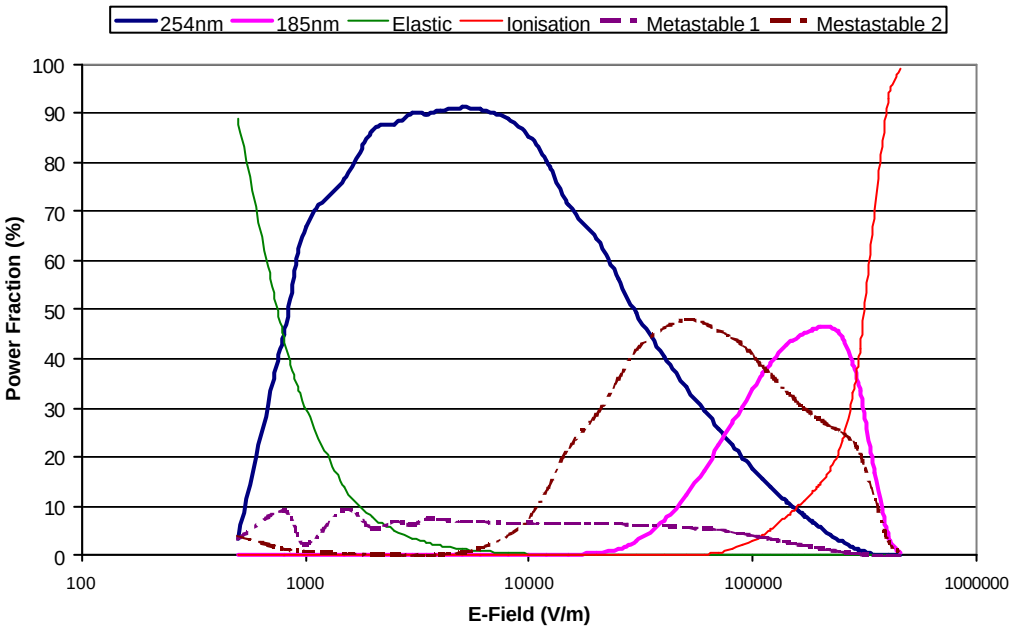

Figure 9: The 10GHz microwave discharge simulation

In addition, figures 10 and 11 agree with the theoretical model that 2.45GHz produces more UV at 254nm than 8GHz at lower microwave powers. Also in agreement with theory is the fact that at higher powers the 2.45GHz powered UV gradient levels off while the 8GHz powered UV is relatively steeper. It is estimated that the IFEM operating at 8GHz will become more efficient, than the 2.45GHz system, at producing UV at 254nm and Ozone at approximately 400 Watts. As the microwave frequency increases so does the UV power

density. However, there are limits to the theoretical model as electric field can only be increased so far before die lectric breakdown and arcing occurs. Wavelengths higher than 254nm has not been included in this simulation.

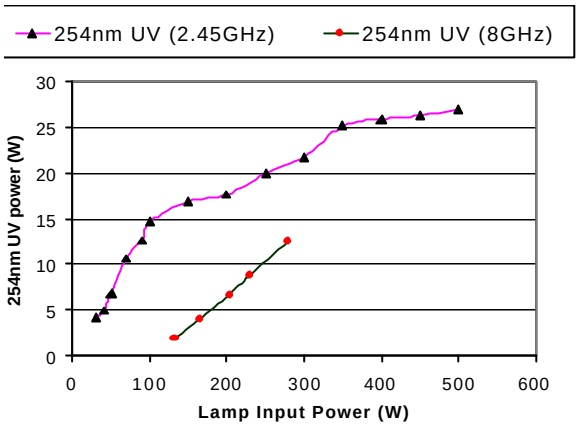

Figure 10: UV Output at 254nm for 2.45 GHz and 8GHz

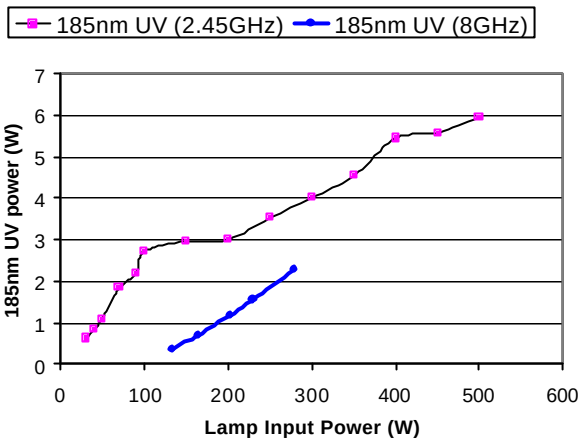

Figure 11: UV Output at 254nm for 2.45 GHz and 8GHz

4. Microwave Thermal Chemistry

This experiment involved the acceleration of chemical synthesis by microwave irradiation. Small samples of dissolved chemical were placed in a sample vessel as shown in figures 12. This was placed in an irradiating chamber mounted in X-band waveguide, figure 13. The waveguide section was terminated in a tuneable short circuit and reflected power minimised using a matching transformer. The procedure used was to tune the transformer and short circuit with a measured quantity of the solvent in the sample tube prior to irradiating the chemical product. During the heating process, an infrared probe at the base of the sample tube monitored the temperature.

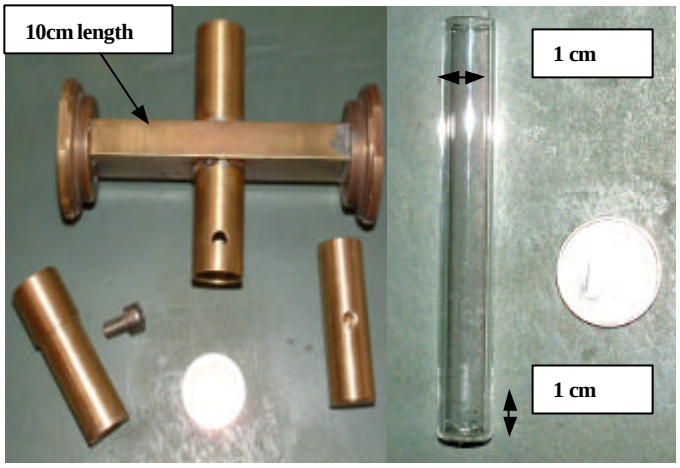

Figure 12: X-Band chemical synthesis reactor

Figure 13: FEM chemistry experimental setup

A selection of three sets of model synthesis have been investigated including the synthesis of cyclohexenes starting from imine and methyl cyanoacetate, see figure 14.

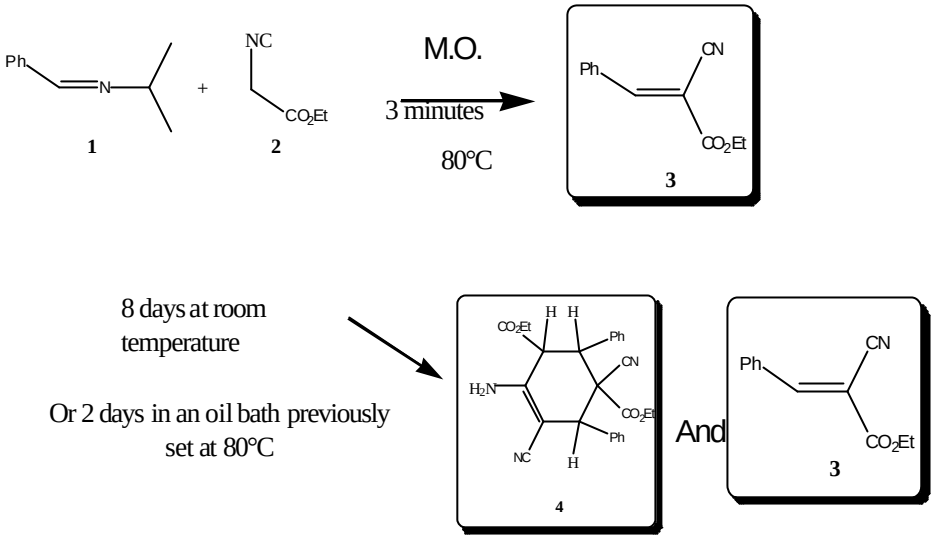

Figure 14: Types of chemicals have been used in FEM system

This model is particularly suitable owing to the fact that according to the conditions, the results are different. At room temperature (8days) or under conventional heating (2 days in an oil bath at 80°C) cyclohexene **4** and alkene **3** are formed, but under microwaves (2.45 GHz) only the alkene **3** is observed at 80°C (3 minutes). The mechanism of the formation of the cyclohexene has been established, the first step being the formation of the alkene **3** (Scheme 4).The FEM experiments led to the synthesis of products that have not been seen using a conventional laboratory microwave oven as the heat source [9,10]. Previously these products have only been seen after eight days at room temperature or five days in an 80° oil bath. In the FEM experiment the production took three minutes, this may be due to the use of higher frequency radiation but it could also be due to the fact that the FEM power is applied in a "pseudo continuous" manner, the "off" periods are around a millisecond, whereas the oven cycles on and off over several seconds just like a domestic oven.

Diagnostics of high power pulsed microwave discharge

Department of Physical Electronics, Masaryk University, Kotlářská 2, CZ-61137 Brno, Czech Republic

Introduction

There is growing interest in using of the pulsed discharges in both research studies and industrial plasmachemical processes. The main advantage of using pulsed discharges is the possibility of promoting complex chemical reactions with rather low average thermal power. Although there are many studies on the plasmachemistry of pulsed discharges, they have mostly used common supplies (dc, radiofrequency, microwave), with relatively low peak power (10^2–10^3 W). However, our work deals with pulse peak powers of the order of 10^5 W.

When studying the volume plasmachemical reactions, the surface reactions are often a complication. Therefore, we used an experimental device in which the role of the plasma – wall interactions is suppressed. We achieved this by separating the plasma and the walls. The discharge is produced only at the vicinity of a focal point of the microwave beam, which is 25 cm from the nearest wall.

In this paper we present the experimental results of microwave and optical diagnostics of low pressure, high power microwave pulsed discharge in nitrogen. We recorded intensities of important emission bands as well as temporal evolution of electron concentration and microwave power transmitted through the plasma.

Experimental

A schematic drawing of experimental apparatus is presented in Fig.1. The plasma is produced in a spherical glass vessel with an inner diameter of 0.5 m. From one side the vessel is irradiated by a horn antenna. On the opposite side wall, an aluminium foil is placed to reflect and focus the microwaves. Microwaves (X-band) are generated by refurbished radar (100 kW peak power, 2.5 μs duration, 400 Hz repetition). The field has a maximum in the centre of the glass vessel and therefore a plasma ball is formed there. It does not touch the walls which suppresses influence of surface reactions.

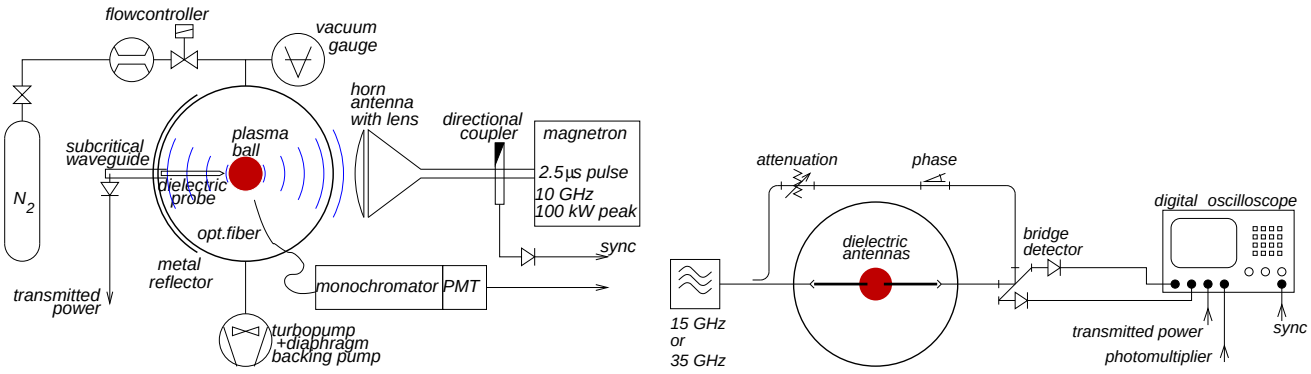

Figure 1: Experimental setup.

The experiment was carried out in a flow regime. The pressure was measured using a capacitance diaphragm gauge and maintained by a gas flow controller. The operating pressure was in the range 20–2000 Pa.

Microwave interferometers operating at 15 and 35 GHz were used to measure the plasma density. They were coupled to the plasma by means of dielectric (PTFE) rod antennae. This configuration permits rather localised measurements, as the dielectric waveguides/antennae were separated by 40 mm. Diameter of the waveguides was selected large enough to achieve propagation of microwaves inside of them without perturbation by outer

plasma. Detailed description and discussion is in [1]. The output signal from the interferometer was detected using diodes and then measured using an HP Infinium 500 MHz digital oscilloscope.

We recorded time resolved intensities of selected spectral lines and bands by means of monochromator (Zeiss SPM2) with photomultiplier (EMI 6255B). The transmitted part of exciting microwave power was measured by dielectric probe, attenuating subcritical waveguide and diode detector.

Results and discussion

The evolution of the important quantities (electron density, transmitted power, intensity of second positive (N_2 $C^3\Pi_u \rightarrow B^3\Pi_g$) and first negative ($N_2^+$ $B^2\Sigma^+ \rightarrow X^2\Sigma^+$) systems of nitrogen is presented in the left part of Fig.2 together with the shape of exciting microwave pulse. It is seen, that microwaves are efficiently absorbed even sooner than electron density reaches our detection limit. The overshoot in emission intensities is caused by combination of rising electron density and falling of electron temperature (see theoretical article [2]).

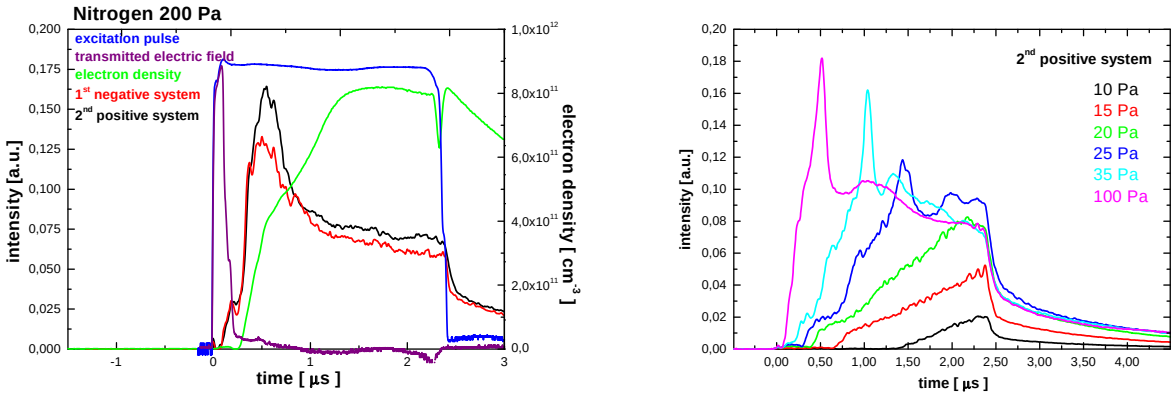

Figure 2: Results of time resolved diagnostics of high power pulsed microwave plasma. Left side: time resolved electron density, incident and transmitted microwave power, intensities of $2^{nd}+$ and $1^{st}-$ systems of nitrogen. Right side: influence of pressure on temporal evolution of intensity of $2^{nd}+$ system of nitrogen.

The right side of Fig.2 shows the dependence of temporal evolution of 2^{nd} positive system on pressure. For optimal pressures (around 100-200 Pa) the discharge develops quickly, but for lower pressures the reaching of steady state is much slower. The same behaviour can be observed in electron density curves.

Conclusion

We performed complex diagnostics of high power pulsed microwave discharge in nitrogen using microwave interferometry, optical emission spectroscopy and microwave power measurements. The results are compared to model.

Characterisation of nitrogen–oxygen flowing afterglow

V. Kudrle, M. Mrázková, P. Vašina, A. Tálský, J. Janča

Department of Physical Electronics, Masaryk University, Kotlářská 2, CZ-61137 Brno, Czech Republic

Introduction

Plasmachemical reactions occurring in N_2–O_2 mixtures are of great interest to many fields of the research. One of promising directions in applied plasmachemistry is a use of the plasma for a low temperature sterilisation, which is needed if e.g. polymer objects are to be sterilised. Generally, as the main agents responsible for killing bacteria are considered [1] atoms, radicals and UV radiation. To maximise the efficiency of the process the optimal operating conditions (mixture, power, CW/pulsed regime, etc.) should be found.

In our experiment in flowing afterglow configuration we measured the concentration of N, O, electrons together with radiation intensity of NOβ and NOγ systems. The measurements were carried out at various flow rates of oxygen and nitrogen. Moreover we investigated the influence of the afterglow position on the measured quantities.

Experimental

A schematic drawing of experimental apparatus is presented in Fig.1. A microwave discharge is produced in a quartz discharge tube with inner diameter of 13 mm by means of surfatron cavity, powered by 20 W microwaves (2.45 GHz). Our experiments being carried out in a flowing regime, afterglow is observed downstream in 1 m long quartz tube with inner diameter of 8 mm. Small amount of oxygen admixture may be added to the nitrogen gas before its passing through the discharge.

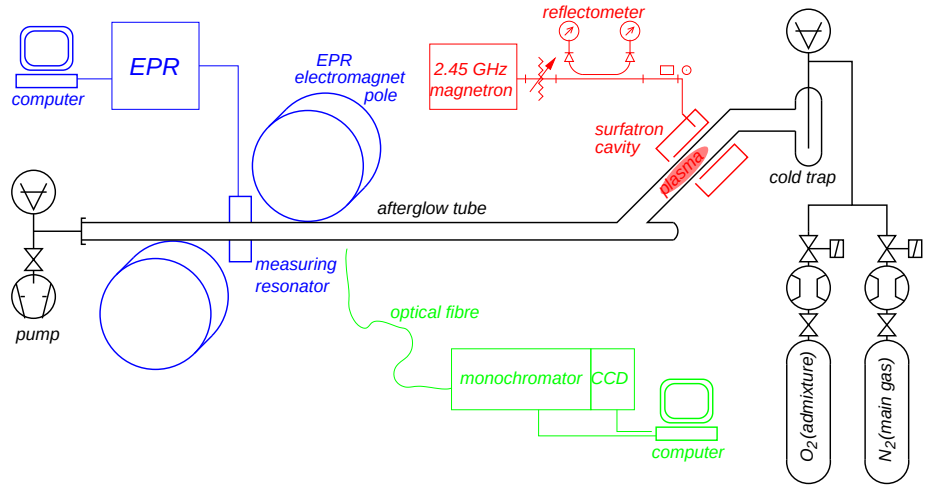

Figure 1: Experimental setup.

The gases are led from gas cylinders through the mass flow controllers to a LN_2 cold trap, which removes traces of unwanted impurities, like a water or hydrocarbons. The purities of all used gases were better than 99.995% according to manufacturers' certificates. Flow rate of oxygen was varied between 0 and 10 sccm and the flow rate of main gas was between 25–200 sccm. The pressure in the discharge was independently set at value between 300 Pa and 700 Pa by throttling the pump.

We employed electron paramagnetic resonance (EPR) spectrometer JEOL JES-3B operating in X-band to measure the concentration of atomic species. This method is based on resonance absorption of microwave energy

by the transitions between Zeeman split levels. After a calibration of the EPR device by molecular oxygen the absolute concentration was obtained. For details of use of EPR spectroscopy in plasma afterglow, see [2].

Optical emission spectroscopy was carried out using Jobin-Yvon TRIAX 330 spectrometer.

Results and discussion

We observed that N concentration reaches a visible maximum[3] for certain oxygen admixture. The evolution of [N] along the afterglow tube is relatively flat for pure N_2 plasma but the losses along the tube are increasing with oxygen admixture.

Oxygen atom density is rising when small amount molecular oxygen is added. For higher O_2 percentages it remains nearly constant. Evolution of [O] along the tube is rather independent of N concentration.

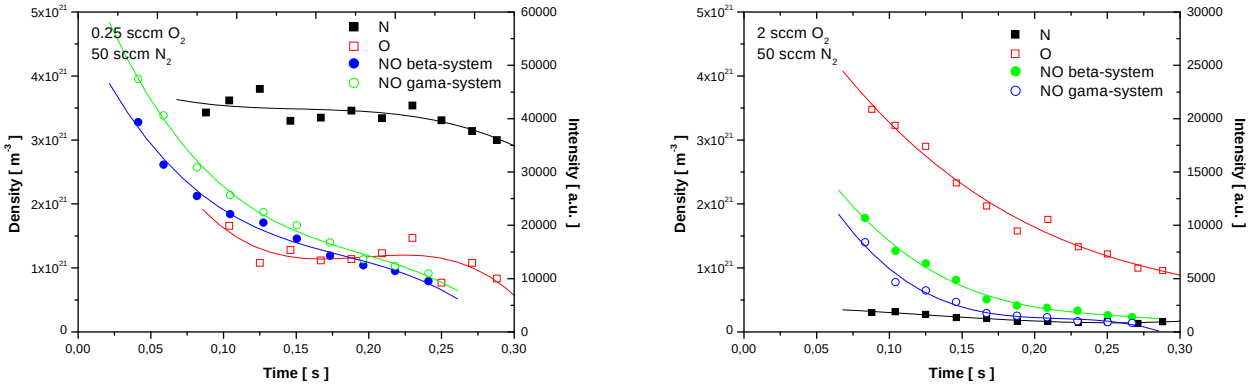

Figure 2: Influence of afterglow position on concentrations of oxygen and nitrogen atoms and intensities of NOβ and NOγ systems. The measurements were carried out at pressure 760Pa.

Two spectral systems of nitric oxide are produced by different reactions. The NOβ system is produced by reaction $N+O(+M) \rightarrow NO^*(+M)$ and NOγ by $N_2(A)+NO \rightarrow NO^*+N_2(X)$. Their recorded intensities give us deeper insight into the processes involved.

In Fig.2 there is presented the temporal evolution of concentrations of oxygen and nitrogen atoms and intensities of NOβ and NOγ systems for two flow rates of oxygen admixture.

Conclusion

Certain mixture of oxygen and nitrogen can be found which maximises the production of UV radiation from excited NO along the whole afterglow tube. In a similar manner there exist another N_2/O_2 ratio for maximal production of N and another one for maximising O production. By varying the amount of oxygen admixture we can therefore optimise the production of wanted species.

Abstract

Despite of the highest melting point and lowest vapor pressure of all metals, tungsten thin film can be obtained with the Thermionic Vacuum Arc (TVA) method. For the characterization of hardness we used depth sensing indentation tester Fischerscope H100 Xyp and the results have indicated a high value for plastic hardness. Also, the AFM measurements have proved the smoothness of the deposition. The structure of the deposited W films was studied using TEM electronic microscope PHYLIPS CM 120 with a magnification of 1.4 M and a resolution of 1.4 Å. The samples of tungsten films deposited on small size NaCl or KCl monocrystals have been submitted to TEM examination (after solving the monocrystal supports in water). HRTEM image confirms the cubic structure of W. (SG: Im3m, a = 3.158 nm).

Keywords: Thermionic Vacuum Arc, tungsten thin film, AFM, HRTEM, nanointendation

Introduction

Coating of carbon fiber composite (CFC) and turbine blades used in the energy applications (future fusion devices, respectively classical thermal power generators) with refractory metal as tungsten is highly desired as thermal barrier in order to increase operation temperature and lifetime of the devices. Tungsten, with the highest melting point and lowest vapor pressure of all metals, has – at temperature over 1923 K - the highest tensile strength. It has excellent corrosion resistance and is attacked only by most mineral acids.

In this work is reported deposition of tungsten films on graphite substrates of 30 x 30 x 8 mm^3 by Thermionic Vacuum Arc (TVA) method. This type of arc ignites in high vacuum conditions in the vapors of the anode material, continuously generated by the electron bombardment of the anode[1]. The electrons, emitted from a heated tungsten cathode, are accelerated towards the anode, by a d.c. high voltage applied across the electrodes.

Experimental set-up

The TVA method [1-4] is characterized by producing plasma in the pure vapors of the metal to be deposited (W) without using any buffer gas. The evaporation of the metal takes place in high vacuum conditions (10^{-3} Pa and less). An external heated cathode (W + 0.2%Th filament) produces thermally emitted electrons of about 100 mA. These electrons are accelerated and focused by a Whenelt cylinder to the anode which is biased to high voltage (1 – 6kV). The electron bombardment creates space tungsten atoms above the anode at a local pressure of about 133 Pa.

The thermoelectrons produced by the heated cathode are able to build up plasma by electron-tungsten atoms collisions. The new electrons generated in the plasma together with the original ones emitted by cathode enhance once more the anode evaporation and produce high quantity of ions. Usually the cathode potential fall is in the range of 200-300 V and therefore the plasma potential in comparison with ground ensure generation of the high energy ions which collide the substrate.

Because this system can heat any material at elevated temperature, it is one of the most adequate methods for the evaporation of high melting point materials. In the case of such materials, instead of a crucible containing the material to be evaporated, a rod of refractory metals is used directly as anode. Moreover, the discharge can be ignited in high vacuum condition, ensuring high purity of the deposition. In Fig 1 is shown the photograph of the TVA arrangement. Such an arrangement has been used for the deposition of Re or Nb [5].

The anode, a W rod of 8-10 mm in diameter and 80 mm in length (20 tungsten wires of 1 mm diameter) was sustained by a Mo support, which could be rotated during deposition by an electrical motor. The ignited thermionic vacuum arc parameters were: cathode filament current - 150 A, arc current; 2 – 3 A, the arc voltage drop on the arc; 1000 - 1200V d.c.

The obtained films were characterized by nanoindentation and atomic force microscopy (AFM). Also a HRTEM was used for information concerning the structure of the tungsten thin films.

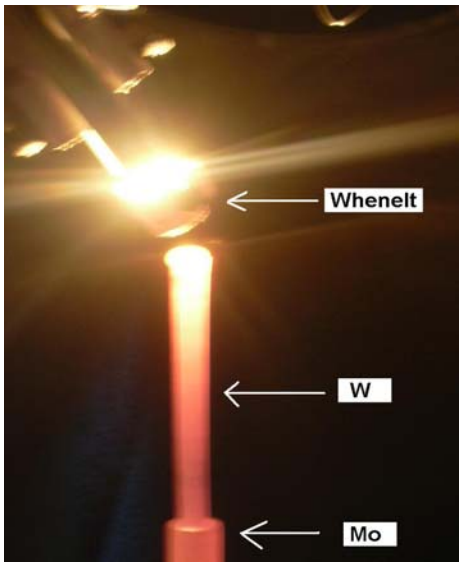

Fig. 1 Photograph of the TVA arrangement.

Results and discussion

The samples (graphite substrates 30 mm x 30 mm x 8 mm coated with W) were tested using depth sensing indentation tester Fischerscope H100 Xyp. We can notice from the Fig. 2 that the tungsten film had significantly higher resistance against indentation.

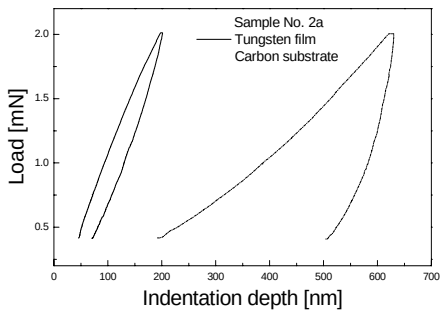

Fig. 2 Comparison of loading / unloading curves for maximum indentation load of 3 mN.

The material parameters obtained on the graphite substrate and the tungsten films are listed below in Table 1, where: - HU- universal hardness (resistance against elastic and plastic deformation)

- W_e/W_{tot} – ratio of the elastic indentation work to the total indentation work
- HU_{pl} – plastic hardness (resistance against plastic deformation – equivalent of the so called Vickers hardness
- h_{max} – maximum depth at given maximum load- $Y = E/(1-\nu^2)$, where E is the Young's modulus and ν is the Poisson's ratio.

Table 1. Results of the nanoindentation test

Sample	HU [N/mm^2]	We/Wtot [%]	HUpl [N/mm^2]	Hmax [μm]	Y [GPa]
Substrate	158	24.81	205	0.692	6.0
tungsten film	30	0.23	5700	0.250	80.0

The AFM measurements have proved the smoothness of the deposited films (however with some droplets as can be seen in Fig. 3) with peak to valley roughness in the range of 20-30 nm.

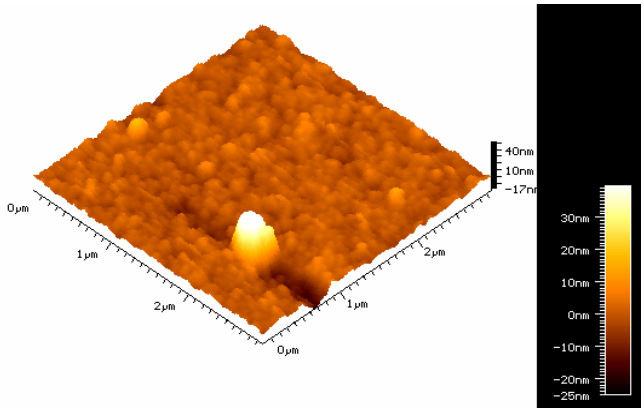

Fig. 3 AFM image of the W film.

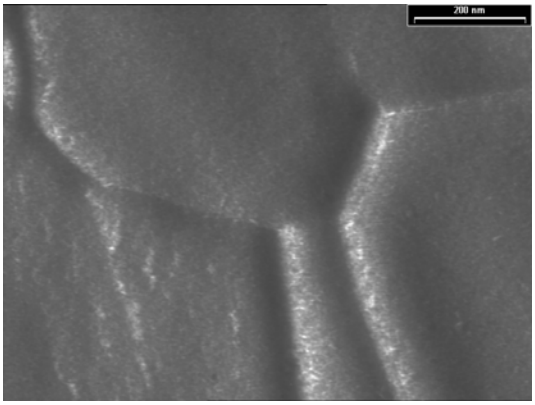
The structure of the deposited W films were studied using TEM electronic microscopy with a magnification of 1.4 M and a resolution of 1.4 Å. The samples of tungsten films deposited on small size NaCl or KCl monocrystals have been submitted to TEM examination (after solving the monocrystal supports in water). TEM analysis of thin layers (10-20 nm thickness) revealed the nanostructured tungsten film with grain size in the range of 10 nm (Fig. 4 and Fig. 5).



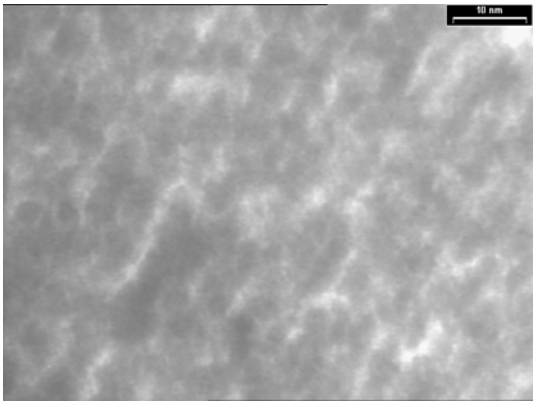


Fig. 4. BF-TEM image of W film**.**

Fig.5 Detail image of W film at 10 nm scale.

Also in Fig. 5 one can see clustered tungsten nanoparticles with mean diameters bellow 10 nm.

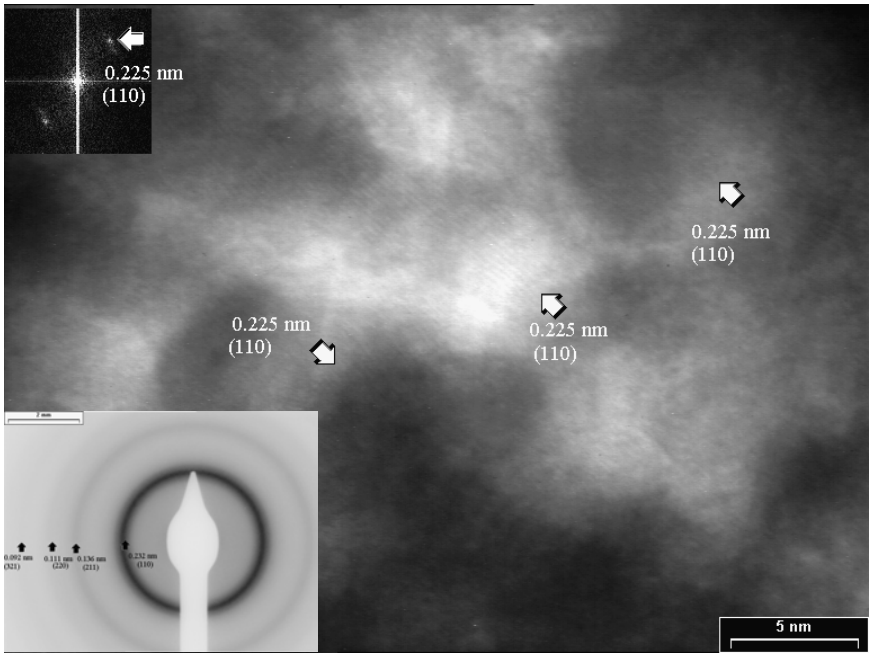

Fig. 6 HRTEM image of the deposited thin tungsten film with FFT (left up inset image) and SAED (left inset down image)

Figure 6 shows HRTEM image of W nanoparticles that exhibits (110) planes. Left inset shows FFT (Fast Fourier Transmission) representation of selected zone. SAED (Selected Area Electron Diffraction) image confirms the cubic structure of W. (SG: Im3m, a = 3.158 nm

Conclusion

The obtained results prove the possibility to use TVA for high quality, pure tungsten film deposition with nanohardness in the range of 5700 N/mm^2 and peak to valley roughness in the range of 20-30 nm. Tungsten film deposition is now considered in fusion programs to be used to cover the wall of the divertors and also as thermal barrier coating on the Nb based superalloys for gas turbine blades.

Power Supply Design for Pulsed Power Plasma Applications

Maciej A. Noras, William A. Maryniak

Trek, Inc., 11601 Maple Ridge Rd., Medina, N.Y., U.S.A.

Abstract: A design of the solid state power supply for pulsed power plasma applications is described and explained. This particular design was created for the PACT (plasma and catalyst integrated technologies) reactor, with current, voltage, shape and frequency of pulses adjusted to requirements of the PACT system. Non-thermal plasma systems frequently utilize a short pulse-width, fast rising time and high repetition rate of the electrical pulses generated by the power supply. The proposed solution allows for adjustment of these parameters. This, in turn, permits optimization of removal rates of volatile organic compounds (VOC), NO_x and other agents. In addition, the output current and voltage monitors provide possibility of discharge energy observations.

1. Introduction

In recent years, non-thermal plasma technologies have been widely researched, and the range of their applications has rapidly expanded. Non-thermal plasmas are also known as non-LTE ("local thermal equilibrium") or as low-temperature plasmas. These definitions come from the fact that during the plasma generation process electrons become highly energized while much heavier ions and neutral particles remain at low energy level. Typical applications of non-LTE plasmas include etching, ion implantation, thin films deposition, chemical neutralization and/or decomposition of pollutants. Low temperature plasma are most frequently created from electronic excitation using DC and pulsed DC or AC coronas, dielectric barrier discharges (DBD), and radio-frequency (RF) discharges. The choice of a particular plasma generation technology depends on the application. Non-thermal plasmas utilized in the air pollution control and VOC removal usually are generated by the pulsed DC or AC corona methods. The DC corona technique and RF discharge plasma create undesirable electrode etching, and, in addition, DC plasma tends to be very non-uniform when applied to relatively large volumes of contaminated air. Therefore, pulsed DC and AC, as well as DBD plasmas, became preferred methods for contaminant gases and VOC removal. DBD technique uses either AC or pulsed DC electric field to create plasma. Regardless of the plasma generation technique, a power supply is a critical component of every plasma generator. A properly designed power source for plasma has to be reliable, efficient, and be able to provide suitable energy coupling between the power supply and the plasma. It should also deliver adequate homogeneity of the plasma and control over plasma parameters. Safety, cost and size of the power supply are also very important issues. Specific parameters required from the power supply, such as voltage amplitude and shape, current, frequency etc., depend on the particular design of the plasma generation system. During the preliminary development stage it is often practical and convenient to use AC power supplies or high voltage amplifiers that permit a certain range of adjustments of the aforementioned parameters. Linear AB class high voltage amplifiers are able to provide precise control of the output voltage waveform: amplitude, frequency, rise and fall time, duty cycle, etc. Once the operating parameters are optimized, the next step is to design the power supply that is small and efficient with respect to performance and cost, as required by most of industrial applications. Figure 1 presents an example, simplified circuit diagram of an output stage of a class AB amplifier. It consists of transistors Q_1 and Q_2 and the resistive load R_L. For the sinusoidal voltage signal V_{IN}, the current drawn from the power supplies is:

$$I_{supply} = \frac{1}{T}\int_0^T i_Q dt \tag{1}$$

$$I_{supply} = \frac{1}{2\pi}\int_0^T i_{output}\sin(\theta)d\theta \quad (2)$$

$$I_{supply} = \frac{1}{\pi} i_{output} = \frac{1}{\pi}\frac{V_{OUT}}{R_L} \quad (3)$$

The input power therefore is:

$$P_{supply} = 2 \cdot V_{CC} \cdot I_{supply} = \frac{2 \cdot V_{CC} V_{OUT}}{\pi \cdot R_L} \quad (4)$$

The power delivered to the load is:

$$P_{load} = \frac{1}{2}\frac{V_{OUT}^2}{R_L} \quad (5)$$

The efficiency is:

$$\eta = \frac{P_{load}}{Psupply} = \frac{\pi}{4}\frac{V_{OUT}}{V_{CC}} \approx 78\% \quad (6)$$

This is the maximum achievable efficiency of the class AB amplifier. Once the desired parameters of

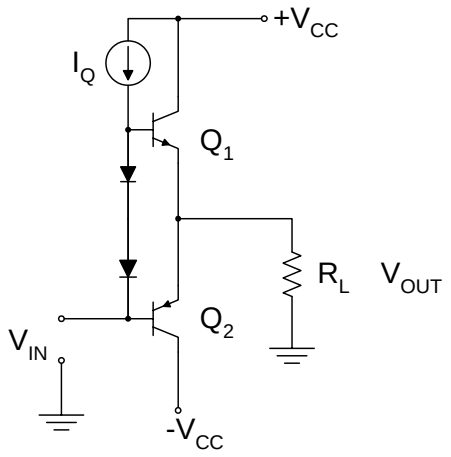

Figure 1: Example circuit diagram of a class AB amplifier output stage.

the power supply for a specific plasma generator are determined, the pulsed DC power supply can be developed. With a proper design, efficiency of a pulsed DC power supply can reach 96% level [1]. In addition, while high voltage amplifiers provide flexibility of plasma parameters adjustment, it may be difficult to meet the size and cost requirements using class AB topology. The power supply presented in this paper is an all-solid-state high voltage pulse generator, designed and built for the PACT reactor - a new type of technology using plasma and catalyst integrated approach for VOC and other contaminants removal. Solid state switching devices usually have larger lifetimes than gaseous discharge elements used in some applications and they also provide much faster and more reliable switching.

2. Power supply design

2..1 Design requirements for "no load" condition

1. Output Voltage Range adjustable from 0 to 12 [kV] peak-to-peak AC.
2. Output Current Range 0 to ± 240 [mA] peak AC.

3. Output Waveform trapezoidal.

4. Output Frequency 10 [kHz].

2..2 Design description

The all-solid-state design was developed basing on the commercially available pulse width modulator (PWM) TL598. A pulsed power supply block diagram is shown in Figure 2.

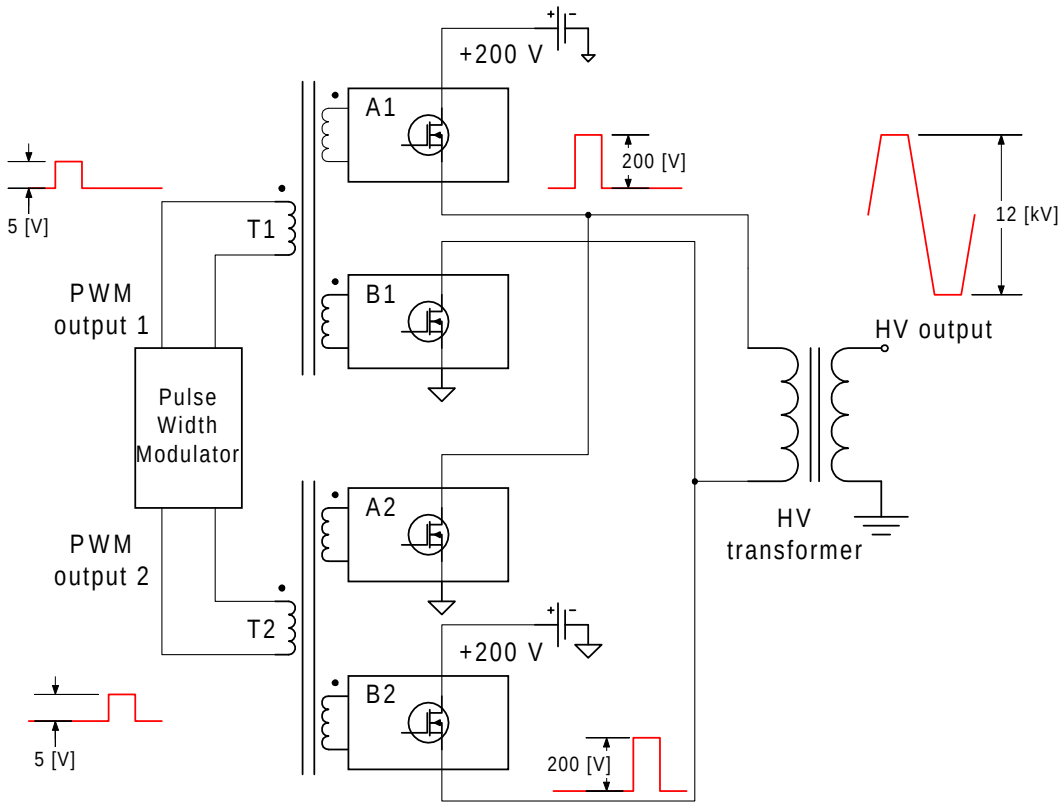

Figure 2: Block diagram of the pulsed power supply.

The TL598 control circuit is capable of directly driving MOSFET switches [2]. The control circuitry is separated from the high voltage driven transistors by transformers T1 and T2. The PWM provides 5 [V] square wave pulses with a positive polarity at the one-half oscillator frequency rate on each of the outputs (Figure 3). The dead time control comparator prevents overlapping of the pulses from the outputs 1 and 2 during push-pull operation. The PWM also prohibits the possibility of either output being pulsed twice during one cycle of operation.

A pulse P1 from the PWM output 1 is supplied to the transformer T1. This pulse, after being transformed, turns the MOSFET amplifying blocks A1 and B1 on. The square pulse of 200 [V] (positive polarity) appears across the high voltage (HV) transformer, resulting in high voltage 6 [kV] peak square signal of the positive polarity at the high voltage output of the power supply. The duration of the high voltage pulse is controlled by the duration of the PWM signal. After the dead time a voltage square pulse P2 is supplied by the PWM output 2 to the transformer T2. It turns the blocks A2 and B2 on, and the 200 [V] square signal appears on the primary winding of the HV transformer. The polarity of this pulse is inverted, so the negative 6 [kV] peak square signal is present at the high voltage output. The frequency and the amplitude of the HV signal can be easily adjusted.

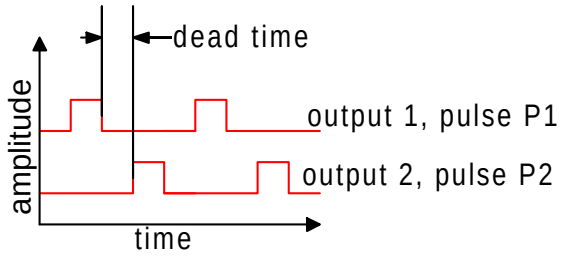

Figure 3: Square wave pulses supplied by the PWM.

2..3 Design verification

The validity of the power supply design was verified by extensive testing. First, the no load parameters of the power supply were confirmed. Figure 4 presents an example of an oscillogram taken with a 1000:1 HV Tektronix P6015A divider along with a TDS402A Tektronix oscilloscope. The square wave signal becomes distorted after reaching 14 [kHz] frequency.

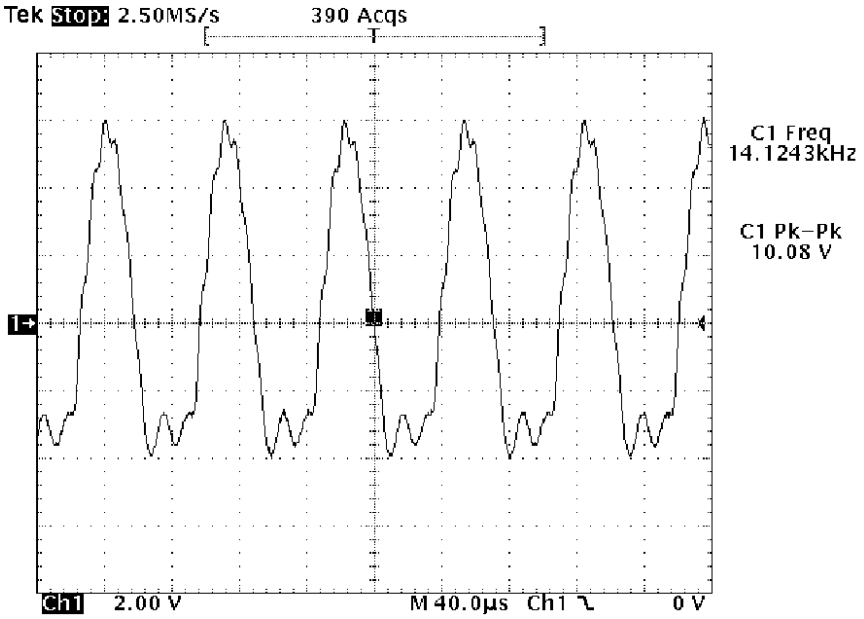

Figure 4: High voltage output waveform under no load condition. The limiting frequency of operation is 14 [kHz].

The power supply was also tested with various capacitive and resistive loads. The PACT system, for which the power supply was designed, represents a 28.2 [pF] capacitive load. Tests of the system with the PACT tube were conducted in the configuration shown in Figure 5.

Figure 6 shows voltage and current waveforms recorded for the PACT reactor:

The very fast and relatively high initial current peaks correspond to charging processes occurring in the PACT system. The current ripple after the initial current surge is due to discharge phenomena occurring inside the reactor. Variations in the current values result in disturbance of the voltage waveform, therefore the voltage is not of ideal square-wave shape. The power supply circuitry has ability of correcting such disturbance with certain, limited speed of response. The power supply has a built-in current limit block protecting from the possible shorted output current damages. Another feature of the PS design is a

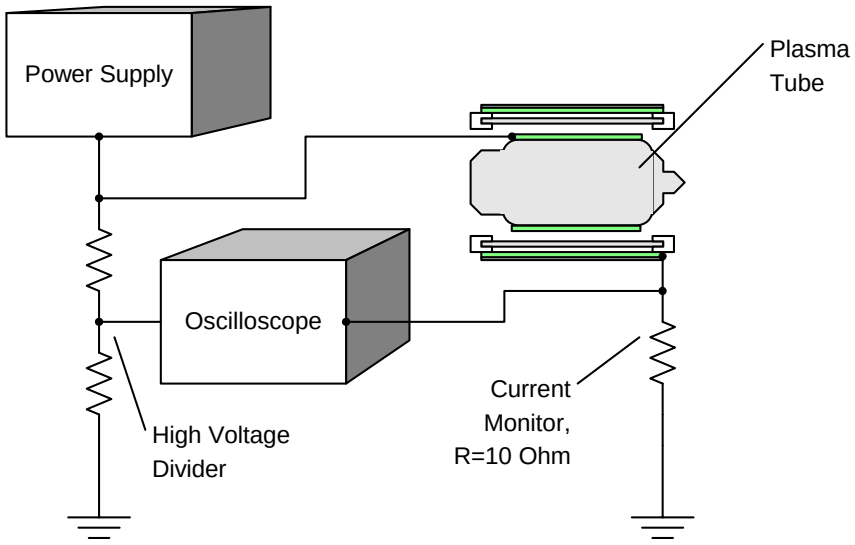

Figure 5: Test setup.

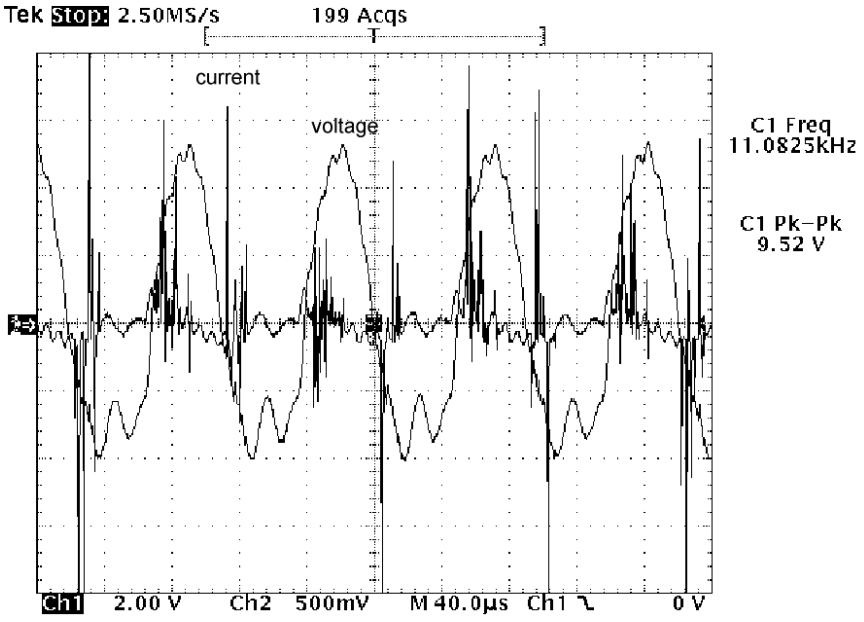

Figure 6: Voltage and current waveforms, voltage signal scale is 1 [kV]/div, current signal scale is 20 [mA]/div.

remote on/off switch.

3. Summary

The power supply described in this paper was designed for driving the PACT reactor. Therefore the capability of the driving system can be judged by the performance of the PACT tube. As reported in [3], the PACT system working with the power supply designed in Trek is very effective in perfluoro-compounds (PFC) decomposition (Figure 7). PFCs are widely used in semiconductor device fabrication processes, especially during etching and cleaning. These compounds are long-lasting agents that are believed to be contributors to the "greenhouse effect". For example, the maximum decomposition rate of $c - C_4F_8$, as shown in Figure 7, was 40%. Voltage and frequency adjustments allow for optimization of the plasma environment inside the reactor. In this way the decomposition rate of pollutants and contaminants can be also optimized. Other parameters of the power supply designed for the PACT tube can be also conveniently altered, if needed, to drive broad variety of pulsed plasma reactors. The efficiency of the plasma power supply described in this work was found to be around 90%.

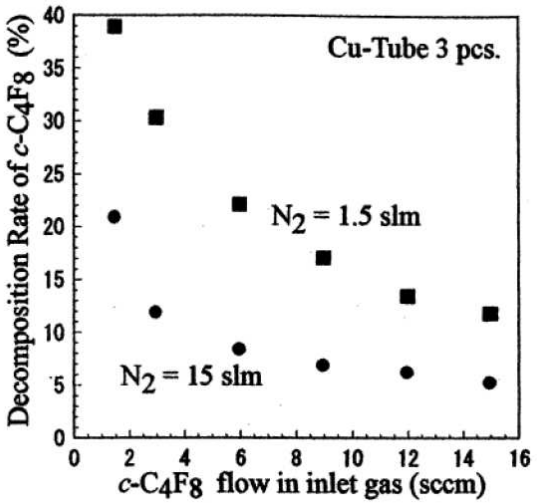

Figure 7: Decomposition rate dependence on $c - C_4F_8$ flow rate at $N_2 = 1.5$ slm or 15 slm [3].

Investigations of Plasma-sprayed hydroxyapatite coating on titanium alloy Reinforced by ZrO_2

Yung-chin Yang

Department of Materials and Mineral Resources Engineering,
National Taipei University of Technology, Taipei 106, Taiwan, R. O. C.

Abstract

The cohesive and adhesive strengths of plasma-sprayed hydroxyapatite coatings (HAC) were strengthened by respectively, adding ZrO_2 particles as a reinforcing second phase (HA+ZrO_2 composite coating), and using an intermediate ZrO_2 layer between the HA coating and the Ti alloy substrate as a bond coat (two-layer HA/ZrO_2 coating). Results indicate that the bond strength of the HA coatings increases from 28.6±3.2 MPa for HA coating to 32.5±4.2 MPa and 36.2±3.0 MPa for HA+ZrO_2 and two-layer HA/ZrO_2 coatings, respectively.

1. Introduction

Among the methods of fabricating HA coatings on metallic implants, plasma-spraying technique appears to be most favorable [1]. It has been well documented that plasma-sprayed coatings suffers from the low adhesion between coating and substrate, as well as the low cohesion within the coating [2]. Failure of the HA-coated Ti alloy implants during in vivo testing can happen (1) at the HA/bone interface, (2) inside the lamellar splat layer of coatings, or (3) at the HA/Ti alloy substrate interface. In evaluating the performance and stability of HA coating in the load-bearing situation after long-term follow-up, researchers suggested the presence of a potentially weak HA/substrate interface or cohesive failure within the coating, rather than at the HA/bone interface [3,4]. One method to improve the weak lamellar splat layer of the coating is to strengthen the microstructure of HA through plasma spray processing, but a second phase can also be added as reinforcement for the same purpose. The improved coating microstructure should be conducive to the enhancement of the cohesive strength, i.e., the strength of the intra- and inter-lamellar bonding of the HA coating. The increase of cohesive strength may also contribute to the strength of the adhesion of the plasma-sprayed HA to titanium. Alternatively, an intermediate bonding layer can be placed between the brittle HA and the substrate to promote their adhesive bonding to the HA/Ti alloy interface. This study aims to elucidate the dominant mechanical weakness in plasma-sprayed HA coating: the adhesion between coating and substrate, or the cohesion within the coating.

2. Experiments

2.1. Specimen fabrication

Powders with compositions of (1) hydroxyapatite (HA powder), (2) zirconia (TZ8Y powder), and (3) mixed 90 wt% hydroxyapatite + 10 wt% zirconia (HA+ZrO_2 powder) were used in the current study. As-sintered HA+ZrO_2 powder suitable for plasma spraying with particle size 74~125 μm was produced using the following

procedure. HA and TZ8Y powders were mixed in a zirconia ball mill using ethyl alcohol as medium. The resulting slurry was vacuum dried, crushed, and ground by pestle and mortar. The mixed powders were then granulated with 10 wt% of aqueous PVA solution (conc. at 5 wt%), and sieved to the desired particle size. Finally, the granulated powders were heated at 600°C for 1h to volatilize the PVA binder and sintered at 1000°C for 4h to consolidate the particles. As-sintered HA and TZ8Y powders were agglomerated and sintered similarly to yield a particle size of 125~177 μm.

As-sintered HA+ZrO_2 powder was plasma sprayed onto the Ti-6Al-4V titanium alloy. Accordingly, plasma-sprayed HA+ZrO_2 composite coatings (abbr. HA+ZrO_2 coating) were fabricated on Ti-6Al-4V substrates with a thickness of 150 μm. Another coating system studied here was the introduction of a plasma-sprayed ZrO_2 bond coat on Ti-6Al-4V substrate prior to the deposition of HA. The thickness of ZrO_2 bond coat was 15 μm and the total thickness of two-layer HA/ZrO_2 coating (abbr. HA/ZrO_2 coating) was 150 μm. The detailed spray parameters are listed in Table 1. Slightly higher power was used for the HA+ ZrO_2 coating and the ZrO_2 bond coat compared to the HA coating since the former coatings exhibit higher melting points.

2.2. Materials characterization

The HA+ZrO_2 coating (nominal thickness: 150 μm) was removed mechanically from the Ti-6Al-4V substrate and pulverized. The powders, mixed with pure silicon as external standard, were subjected to X-ray diffraction analysis (XRD) for phase identification (Rigaku D/MAX III.V, CuKa radiation). The morphology of the coating surface, the cross-sectional microstructure and the chemical composition were examined by scanning electron microscopy (SEM) (Philips XL-40 FEG) in conjunction with an energy dispersive X-ray spectrometer (EDS) system.The XRD analyses for phase identification of ZrO_2 bond coat and HA top coat of the HA/ZrO_2 coating were carried out as in the case of HA+ZrO_2 coating, and so were the SEM investigation. Moreover, the surface roughness of the grit-blasted Ti-6Al-4V alloy and the ZrO_2 bond coat were evaluated by Surfcorder SE-40D, Kosaka Laboratory Ltd.

2.3. Bond strength testing and fracture surface investigation

Bond strength was measured using a tensile test (ASTM C633-79) especially designed for plasma-sprayed coatings. Each test specimen was comprised of a substrate rod, to which the HA+ZrO_2, HA/ZrO_2, and HA coatings were applied, and a loading rod. The facing of the loading rods were then grit-blasted and attached to the surfaces of coatings using a special adhesive-bonding glue (METCO EP-15). The segments were held perpendicularly and put into an oven at 180°C for 2h. The couples were then subjected to tensile tests at a constant cross-head speed of 0.02 mm/s until failure. For each testing material, ten specimens were used, and the bond strength data were reported as the average values. To characterize the fractography, the optical pictures of the fracture surfaces for bond strength specimens from HA, HA+ZrO_2 and HA/ZrO_2 coatings on the Ti-6Al-4V substrates were analyzed by the OPTIMAS 6.0 software.

3. Results

3.1. Coating characterization

Fig. 1(a) shows the X-ray diffraction spectrum of as-sintered HA+ZrO_2 powder pre-mixed with pure silicon. The XRD pattern is characteristic of hydroxyapatite in accordance with the standard XRD spectrum (JCPD 9-432). In addition, peaks of cubic ZrO_2 are present as indicated by the symbol F (JCPD 30-1468). The result of the XRD analysis of the pulverized plasma-sprayed HA+ZrO_2 coating on the Ti-6Al-4V substrate is shown in Fig. 1(b). The XRD pattern of Fig. 1(b) retains the characteristics of Fig. 1(a) except that a few extra small peaks occur at approximately 30.71° and 37.52° (2θ). These extra peaks belong presumably to α-tricalcium phosphate (α-TCP, JCPD 9-348) and calcium oxide (CaO, JCPD 37-1497), respectively.

Fig. 2 shows the XRD spectra of as-sintered ZrO_2 powder (Fig. 2(a)) and as-sprayed ZrO_2 bond coat on the Ti alloy substrate (Fig. 2(b)). No phase change occurred in the cubic ZrO_2 during the plasma-spraying process (JCPD 30-1468). The appearance of Ti (101) and Ti (002) peaks in the Fig. 2(b) is caused by the penetrating X-ray beam. Fig. 3 shows the XRD spectra of as-sintered HA powder (Fig. 3(a)) and as-sprayed HA top coat deposited upon the bond coat (Fig. 3(b)). From Fig. 3(a), it is obvious that a well-crystallized HA powder suitable for plasma spraying was obtained after the sintering and consolidating processes, in which the decomposition of HA was not observed. However, similar to the case of spraying HA+ZrO_2 coatings, traces of α-TCP, tetracalcium phosphate (TP) and CaO are present in the HA top coat as shown in Fig. 3(b).

The surface roughness of the ZrO_2 bond coat is 5.7 ±0.2 μm, while that of grit-blasted Ti-6Al-4V substrate is 3.6±0.1 μm only. Hence the ZrO_2 bond coat provides a rougher surface than that provided by grit-blasted Ti-6Al-4V for the deposition of HA in the HA/ZrO_2 coating.

Typical SEM surface morphologies of the plasma-sprayed HA/ZrO_2 coating and the HA+ZrO_2 coating are shown in Fig. 4. Comparison of the surface morphology shows that the ZrO_2 containing HA+ZrO_2 coating exhibits more unmelted small particles than does the HA top coat in the HA/ZrO_2 coating. It reveals that the melting conditions in HA+ZrO_2 coating are poorer than that of the HA coating using the present plasma-spraying parameters. SEM cross-sectional views with EDS analysis of the HA/ZrO_2 and HA+ZrO_2 coatings on Ti-6Al-4V substrates are shown in Figs. 5, and 6, respectively. From the result of EDS Zr mapping in Fig. 6(b), it reveals that the ZrO_2 particles are distributed in the HA+ZrO_2 coating.

3.2. Bond strength measurements and fracture surface investigation

The bond strength data measured by the adhesion test according to ASTM C633-79 are listed in Table 2, where each value in the table represents the average of ten data. It is found that the bond strength increases from 28.6±3.2 MPa for the HA coating to 36.2±3.0 MPa for the HA/ZrO_2 coating, whereas the value for the HA+ZrO_2 coating is intermediate at 32.5±4.2 MPa. The results verified by a statistical *t-test* reveal that the bond strength obtained in each coating is significantly different from the others ($p < 0.005$).

The morphology of the fracture surfaces of the bond strength specimens after the ASTM C633-79 test is shown

in Fig. 7. Figs. 7(a), (b) and (c) represent the typical failure morphology of HA, HA+ZrO_2 and HA/ZrO_2 coatings on the Ti-6Al-4V substrate, respectively. The site that is characteristic of adhesive failure (ad) is indicated by an arrow as shown in Fig. 7(c), and so is the site of cohesive failure (co). The area percentage of adhesive failure in each coating was calculated according to the image analysis and reported as the average of data from ten specimens (Table 2).

Addressing the potential weakness of the HA/Ti alloy interface [3,4], some researchers have suggested to introduce a bond coat between the HA coating and the Ti alloy substrate to improve the adhesion [5,6]. In our present study, the bond strength of the HA coating was increased from 28.6±3.2 MPa to 36.2±3.0 MPa by application of a ZrO_2 bond coat (Table 2). The area percentage of adhesive failure in a HA/ZrO_2 coated Ti-6Al-4V substrate was estimated to be 15.8±3.8 %. The reduction of adhesive failure in HA/ZrO_2 coatings as compared to that in HA coatings (26.8±5.2 %) indicates that the adhesive strength of a HA coating is reinforced by the introduction of a ZrO_2 bond coat. Furthermore, higher bond strengths obtained in the HA/ZrO_2 coatings than in the HA+ZrO_2 coatings indicate that the enhancement of the adhesion between the HA coating and the Ti alloy substrate is more important than the strengthening of the HA coating per se. Namely, the HA coating/Ti alloy interface is a site of critical weakness when compared to the cohesive strengths of the inter- and intra-lamellar structure of HA coating. However, it should be noted that both cohesive strength, i.e. the strength of intra- and inter-lamellar bonds of the HA coating, and the adhesive strength of the HA coating to the substrate will influence the bond strength of the HA coating on the titanium implant.

The strengthening effect of the HA/ZrO_2 coating is believed to arise from the following mechanisms: (1) the promotion of mechanical interlocking between the coating and the metal substrate. It is obvious from Table 2 that a rougher surface morphology was provided by the ZrO_2 bond coat for the deposition of the HA top coat. (2) the elemental interdiffusion between HA top coat and ZrO_2 bond coat [7], which might also promote the bonding.

4. Conclusions

The bond strength of HA coatings on Ti alloy substrates can be improved from 28.6±3.2 MPa to 32.5±4.2 MPa with ZrO_2 particles added as a reinforcing second phase, to 36.2±3.0 MPa with a ZrO_2 intermediate layer applied as a bond coat. A possible strengthening mechanism of the two-layer HA/ZrO_2 coating is the rougher surface provided by the ZrO_2 bond coat, which promotes a better mechanical interlocking between the HA top coat and the ZrO_2 bond coat. The cohesive strength of HA coatings can be reinforced by ZrO_2 particles and hence the improved cohesive strength will contribute to the bond strength of the HA coating on Ti-substrate. However, other mechanism of a reduction of the CTE mismatch stress between the HA+ZrO_2 coating and the Ti-6Al-4V substrate can not be excluded. The interface of the HA coating/Ti alloy substrate is a site of critical weakness when compared to the cohesive strength of the inter- and intra-lamellar structure of HA coating.

Abstract

Deposition of Titanium Carbide (TiC) layer on Ti surface has been demonstrated by means of an ion-enhanced triode plasma chemical vapor deposition (CVD) method using a $TiCl_4+CH_4+H_2$ gas mixture. The plasma reactor used was equipped with a triode system, in which a substrate bias circuit with two diodes is employed to accelerate the deposition through ion bombardment processes. The deposition rate of the TiC film was 2.5 μm/h at T_{sub} = 750 ℃ with the bias voltage V_b = -400 V. The Vickers hardness of the film was about 5500 Hv. The X-ray diffraction pattern suggested that the deposited TiC film is in a state of TiC crystal with (111) , (200) and (220) orientations.

Keywords Titanium Carbide (TiC), Plasma CVD, Hard coating, Ion-enhanced triode plasma CVD, Biomedical instruments

1. Introduction

Titanium Carbide (TiC) is a useful material for biomedical instruments, such as an abrasion resistant implant material, and surface hardening of cutting tools because of its properties which include high surface hardness, good corrosion resistance and low friction coefficient. Usually, TiC films are produced by the techniques of physical vapor deposition (PVD), thermal chemical vapor deposition (CVD) and plasma vapor deposition (PCVD). However, these methods need the substrates for deposition to be high-temperature (>1000℃) , which sometimes causes thermal damage to the deposited films. Therefore, it is desirable to develop a deposition technique using low-temperature (<800℃) substrates preventing the films from the thermal damage.

In this study, we demonstrate TiC film deposition on titanium (Ti) substrate at about 750℃ by an ion-enhanced triode plasma CVD method using a $TiCl_4+CH_4+H_2$ gas mixture. The production characteristics of the TiC films are investigated in the low frequency of power from 50 to 200Hz and the bias voltage (V_b) ranging from -100 to -400V with the triode technique. We have observed the Vickers hardness and the X-ray diffraction pattern of the TiC films. In addition, the optical emission spectra of the plasmas near the heated substrate (T_{sub} = 750 ℃) have been measured to make clear the state of the dissociated atoms and molecules in the $TiCl_4$ (5%) + CH_4 (10%) + H_2 (85%) mixture plasmas.

2. Experimental details

The experimental apparatus is similar to that of Ref.[1] and shown schematically in Fig.1. The cylindrical plasma reactor is 40 cm in diameter and 40 cm in height. Before the deposition, the reactor is evacuated to

about 1×10^{-5} Torr by a diffusion pump subsidized by a rotary pump. While the deposition is in progress, the evacuation is made by the rotary pump only, and the total pressure in the reactor is monitored by a Baratron pressure gauge. A pair of plane electrodes is made of 10 cm-diameter stainless steel and the gap length between the electrodes is 5 cm. The low frequency (50 to 200 Hz) power is supplied to the upper electrode, while the lower electrode is grounded. The stainless steel rod connected with the heater is inserted into the middle of the inter-electrode gap. The rod is electrically insulated from the grounded reactor and is negatively biased (about both the electrodes) by the diode circuit connected to it. The cubical substrate of stainless steel [2] which mounts Ti tips is attached to the rod heater. The Ti tips are in size of about 10 × 10 mm and 1mm thickness. The tips are cleaned beforehand by the ultrasonic cleaner using acetone and alcohol.

The plasmas between the upper electrode and the center rod and between the lower electrode and the center rod are driven alternately by the diode circuit, and these are generated symmetrically with respect to the substrate rod. Various negative bias voltages are applied to the substrate rod, and the potential energy of positive ions in the plasmas can be controlled by the bias voltage.

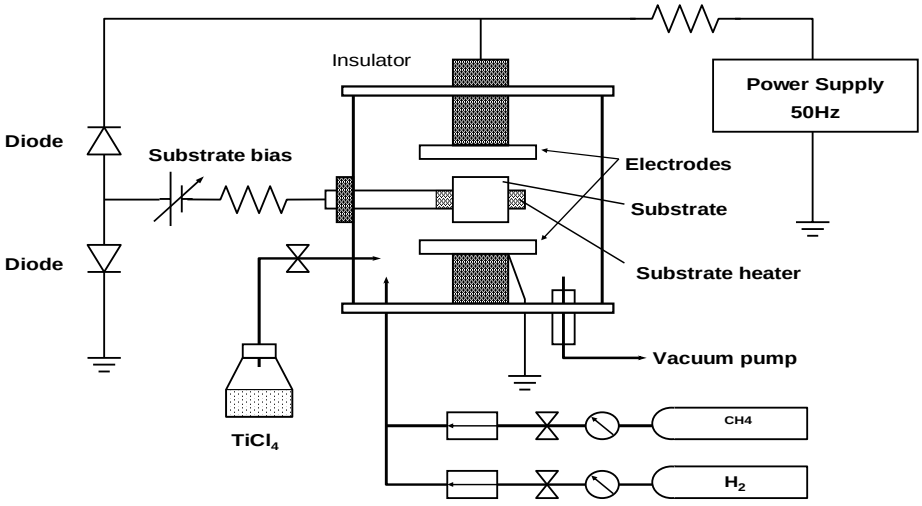

Fig. 1 Schematic diagram of the ion-enhanced triode plasma CVD apparatus.

The substrate temperature T_{sub} is measured by the thermocouple in the rod heater. The gases used are $TiCl_4$ (99.9 %), CH_4 (99.9 %) and H_2 (99.999 %), and these are introduced into the reactor at flow rates of 10-15 sccm, 25 sccm and 250 sccm, respectively. Before the deposition, Ti substrate is heated to a temperature around 750 ℃ by the rod heater, and the $TiCl_4 + CH_4 + H_2$ mixture gas is put into the reactor. The substrate temperature is kept 750 ℃ constantly throughout the entire course of the work. Deposition parameters for TiC films in this work are listed in Table 1.

We estimate the deposition rate of the TiC film by using a surface profile recorder. The Vickers hardness of the deposited TiC films is measured by a micro-Vickers hardness tester. The preferred orientation of the deposited film is evaluated by the X-ray diffraction (XRD) method. Optical emissions from the plasmas are observed using a Photonic Multi-Channel Analyzer (PMA, Hamamatsu C7473) connected to the plasma reactor. The PMA has an adequate sensitivity in the wavelength from 200 nm to 800 nm. The light guide window is made of quartz plate.

Table 1. Deposition conditions

Plasma power	20 - 50W
Power frequency	50 - 200 Hz
Plasma current	50 - 100 mA
Gap length	5 cm
Pressure	1Torr
Substrate temperature T_{sub}	700-800℃
Gas flow rate: $TiCl_4$	10 – 15 sccm
CH_4	25 sccm
H_2	250 sccm
Bias V_b	-200 - 400 V
Substrate	Ti

3. Results and discussion

3.1 Photo-emission from the $TiCl_4$+CH_4+H_2 mixture plasma

In order to investigate the composition of the dissociated atoms and molecules in the $TiCl_4$+CH_4+H_2 plasmas, optical emissions from the plasma near the heated substrate (T_{sub} = 750) were observed. Figure 2 shows a typical emission spectrum from the $TiCl_4$ (5%) + CH_4 (10%) + H_2 (85%) mixture plasma. Emissions from Ti^+, CH and H were clearly identified, and this indicates that $TiCl_4$, CH_4 and H_2 were decomposed into those particles. The $TiCl_4$ molecules are possible to be decomposed into a variety of other particle species such as TiCl, $TiCl_2$, $TiCl_3$, and Cl, but the emissions from these species were not observed. The emission from C atom might have occurred below 200 nm wavelength (100 to 150 nm) [9].

It is expected that the ions are accelerated to reach the substrate surface and to collide with it by the negative bias during a relatively long term of the low frequency cycle, which must be difficult in rf plasma reactors.

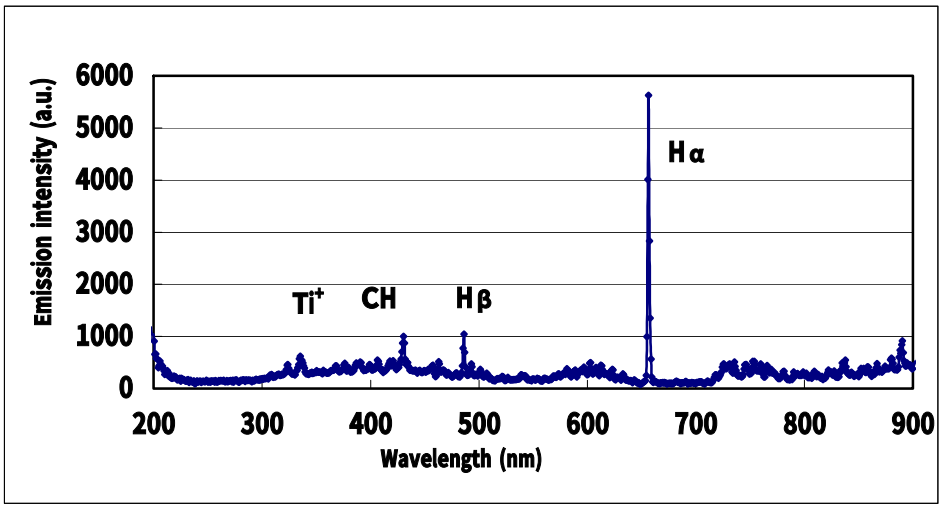

Fig. 2 Emission spectrum from the $TiCl_4$ (5%) + CH_4 (10%) + H_2 (85%) mixture plasma.

3.2. Deposition rate of the TiC

The deposition rate of the TiC film was measured by a surface profile recorder. Figure 3 shows the deposition rate on the substrate bias voltage V_b. The deposition rate of the TiC film increases from 0.2 μm/h to 1.7 μm/h as decreasing V_b from -100 to -400V with a condition of the plasma current 50mA (input power is about 25W). The thickness of deposited TiC film at the plasma current 100mA with V_b = -400V was about 5μm

for two hours deposition period of time. The TiC film around 5μm thickness can be used for surface hard coating of biomedical instruments and cutting tools. The deposition rate of TiC films in this method is greater than that of the pulsed laser deposition method (0.22μm/h) [3].

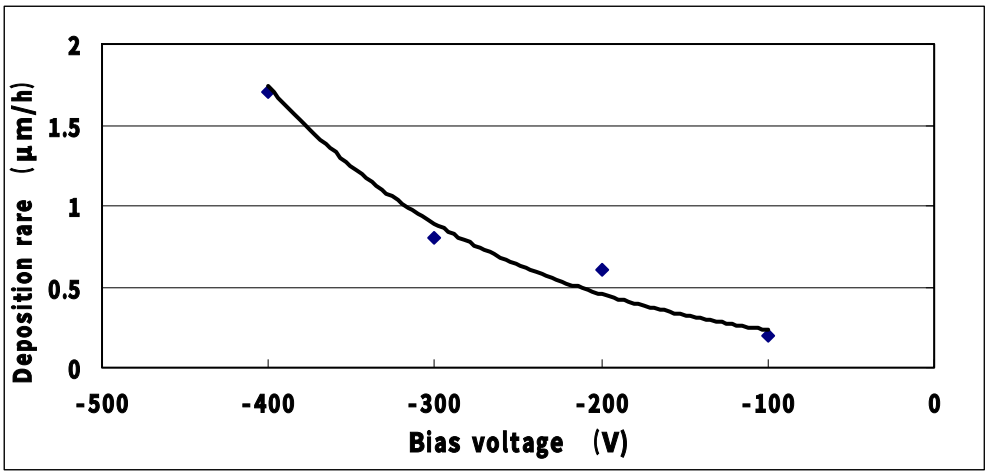

Fig. 3 Deposition rate of the TiC film against bias voltage at plasma current 50mA.

3.3. Vickers hardness of TiC

The Vickers hardness of the deposited TiC films on Ti tips was measured by a micro-Vickers hardness tester with a load of 10-200gf (gram-force). As shown in Fig .4, the Vickers hardness of the TiC film increases up to the value of about 5000 Hv (at V_b = -400 V and 25gf) as V_b decreases. The present value of the Vickers hardness for TiC is higher than that produced by thermal CVD or PVD method. Figure 5 shows that the Vickers hardness value of the film at 5μm thickness decreases with an increase in the lord. The TiC film on Ti was cracked by a load of more than 300gf. The Vickers hardness of the deposited TiC films at 750 ℃ with bias voltage V_b =–400V was above 3500Hv with a lord of 100gf, which is equivalent to the value of stoichiometric TiC's. This high value of the hardness may be attributed to the present unique plasma process in which the substrate potential is always lower than that of both (upper and lower) electrodes at every half cycle, causing the positive ions in the plasma to hit the substrate of the negative potential. We suppose that the bombardment energy of ions is consumed by the migration for giving rise to rearrange the atoms deposited on the substrate surface leading to a denser material layer.

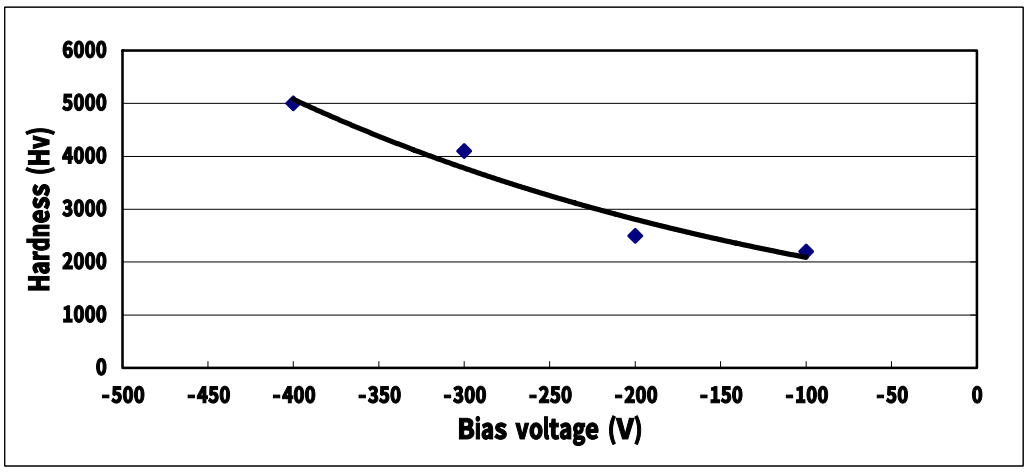

Fig. 4 Vickers hardness of the TiC film against bias voltage at plasma current 50mA.

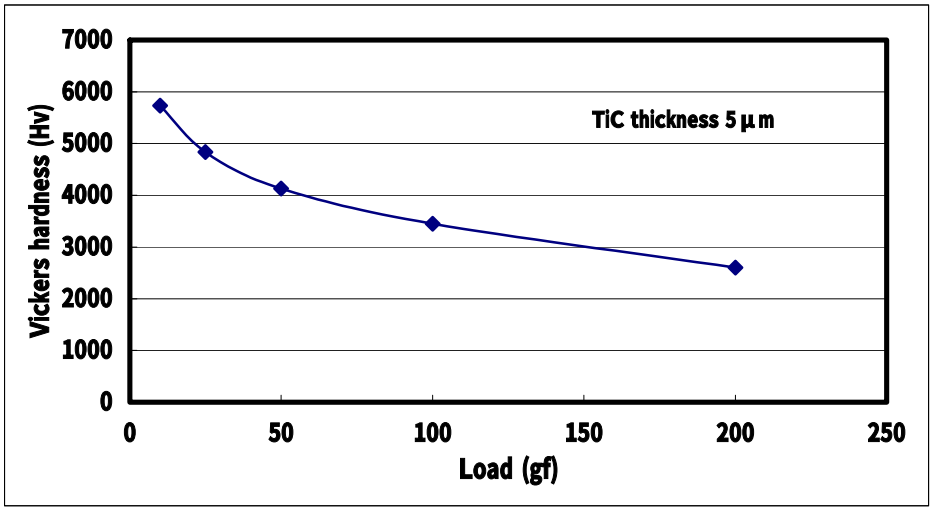

Fig. 5 Vickers hardness of the TiC film against load.

3.4. Crystal structure

The crystal structure of the deposited TiC films was determined by the X-ray diffraction (XRD) method. The XRD pattern originating from the deposited TiC on Ti substrate is shown in Fig.6. Peaks of Ti from bulk Ti substrate and of TiC from deposited TiC film appear in the XRD pattern. The pattern for TiC suggests that the film contains TiC crystal with TiC(111), TiC(200) and TiC(220) orientations. The peaks representing these orientations are in about 2.0 degrees of FWHM, while the peaks for Ti are sticking out sharply. The diffraction peak pattern for C atom was not observed, suggesting that the TiC film has a good crystal structure. From the observation of a SEM micrograph, it was confirmed that the deposited TiC film possesses a very flat surface.

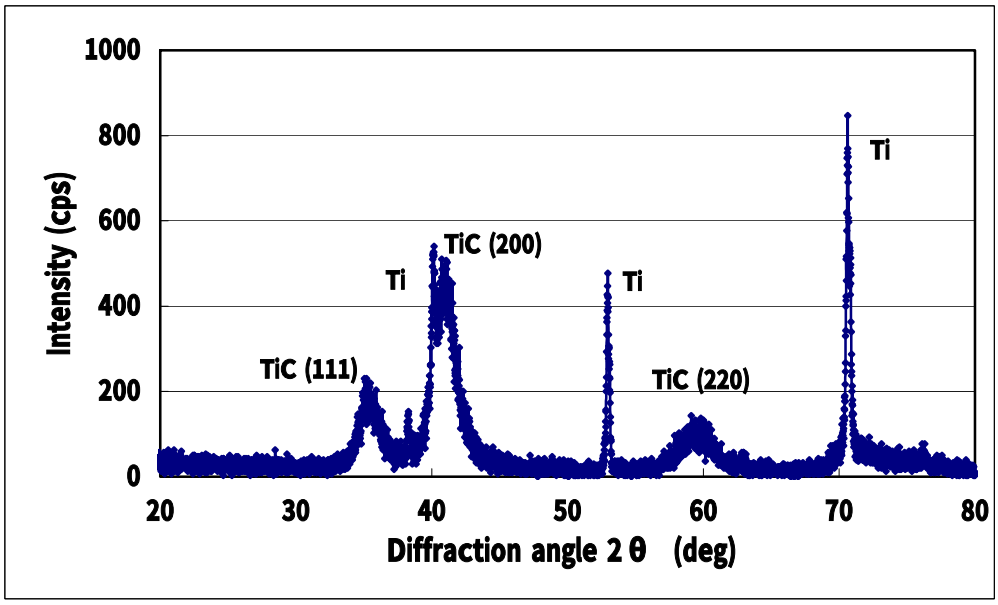

Fig. 6 X-ray diffraction pattern of deposited TiC film on Ti substrate.

4. Conclusion

In this study, the deposition of TiC films on Ti substrate was demonstrated by the triode low frequency plasma technique with the gas mixture of $TiCl_4$+CH_4+H_2. The deposition rate and the Vickers hardness of the

deposited TiC were 2.5 μm/h and 5000 Hv, respectively, at a substrate temperature of T_{sub} = 750 ℃ with a bias voltage V_b = -400 V and a plasma current 100mA

X-ray diffraction (XRD) spectra suggested that the deposited TiC film contains the preferred orientations of TiC (111), TiC(200) and TiC(220). It was confirmed from observation of the SEM micrograph that the deposited TiC film has a very flat surface.

We reached the conclusion that the Vickers hardness above 5000Hv can be achieved even under a relatively low–temperature condition by taking advantage of the negative-bias circuit with two diodes. In this system, the substrate potential is always lower than those of the upper and lower electrodes at every half cycle, which enables the substrate to attract positive ions by the negative potential enhancing the deposition process. It was conjectured that the bombarding energy of the ions to the substrate is consumed by the deposited atoms for rearranging the state of the surface structure.

Abstract

The paper study surface modification of medical PVC by remote argon plasma and analyze surface structure, performance of treated material by contact angle measurement, SEM and XPS. Relative concentration of free radicals of treated material analyzed by ESR. The result shows, The surface wettability and anticoagulant property of PVC film can be improved by remote argon plasma, it is advantaged to improved biocompatibility of medical PVC. Remote argon plasma can inhibit the ion and electron etching reactions and enhance free radicals reaction.

Keywords Remote Argon plasma; PVC; Surface modification; ESR

1.Introduction

Plasticized PVC films are used in biological and medical applications in storing of substances (e.g. blood and blood products, drugs and injectables), for catheters with antithrombogenic activity[1]. In these applications it is necessary to use materials having a morphology, a chemical composition, and a polarity of the surface which do not affect the biological environment.

Plasma treatment is a useful technique to study and develop biomedicine materials for its many merits, such as speediness, simplicity, sterilization, and ability to treat complex shape surface[2,3]. However, So far, researches about plasma surface modification have merely been limited to a mixed atmosphere constituted by all active species. The main reactions occurring on polymer surface in plasma are etching, cleaning, crosslinking, grafting and other chemical reactions dependent on the presence of active species in plasma[4]. How much do the different active species contribute to surface modification? Such perplexities occurred at plasma chemistry basic theory research and the key techniques in application haven't been seen whether in native or foreign reports yet.

Plasma contains highly activated species such as electron, ions, and radicals. Radicals can be isolated from the plasma because of their longer life-spans than electrons and ions (the rate constants of electron-positive ion recombination and radicals recombination are $10^{-7}cm^3/s$, and $10^{-33}cm^6/s$, respectively)[5]. High-concentration of radicals can be obtained at certain position away from the plasma source. When materials are positioned at a remote zone, uncontrolled rupture of large molecular chain caused by direct attack can be avoided, activated species interacted with samples are reduced, and the complexity of interface reactions between solid and gas are reduced. All of these make the surface modifying reaction (radical

reactions) dominant, while electron and ionic etching reactions are inhibited. Therefore, the control of a plasma reaction can be realized to a certain extent, and more desirable surface modification effect can be obtained, in contrast with conventional plasma treatment. The paper studied surface modification of medical PVC by remote argon plasma to obtain favorable surface performance.

2. Experimental part

2.1. Materials

Medical PVC film(20μm thickness, made by Blood Center of Shanghai) was cut into pieces of dimensions 20mm×10mm. Prior to the experiment, the sheet was washed with distilled water and dried naturally at room temperature.

2. 2. Remote plasma treatment

A self-designed reactor was used. In Fig. 1, we show the "Remote plasma" reactive system. The reactor includes four parts-gas inlet, reaction chamber, gas exhaust, power supply and matching network (SY-500W power supply and SP-Ⅱ matcher which are made in Chinese Academy of Science Micro-electronics Center). The reaction chamber is hard glass tube (length 1000mm, diameter 45mm), where inductance-coupling discharge is applied.

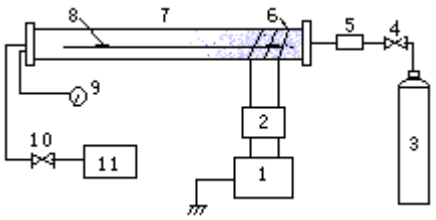

Fig. 1. Schematic structure of remote plasma reactor.

1.RF generator 2.Matching system 3.Gas bottle 4.Valve 5.Mass flowmeter 6.Inductance coil 7.Reaction chamber 8.Sample 9.Vacuum gauge 10.Electromagnetism valve 11.Vacuum pump

The PVC films were positioned on the carrier at a constant distance of 0, 20, 40, 60, and 80cm from the center of the inductance coil to distinguish remote plasma treatment from conventional plasma treatment (discharge zone). The purity of argon was more than 99.99%.

2.3 Contact Angle Measurement

The contact angle was measured by a contact angle meter (JY-82) made in Chengde, China. To lessen the effect of gravity, the volume of each drop was regulated to about 0.2cc by a micro syringe. The measurement was carried out at a 20℃ and humidity of 45% RH; the averaged value of the angles of the both sides of each drop was counted as one measurement. Each sample was measured at different points more than 10 times, and the contact angle was determined by their average values. The measurements were carried out immediately after plasma treatment.

2.4 X-ray photoelectron spectroscopy

X-ray photoelectron spectroscopy (XPS) (PHI5400ESCA, Perkin-Elmer USA) was used to analyze chemical compositions of surface layers of the PVC film at a pressure lower than 5×10^{-8}Pa; MgK_{α}(1256.6eV) X-ray was used as the source.

2.5 scanning electron microscopy (SEM)

The surface morphology of the PVC film was examined using scanning electron microscopy (SEM) in a JEOL instrument (Model JSM－5800, Japan) after vacuum coating the specimens with gold.

2.6 Electron spin resonance (ESR)

Crude wool washed is used as the trapping agent of free radicals in remote plasma field [6]. The wool is positioned on the carrier at a constant distance of 0, 20, 40, 60, and 80cm from the center of the inductance coil to be treated by remote argon plasma. Concentration of free radicals of surface layers is measured by Electron spin resonance (ESR) after 24h storage.

ESR spectra were recorded at room temperature (22-24℃) on a Bruker ESP-500E spectrometer Operating at 9.8GHz，x-band with 100kHz field modulation. The following instrumental settings were employed; microwave power 3.177mw; modulation amplitude 0.08G.

3. Results and discussion

3.1 concentration distribution of free radicals in remote argon plasma

The long life-span free radicals are formed at the polymer surface by the interaction between the polymer surface and the free radicals. When the power is 90W，treatment time is 3min，Ar flux is 20 sccm，figure 2 shows the ESR spectrum of wool of various remote distance.

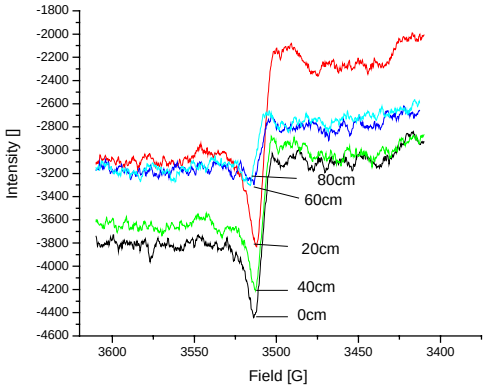

Fig.2 The ESR spectrum of wool of various remote distance (power: 90W; Ar flux: 20 sccm; treatment time:3min)

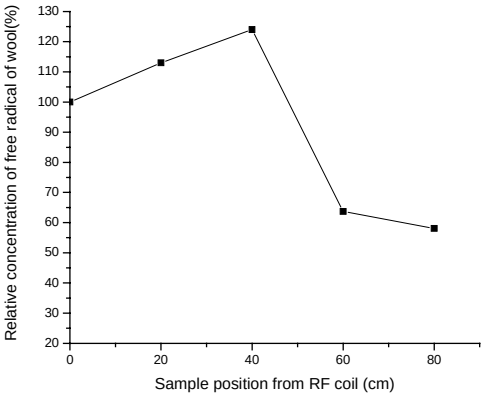

Fig. 3 Relative concentration of free radicals (c/c_0) on remote distance

As shown in figure 2, the samples at different remote distances appear absorb peak value of the same figures

but different intensity at the value of 3413.3g. It shows that all samples are the same kind of free radicals, but the remote distance effects the concentration of free radicals. As to a same kind of free radicals, the hight of absorb peak value can be used as its intensity, the rate(C/C_0) of the content of free radicals of samples(C) and of samples at a distance of zero(C_0) is used as the relative concentration. Relative concentration of free radicals (C/C_0) on remote distance is shown in fig.3. As it shows, with the increase of the remote distance, relative concentration of free radicals increases slowly at first and forms a zone of high concentration of free radicals and then decreases and tends to be stable at the remote distance of 80cm when the relative concentration of free radicals is still 58%. Therefore, there is a zone of comparative high concentration of free radicals in remote argon plasma which can enhance free radicals reaction.

3.2 etching of the surface of medical PVC by remote argon plasma

When plasma power is 60W, treatment time is 3 min, Ar flux is 20sccm, the SEM of plasma-treated PVC films are showed in fig.4. It can be known that compared with untreated samples the degree of etching of medical PVC film surface at discharge zone is very high. As the remote distance increases, the degree of etching of medical PVC film surface is weaken. There is only slight etching at the distance of 40cm and no etching at 60cm. It shows that in remote argon plasma, electrons and ions produced in discharge zone have strong etching action. But with the increase of the distance from discharge zone, electrons and ions annihilate quickly. Therefore, etching actions are inhibited in remote zone. As the distribution of concentration of free radicals in remote argon plasma shown above, Remote argon plasma can inhibit the ion and electron etching reactions and enhance free radicals reaction.

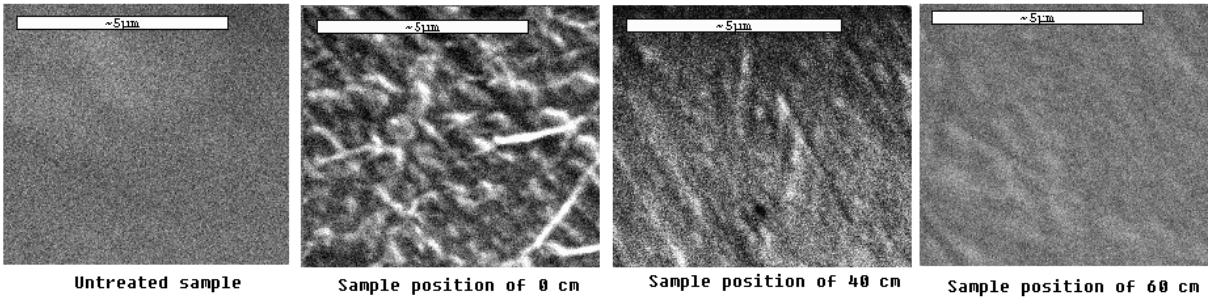

Fig. 4. Scanning electron micrograph of plasma-treated PVC film
(power:60W;treatment time:3min; Ar flux: 20 sccm)

3.3 Effect of plasma treatment conditions on the surface wettability of medical PVC

The research shows that if the surface of polymer is made to have strong wettability, the polymer will have good anticoagulant property and biocompatibility. We use contact angles to express the wettability of PVC surface to evaluate the biocompatibility of medical PVC surface modified by remote argon plasma.

When the treatment time is 3min and Ar flux is 20sccm, the effect of RF power and remote distance on the contact angles to water of PVC is shown in fig.5. Fig.5 shows that with the increase of discharge power , the contact angles of every sample all decreased rapidly from the untreated 109° （-20cm）. After it reaches

150W, it increases slightly, but the range of decrease is different in different distances. These curves implied that a quantity of argon molecule acquired more energy resulted from the increase of discharge power, so ionicity of argon and the average energy of active particles increased, and the reaction chance and intensity of active particles with PVC are further enhanced. so that the effect of surface modification is improved. However, after the power reaches 150W, ionicity of argon and the average energy of active particles increased, and the collision and recombination between activated species are accelerated. Therefore, the contact angles increased. The effect of discharge power on contact angles is similar to the result studied by Cooper and his colleagues [7].

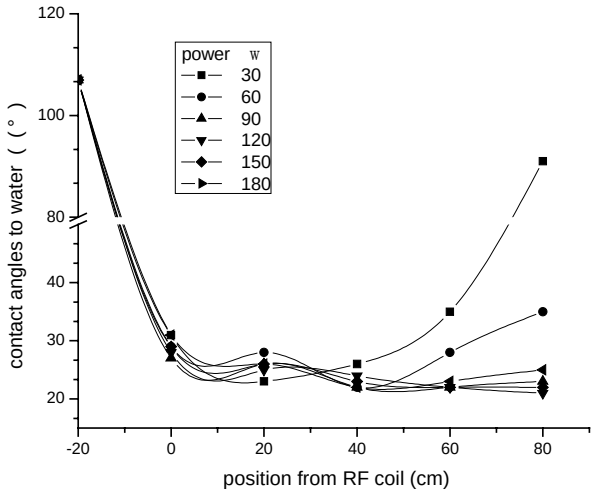

Fig.5 Effect of RF power on the contact angles to water of PVC
(treatment time 3min; Ar flux:20sccm)

3.4 chemical composition of the Surface of PVC

Table 1 The Atom concentration plasma modified PVC film

Sample	C_{1s}(%)	N_{1s}(%)	O_{1s}(%)	O+N/C
Untreated	82.66	0.39	5.55	0.072
Sample position of 0 cm	81.49	0.91	10.96	0.14
Sample position of 40 cm	79.17	2.99	14.69	0.223

The content of each group and O/C ratio are given in Table 1. The O/C ratio increases remarkably after treatment, especially in the remote area. That oxygen content increases shows that oxygen-containing and nitrogen-containing groups are introduced into the material surface, especially in the remote position. The oxygen content of samples is much higher than that of the discharge area. Thus, in the remote area, polarity and hydrophilicity of the surface increase more due to the intensified radicals reactions in the remote area.

Form the above, it can be seen that to enhance surface hydrophilicity of PVC, remote plasma treatment is more desirable than conventional plasma treatment.

4. Conclusions

Experimental results are summarized as follows:

(1) Both remote and conventional plasma can improve the surface of PVC film hydrophilic, but the increase of oxygen and nitrogen polar functional group on the surface of treated PVC by remote plasma is higher than conventional plasma. It shows that remote plasma treatment is more effective in surface modification.

(2) Surface modification effects depend on remote distance, discharge power, exposure time and argon flux. The optimal results was achieved when plasma treatment parameters were set, that was treatment time 3min, Ar flux at 20 sccm , power at 60W, Sample position of 40cm.

(3) Remote plasma treatment can enhance radicals reaction and inhibit electrons and ions etching reaction

Abstract

The paper investigated the possibility and several possible influencing factors of the "on-line" indoor air sterilization utilizing non-thermal plasma. We also analyzed the mechanisms and evaluated further the role of all kinds of active species such as electrons, ions and free radicals involved in plasma sterilization at a "remote plasma" field. The results showed that air-based non-thermal plasma could control the total number of bacteria continuously and efficiently even when people were in the room. The inactivation rate of microorganisms could reach about 95%.

Keywords Air; Sterilization; Non-thermal plasma; Inactivation rate

1. Introduction

Plasma is usually considered the forth state of matter being free of the solid, liquid and gaseous state [1]. According to the research, the active species in plasma can destroy a broad spectrum of microorganisms or disturb their organism functions through the reaction with the inner protein and nucleic acid [2]. When the glow discharge takes place in the gas, the UV radiation produced simultaneously will eliminate microorganisms cooperatively [3]. Non-thermal plasma technique makes it possible that the air-born pathogenic bacteria are killed in the room temperature, and once the discharge is terminated, those active species are no longer present in a few milliseconds, so this sterilization method has little danger for the personnel due to no leakage radiation. And it has other prominent advantages including convenient operation, short sterilization time and no toxicity [4].

So far, researches about plasma sterilization have merely been limited to a mixed atmosphere constituted by all active species, which are produced in some special discharge gases such as N_2, O_2, Ar and so on[5]. However, how much do the different active species contribute to sterilizing the workpieces or the air? And how to achieve "on-line" air sterilization on the working circumstance, such perplexities occurred at plasma chemistry basic theory research and the key techniques in application haven't been seen whether in native or foreign reports yet.

Supported by National Natural & Science Foundation Council of China, we put forward an innovative idea – remote plasma, that is, taking advantage of the different life-spans of various active particles such as electrons, ions and free radicals (Rate constants of recombination and dissociation reactions between electrons and ions, free radicals and free radicals are orders of $10^{-7}cm^3/s$ and $10^{-33}cm^3/s$ respectively) to make them separated at a special plasma field and attain super pure and high free radicals concentration at a distance from the plasma discharge region. In the presentation, we studied the possibility of the "on-line" indoor air sterilization utilizing non-thermal plasma at a high-voltage pulse corona discharge plasma field. In addition, we analyzed the mechanisms involved in air plasma sterilization and evaluated further contributions of the electrons, ions and free radicals to air sterilization at a "remote plasma" field.

2. Materials and methods

2.1 Plasma reactive system

2.1.1 “On-line” plasma reactive system and sterilization experiment

The “on-line” plasma reactive system (high-voltage pulse corona discharge plasma reactor) is shown in Fig.1. The airflow is forced into the reaction chamber through mass flowmeter, then purified and expelled from ventilating fan fit at the bottom of the chamber. The plasma reactor consists of chamber, electrodes and high voltage pulse power supply. The reaction chamber is made of the organic glass, on the right side of which, there is a gate for sending the sample into the chamber. The electrodes include comb type electrodes and plane-parallel plates used simultaneously for the sterilization-bed. And the pins number of the comb type electrodes, the space between the pins and the plates is adjustable. A self-made pulse power supply is employed in the reactor, which can range from 12V to 24V. When the signal is transmitted into the amplifier, the peak pulse voltage will exceed 20kV, and the discharge power will reach 50W at one atmosphere pressure. To test the “on-line” air sterilization, we change the plasma treatment parameters (discharge power, treatment time, peak value voltage, space between electrode pins and plane-parallel plates and pins number) and make the airflow pass through the reactor at constant flow rate.

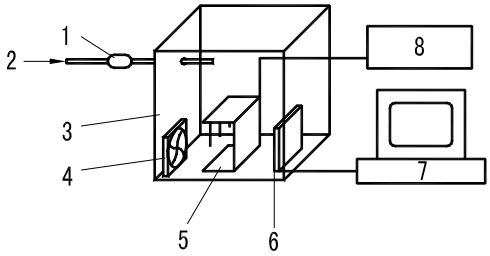

Fig.1. Schematic of high-voltage pulse corona discharge plasma reactor

1.Mass flowmeter 2.Inlet of air 3.Reaction chamber 4.Ventilating fan 5. Electrode pins and plane-parallel plates 6.Sensor 7.Personal Computer 8. High-voltage pulse power supply

2.1.2 “Remote plasma” reactive system and sterilization mechanism experiment

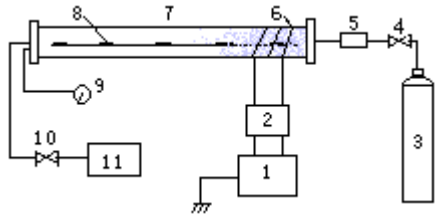

Fig.2. Schematic structure of remote plasma reactor

1.RF generator 2.Matching system 3.Gas bottle 4.Valve 5.Mass flowmeter 6.Inductance coil 7.Reaction chamber 8.Sample 9.Vacuum gauge 10.Electromagnetism valve 11.Vacuum pump

In Fig. 2, we show the “Remote plasma” reactive system. The reactor includes four parts -- gas inlet, reaction chamber, gas exhaust, power supply and matching network (SY-500W power supply and SP-Ⅱ matcher are made in Chinese Academy of Science Micro-electronics Center). The reaction chamber is hard glass tube

(length 1000mm, diameter 45mm), where inductance-coupling discharge is applied.

To compare the characteristic and effect of the remote plasma with that of the routine plasma on sterilization, we fix the microorganisms, which are captured from the air and deposited on the filter membrane, on different distances (0, 10, 20, 30cm separately) from inductance coil on the carrier, then evaluate the sterilization efficacy by changing the plasma treatment parameters (Also see 2.1.1).

2.2 Sample preparation

According to conventional air sampling method[6], when sampling, we set the cellulose acetate ester millipore membrane(diameter 55mm, aperture 0.45μm) disinfected in advance (boiled in distilled water for 15 to 30 minutes and repeated three times) on the tray of the sampler, and make the rough surface upward, then cover the cylinder and fasten it and tray with the special clip. The airflow rates on both inlet and outlet can be controlled through the rotameter between the vacuum pump and sampler.

The sample (millipore membrane) containing the microorganism was placed into plasma reaction chamber where discharge parameters were controlled. After treatment for a time, the sample was taken out. And the sampling surface was wiped with the aseptic cotton swab as soon as possible, which was immersed in the sterile physiological saline solution before. When operating, we must wipe the millipore membrane evenly five times toward both horizontal and vertical direction, and rotate the cotton swab simultaneously. Then the cotton swab was cut off the part that hands held first, and added to 10ml of sterile saline in a test tube and blended for 30 seconds in the shaker. After proper dilution, 0.2ml of the above suspension was inoculated on nutrient agar media including 3g beef extract, 10g peptone, 5g sodium chloride, 15g agar and 1000g distilled water [6], and incubated for 24h at 37℃ in a constant temperature incubator. The millipore membrane not subjected to plasma treatment served as the controls, other operations were as same as the above.

2.3 Statistical analysis of the inactivation rate

The initial colony formation units and the survivors after plasma treatment were counted after incubation for 24h at 37℃, further the inactivation rate could be calculated. All the experiments were repeated at least three times.

3. Results and discussion

3.1 Effect of discharge power

Effect of discharge power and remote distance on inactivation rate is shown in Fig. 3, and the discharge operating conditions are given in it. As shown in Fig. 4, with the increase in the discharge power, inactivation rate accordingly was raised no matter how far the samples were to plasma region, but its increase speed was obviously different in the different distances. When the millipore membranes were placed at sample positions of 0 and 20cm from discharge center, the inactivation rate increased rapidly with the increase of discharge power. Conversely, it increased slowly at the distance of 20cm and 30cm at the lower discharge power than 30W. Once exceeding the power, the inactivation rate was raised sharply. These curves implied that a quantity of air molecule acquired more energy resulted from the increase of discharge power, so ionicity of air and the average energy of active particles increased, and the reaction chance and intensity of active particles with bacteria was further enhanced. Therefore, the inactivation rate increased.

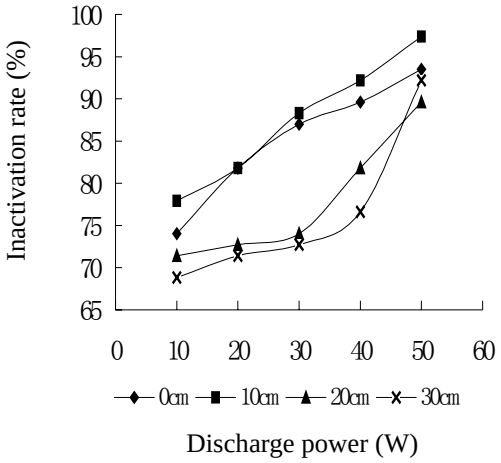

Fig. 3. Effect of discharge power and remote distance on inactivation rate of bacteria (discharge operating conditions: 60s, peak value voltage at 20kV, 40 electrode pins, space between electrode pins and plane-parallel

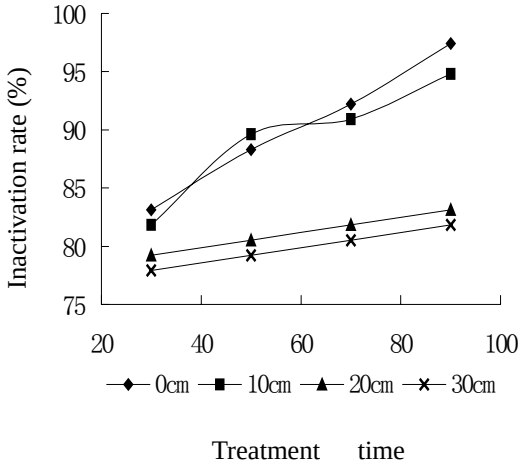

Fig. 4. Effect of treatment time and remote distance on inactivation rate of bacteria (discharge operating conditions: power at 40W, peak value voltage at 20kV, 40 electrode pins, space between electrode pins and plane-parallel

3.2 Effect of treatment time

Fig. 4 shows effect of treatment time and remote distance on inactivation rate as well as discharge conditions. As can be seen from Fig. 5, the inactivation rate increased along with the treatment time despite the remote distance, for the absolute dead bacterial count was accumulated with the increase in treatment time. But it increased at the completely different speed at different positions located in the remote region. For example, inactivation rate in the discharge region (within10cm) increased sharply, but it increased slowly in the remote region (20cm, 30cm), and at the same treatment condition, inactivation rate decreased with the increase of the remote distance. The above results demonstrated that it was the electrons and the ions that contributed to sterilization. As for the mechanisms of the free radicals reacting with microorganisms, which maybe include killing, inhibiting and variating processes, we will discuss in detail in later paper.

3.3 Effect of peak value voltage

The curve in Fig. 5 expresses the relation between the inactivation rate and the peak value voltage. Adjusting the peak value voltage that ranges from 5 to 28 kV and setting the discharge conditions as Fig.6, we can notice that the inactivation rate increased rapidly when the peak value voltage was boosted. And the trend didn’t reduce gradually until the inactivation rate reached 90%. The reason for this was that the boost in peak value voltage resulted in the intensification of electric intensity in the discharge region and correspondingly the active particles acquired more energy, and finally led to the increasing inactivation rate. However, once the voltage was more than 20kV, the inactivation rate would remain around 90% without evidently rise, because the energy of active particles was saturated in a quantity of air, and the further rise of the peak value voltage made the electric field energy superfluous. Consequently, taking both energy consumption and inactivation rate into account, we can select an optimal voltage (it was 20kV at our experiments).

3.4 Effect of space between electrode pins and plane-parallel plates

The relation between the space (within electrode pins and plane-parallel plates) and the inactivation rate is

shown in Fig. 6. Discharge conditions are also given in it. Fig. 6 shows that the inactivation rate changed little when the space between electrode pins and plane-parallel plates varied from 15 to 25mm, but it declined sharply along with the increase of the space, This is because that at certain power and voltage, the electric intension changed in inverse proportion to the space, with the rise of the space, the electric intension weakened which resulted in the decrease of the inactivation rate.

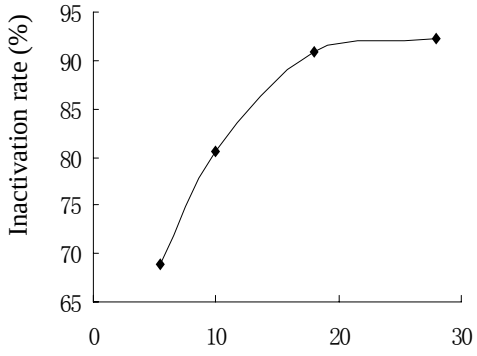

Fig. 5. Effect of peak value voltage on inactivation rate of bacteria (discharge operating conditions: 60s, power at 40W, 40 electrode pins, space between electrode pins and

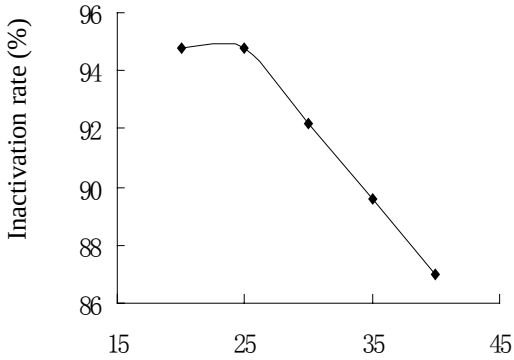

Fig. 6. Effect of space between electrode pins and plane-parallel plates on inactivation rate of bacteria (discharge operating conditions: 60s, power at 40W, peak value voltage at 20kV, 40

3.5 Effect of pins number

In the part of experiment, pins number varies from 25 to 60, and other discharge conditions are listed in the Fig. 7, which illustrates the relation between pins number and the inactivation rate.

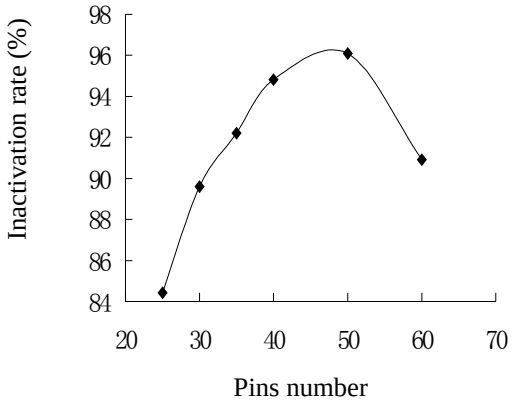

Fig. 7. Effect of pins number on inactivation rate of bacteria (discharge operating conditions: 60s, power at 40W, peak value voltage at 20kV, space between electrode pins and plane-parallel plates at 20mm)

As shown in Fig. 7, the inactivation rate increased sharply until the comb type electrode was added to 50 pins, instead, it decreased with the rise of pins number when the pins exceeded 50 pins. Because the density of active particles produced in gas discharge was raised with the increase of pins number, which expressed directly the increase of inactivation rate. But the internal energy of active particles decreased due to a constant discharge power when there were too many pins, so some active particles had no enough energy to

kill the bacteria, despite its increasing density, the inactivation rate decreased yet.

4. Conclusions

(1) We realized the “on-line” air sterilization on the working circumstance at a high-voltage pulse corona discharge plasma field. At a certain condition, the inactivation rate could reach 95% in tens of seconds. This demonstrated non-thermal plasma could kill a broad spectrum of microorganisms, and it was a concurrent, rapid and safe sterilization method.

(2) Discharge operating conditions including discharge power, treatment time, peak value voltage, and the structure of plasma reactor could affect biocidal effects. The change of inactivation rate obeyed the following rules, with the increase in the discharge power, the treatment time, and the peak value voltage, inactivation rate accordingly was raised. Conversely, Inactivation rate decreased along with the increase of the space between the electrode pins and the plane-parallel plates. With the change of the pins number, inactivation rate increased first, reaching a maximum, then decreased. The optimal results was achieved when plasma treatment parameters were set: 80s, power at 45W, 45 electrode pins, peak value voltage at 25kV, space between the electrode pins and the plane-parallel plates at 20mm.

(3) At a “remote plasma” field, sterilization efficacy in discharge region (within 10cm) was far superior to that in remote region (beyond 20cm). This further demonstrated that it was mainly the attack of the electrons and ions on the microorganisms that played the most important role in plasma air sterilization, and the high active free radicals had little influence on the microorganisms. The mechanisms that the free radicals react with the microorganisms are in investigation from molecule biology.

Abstract
PECVD technology has been proposed for protection of silver-based alloy artefacts from tarnishing by SiO_2-*like* coatings. The deposition performed in RF plasma fed with tetraetoxysilane/oxygen/argon mixture, by increasing both O_2/monomer ratio in the feeding gas and input power produces layers with excellent barrier effects against diffusion of water and gaseous aggressive agents from the environment towards the metal surface; the coating adhesion increases if the deposition process is performed after hydrogen plasma treatment.

Keywords
PECVD, Silver alloys, SiO_2-*like* coatings, Tarnishing, Cultural Heritage

1. Introduction

This research has been developed in the framework of a European Project, named PROMET [1], devoted to find innovative conservation approaches for monitoring and protecting ancient and historic metals collections from the Mediterranean basin. Museums and historical sites in the Mediterranean region exhibit collections of Phoenician, Hellenistic, Roman, and Islamic metallic works of art that are witnesses of mankind past. Unfortunately, these artefacts often suffer of serious problems of conservation due to the corrosion and degradation phenomena that may, for example, take place during burial and/or after their excavation during storage and exhibition. The high relative humidity and aggressive agents in the atmosphere may accelerate these corrosion attacks.

In order to decrease the kinetic of the degradation phenomena, it is difficult to protect the metal collections by placing them in strict environmentally controlled areas or by treating them on a regular basis, due to the large number of objects and the heavy cost of repeated maintenance, so the development of a protective layer with good aesthetic appearance and excellent barrier properties against atmospheric pollution has to be preferred.

Among the ancient artefacts, the precious noble metals objects are characterized by a wide chemical composition range (Cu, Ag and Au-based alloys, Ag and Au coated artefacts) and have been produced via different complex manufacturing techniques that have greatly influenced their chemical and metallurgical stability. Dealing with the degradation state, ancient precious artefacts are often fragile and subjected to various alteration and corrosion processes, Fig. 1.

Indeed, even though the chemical nobility and the good ability to resist to corrosion is one of the properties of silver and silver-based alloys, the well-know tarnishing phenomenon takes place if silver is exposed to sulphur compounds present in the environment.

The gold-based or nearly pure gold artefacts are more stable with respect to the silver objects but the presence of less noble metals as traces or alloying elements, such as Pb and Cu, could play a detrimental effects on the chemical and physical stability of the object due to the formation of separated metal islands or secondary precipitated phases. The resulting alloy, whose equilibrium state is not a single phase, is less resistant to long-term corrosion.

Furthermore, on the Ag or Au-based surface of ancient artefacts, a thin *patina* is formed where relicts of metal and insoluble corrosion products (Ag_2S, AgCl, CuS, CuO, Cu_2O, etc.) are mixed to form a complex composite structure.

Fig. 1 – Roman coins of the 1st century B.C.: Suberatae coin, constituted by a core of copper coated with a silver layer, corrosion attacks are evident on the surface of the artefact due to the corrosion of the copper interior with the formation of copper corrosion product as malachite (left); Serratus, silver coin characterized by a notched edge, in dependence on the conservation conditions tarnishing may appear on the surface of the artefact darkened in some areas (right)

The removal of tarnished film on silver-based alloys usually requires the use of chemicals to convert the silver sulphide into soluble compounds, or abrasives, which use mechanical action. These methods may cause loss of silver from the artefact, because in addition to removal of the silver combined as silver sulphide some of the metallic silver is abraded. Moreover the freshly cleaned surface is very reactive and will quickly retarnishes again, so repeated cleaning may increase the damage.
At present there is not a satisfactory methodology for the overcoming of the never-ending problem of cleaning, protecting and preventing further damages of restored artefacts.
As said before a possible solution may be to coat the surface of metal precious artefacts with a protective layer. In this context the high chemical stability, the low gas and vapour permeability and the optical transparency of thin films deposited in organosilicon containing plasma render them particularly promising for the protection of precious metal artifacts [2, 3].
In this paper the description is limited to the deposition of SiO_2-*like* thin films on Ag-Cu alloys of chemical composition and microstructure similar to the ancient artefacts. This study will help archaeologists and curators to preserve, restore and protect the artefacts in order to display them in museums without causing further damaging

2. Experimental

The deposition of SiO_2-*like* coatings has been carried out on mirror polished samples (20x20x2 mm) of Ag-Cu alloys of different composition (from 10 to 90 atomic % of Ag). The Ag-based alloys have been melted in a graphite crucible under a reducing atmosphere in order to reduce surface oxidation, nevertheless noticeable amount of oxygen has always been detected on the silver alloy surfaces. The capacitively coupled apparatus used is a home-made parallel-plate-reactor with an asymmetric electrode configuration. It consists of a stainless steel vacuum chamber with a upper powered electrode connected to a 13.56 MHz RF power supply through an impedance matching unit, and a bottom grounded electrode [4].
The samples were processed on the grounded electrode at the floating temperature reached by the plasma (T<70°C), by applying the RF power, 50-250W, to a gas mixture containing tetraetoxysilane (TEOS), oxygen and argon (feed composition: TEOS 2 sccm, O_2 0÷45 sccm, Ar 22÷67sccm; total flow rate: 69 sccm), at a pressure of 100 mTorr. A pre-treatment step in H_2-containing plasma has been performed, by applying the RF power of 15 W to hydrogen, 20 sccm, at P = 1000 mTorr.
The chemical characterization of the coating has been performed by means of Fourier Transform Infrared Absorption Spectroscopy in transmission mode (EQUINOX 55 BRUKER FT-IR) on coatings deposited onto polished silicon, and X-ray Photoelectron Spectroscopy (XPS). XPS spectra have been obtained with an ESCA PHI5300 spectrometer by means of non-monochromatic MgKα X-ray source. The acquisitions were performed at a take off angle of 45° within 2h from the deposition. Coated samples were also analyzed during continuous sputtering of the surface by means of an *in situ* 3 KeV Ar-ion beam (depth profile mode), this allowed to evaluate the effect of feed gas composition and RF power value on the film chemistry as well as to investigate the substrate-coating interface with and without pre-treatment. Quantitative analysis has been performed with C1s, O1s, Si2p, Ag3d, Cu2p high resolution peaks, while for a better comprehension of the oxidation state of Ag and Cu the Auger signals Cu L_3VV and Ag M_4VV were investigated [5]. Depth

profile analysis was also carried out on the Ag-based alloys and on freshly polished pure silver and copper, for comparison.
Tarnishing tests have been performed in 0.1 M Na_2S aerated solution at room temperature by intermittent immersions in the solution (24h immersion, 24h air exposure, 48h immersion, 24h air exposure and finally 72h immersion). Tarnishing has been evaluated quantitatively by means of CIE L*a*b* colorimetric measurements (Chroma-Meter CR-400, Minolta).
The protective effectiveness of the coatings has been also assessed by means of Electrochemical Impedance Spectroscopy (EIS). Impedance measurements have been performed at room temperature in aerated 0.1 M NaCl solution, in the frequency range 100 kHz -10 mHz. The experimental data have been interpreted on the basis of a suitable equivalent circuit model [4, 6] in order to evaluate, the charge transfer resistance, R_{ct}, which can be directly related to the protective properties of the coatings.
Morphological characterisation of the coatings has been performed by means of Scanning Electron Microscopy (SEM-EDS, Philips 515 SEM and EDAX 9900 energy dispersion microprobe, equipped with a W filament and a Robinson back scattered electron detector) and by means of an Atomic Force Microscope (AFM, Thermomicroscope Auto CP). The film thickness has been evaluated by means of an α-step Tencor Profilometer.

3. Results and discussion

3.1 Chemistry and morphology of SiO_2-like layers

The identification and the correlation between the chemical composition and the barrier properties of the coatings have been carried out by means of FT-IR investigations, Fig.2.

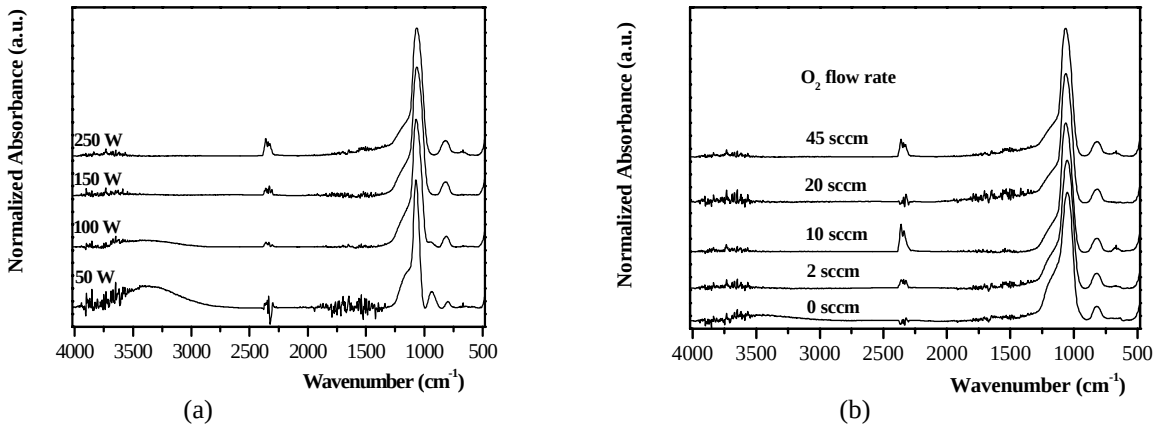

Figure 2 - IR absorption spectra of SiO_2-*like* coatings deposited at: (a) different RF Power values (100 mTorr, TEOS=2 sccm, O_2= 45 sccm, Ar=22 sccm) and (b) different O_2 flow rate in the feed gas (250 W, 100 mTorr, TEOS=2 sccm). The Ar flow rate is changed to keep the total flow rate at 69 sccm

In agreement with our previous results obtained on SiO_x films deposited in hexamethyldisiloxane (HMDSO)/O_2 fed plasmas [7], the RF power largely influences the chemistry of the layer. As a matter of facts, for coatings deposited at a fixed O_2-to-monomer ratio (22.5) with increasing RF power (Fig. 2a), the absorption features are consistent with an inorganic SiO_2-*like* matrix: the Si-O-Si stretching and bending absorption bands (at 1068 cm^{-1} and 820 cm^{-1}) and the features of silanols (Si-OH) at 935 cm^{-1} (bending) and 3450 cm^{-1} (stretching) may be detected. Moreover, the FTIR spectra highlight also the decrease of the silanol groups content by increasing the input power; SiOH absorption peaks completely disappear at input power higher than 100 W, because of the higher ion bombardment energy and dose, which are expected to enhance the OH groups abstraction. The presence of silanols decreases the barrier effects of coatings because of the higher porosity of the films and of their intrinsic reactivity. The effect of feed gas composition, in terms of O_2/TEOS flow rate ratio, on the chemistry of the film has been studied at 250 W of input power (Fig. 2b). It is important to underline that any absorption can be ascribed to organic moieties even when the feed gas does not contain oxygen. The coating obtained with pure TEOS (without oxygen) shows a light absorption of OH groups at 3450 cm^{-1}, indicating that input power plays an important role also in the removal of the organic fraction of the coating. The morphology of the SiO_2-*like* film has been investigated by means of AFM and

SEM observations. AFM images highlights that the layers uniformly cover the surface; they are also characterized by good adaptability to the underlying substrate independently from the different surface roughness (Fig.3).

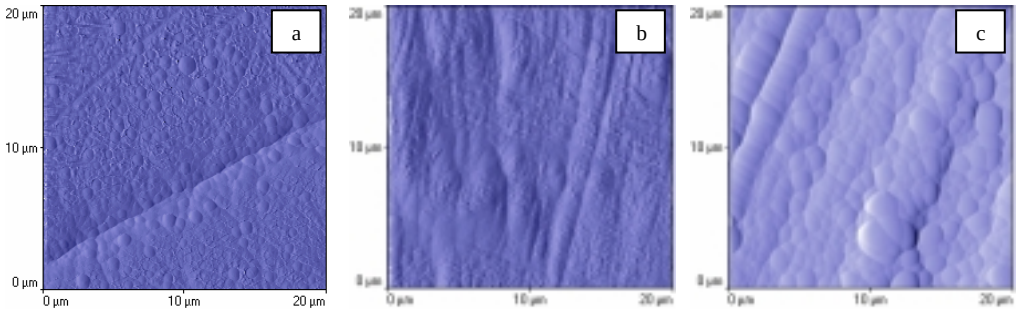

Fig. 3 – AFM images of SiO_2-*like* film (TEOS=2 sccm, O_2= 45 sccm, Ar=22 sccm, 250W, 100mTorr) deposited on Ag90Cu10 alloy samples with different surface roughness; the medium square roughness is: a) 24 nm, b) 78 nm, c) 224 nm

The good conformability of these layers to the metal surface has been also confirmed by the SEM observation of the cross-section of a patterned Si wafer coated with SiO_2-*like* film (Fig. 4). This high degree of adaptability to any kind of surface is a key factor in order to meet the requirements of curators involved in the conservation of historical and archaeological artefacts that are usually characterised by very complex shapes and decorations.

The substrate/coating interface, essential for good adhesion of the coating and a consequent good barrier effect, has been studied by means of XPS depth profile analysis. An important parameter affecting the quality of the substrate/coating interface is the pre-treatment step, in the case of silver-alloys performed in hydrogen.

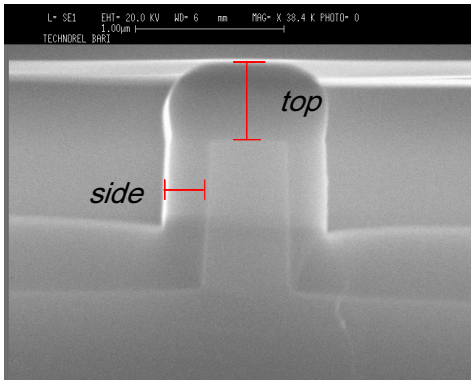

Fig. 4 – SEM image of the cross-section of a patterned Si wafer coated with SiO_2-*like* film (TEOS=2 sccm, O_2= 45 sccm, Ar=22 sccm, 250W, 100mTorr)

The XPS profiles recorded on as polished Ag after SiO_2-*like* film deposition are shown in Figure 5. With and without H_2 pre-treatment, the oxygen profile is close to that of silicon, and the average O/Si ratio in the bulk of the coating is slightly higher than 2, as is usually observed on inorganic PECVD coatings deposited at low temperature. Furthermore the carbon content at the metal-coating interface is lower in the pre-treated sample. When the depth profile analysis is performed on Ag samples polished and exposed to the atmosphere for few days, the modified Auger parameter for silver passes from 724.4 eV for the untreated sample (a typical value for Ag_2O) to 725.2 eV for H_2 plasma pre-treated samples, which corresponds to the unoxidized state [9]. Moreover the Cu 2p signal of the untreated alloy is broad because it includes the features of not oxidised and oxidized copper. After H_2 plasma pre-treatment the intensity of the shake up, typical of Cu^{2+}, drastically decreases and the Cu2p signal features become sharper. These results highlight that on oxidized alloys the H_2 plasma pre-treatment leads to a surface chemical reduction of Ag and Cu.

Summarizing, the H_2 pre-treatment improves the coating adhesion and, as shown below, the tarnishing resistance of silver-based alloys, mainly for two reasons: i) removal of organic contaminants from the metal surface, ii) reduction of silver and copper oxides on the surface.

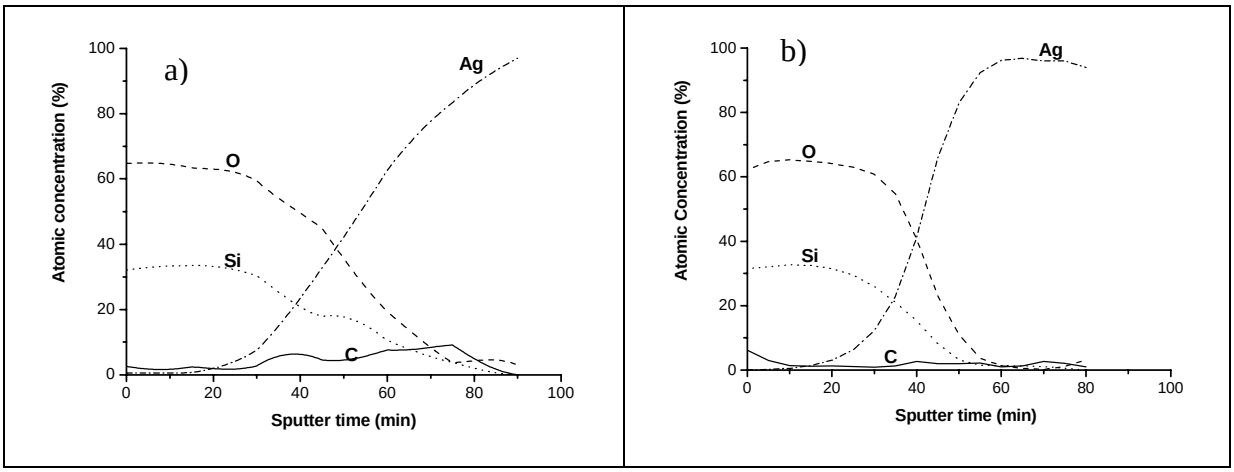

Figure 5 - XPS depth profiles of Ag samples coated with SiO_2-*like* film (a) without H_2-plasma pre-treatment and (b) after pre-treatment. The profile concentrations of C, O, Si and Ag are reported

3.2 Tarnishing Test

Usually, silver-based alloys tarnishing very quickly if exposed to sulphide containing environment. Notwithstanding the low thickness, the deposition of a SiO_2-*like* layer increases noticeably the tarnishing resistance of these substrates, as evidenced by the colorimetric measurements. The tarnishing susceptibility has been evaluated by taking into account the trend of the colour vector ΔE ($\Delta E=(\Delta L^{*2}+\Delta a^{*2}+\Delta b^{*2})^{1/2}$) as a function of the immersion time in the 0.1M Na_2S solution.

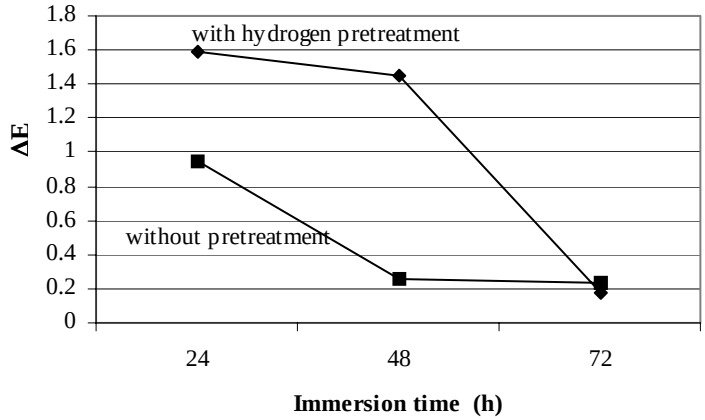

Fig.6 – Colorimetric measurements carried out as a function of the immersion time in 0.1M Na_2S solution on Ag90Cu10 alloy samples coated with 900 nm SiO_2-*like* film (TEOS=2 sccm, O_2=45 sccm, Ar=22 sccm, 250W, 100mTorr) with and without H_2-plasma pre-treatment

As evidenced in Fig.6, surface pre-treatment is a fundamental step in order to achieve high protective coatings. As a matter of fact, on Ag90Cu10 alloy treated in H_2-plasma before the deposition process, more than 48h of exposure are necessary for identifying an appreciable darkening of the surface; tarnishing becomes noticeable after 72h of immersion. On the contrary, a serious tarnishing occurs quickly (after 24h of immersion) on sample coated without any plasma pre-treatment. In this case, the high tarnishing susceptibility can be correlated to the poor adhesion of the SiO_2-*like* film on the metal surface. Consequently, the detachment of the layer takes place, starting from the coatings defects, which allow the penetration of the electrolyte, as evidenced by SEM observations not reported for brevity [5].

3.3 Electrochemical characterisation

The impedance measurements confirm the good protective effectiveness of the SiO_2-*like* films deposited after H_2-plasma treatment, as evidenced by the trend of the charge transfer resistance, R_{ct}, as a function of the immersion time in the 0.1M NaCl solution (Fig.7). For film deposited on the coated alloy the R_{ct}, decreases rapidly after 240h, while a constant trend is observed in the case of pre-treated and coated sample thereby indicating that the electrochemically active area increases to a lesser extent upon prolonged exposure, which points out to the better barrier effect and longer maintenance of protective properties.

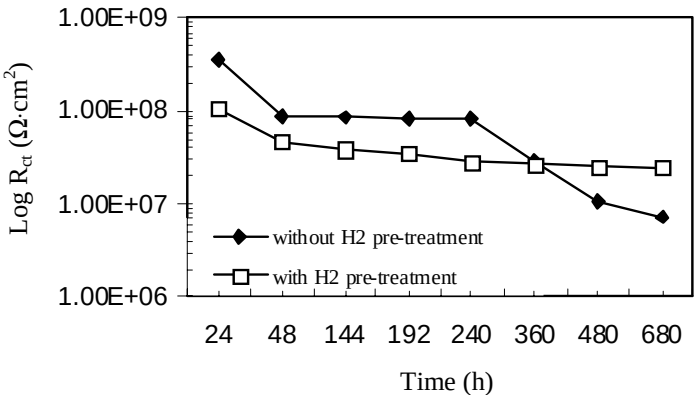

Fig.7 – Colorimetric measurements carried out as a function of the immersion time in 0.1M Na_2S solution on Ag90Cu10 alloy samples coated with 1500nm SiO_2-*like* film (TEOS=2 sccm, O_2= 45 sccm, Ar=22 sccm, 250W, 100mTorr) with and without H_2-plasma treatment

4. Concluding remarks

The conservation field of Cultural Heritage requires a multidisciplinary approach in developing new tailored strategies for protecting artefacts, which are based on science and technology as well as must be adapted to meet the conservation problems and needs of archaeologist and curators.

SiO_2-*like* coatings deposited by PECVD are proposed for protection of silver-based alloy artefacts from tarnishing; these coatings are effective in the protection of the artefacts: serious tarnishing has been observed on coated samples only after 72h of immersion in the sodium sulphide solution. The optimization of the deposition conditions lead to the identification of the influence of different process parameters. The protective effectiveness is higher for coatings deposited in oxygen rich plasmas at high input power, because under these experimental conditions the coatings have low defect density and no silanol groups. Moreover, protection against tarnishing increases if the deposition is performed after a pre-treatment in hydrogen plasma since better adhesion is obtained.

Abstract
In this study a systematical investigation of the tribological and electrochemical behaviour of SiOx and SiNx thin films has been undertaken. Moreover, the deposition of multilayers, such as Ti/TiN/SiOx and Cr/CrN/SiOx has been investigated, too.
Corrosion tests carried out by means of EIS has shown that when SiOx or SiNx coatings are deposited by means of plasma at low temperature, a marked increase of the protective properties is detected, if the process is preceded by a suitable plasma treatment, which depends on the particular metal under study.
Moreover, a huge increase of the corrosion behaviour, without affecting their mechanical properties, has been observed for Ti/TiN/SiOx and Cr/CrN/SiOx coated steel in comparison to magnetron sputtered ones.

Keywords
PECVD, SiO_x, SiN_x, corrosion, tribological properties

1. Introduction

Among main objectives of surface engineering are the applications of thin films and modification treatments in order to improve the surface properties without affecting the characteristics of the base materials.
In this context, it is particularly interesting from the scientific and technological point of view to develop coatings with different chemical composition and properties in order to increase the wear, sliding and corrosion characteristics of metallic materials.
Plasma Enhanced Chemical Vapour Deposition (PECVD) using silicon containing organic compounds emerged as a viable technique for depositing SiO_x thin films that, notwithstanding the low thickness, can improve the corrosion resistance of metals in different aggressive environments.
Silicon based materials including more or less C, O, N and H show high potential for corrosion protection essentially because they are dense (low permeability to water and gases), amorphous, chemically inert and show a low electrical conductivity or can be insulator depending on their composition. Moreover, the coating promotes no galvanic coupling deleterious to the uncoated metallic surfaces.
As a matter of facts, some interesting results have been obtained by these authors showing the increase of corrosion protection of low carbon steel and Mg alloys when coated with SiO_x thin films [1-2].
However, from the mechanical point of view, SiO_x coatings can be rather brittle. Therefore, the substitution of oxygen by nitrogen and/or carbon should allow getting higher tribological properties keeping the insulating nature, that is one of the parameters responsible for corrosion protection [3, 4].
Nowadays, Physical Vapour Deposition and magnetron sputtering processes are usually employed to deposit hard and wear resistant coatings for many industrial applications. These films make a significant impact also in many application areas, such as decorative coatings and coatings with specific optical or electrical properties. Unfortunately, most of these coatings often exhibit growth related defects (pores, pinholes) that are detrimental to the corrosion resistance in environments containing corrosive agents; defects are deleterious as they provide direct paths for corrosive electrolytes to reach the coating/substrate interface, where the localised corrosion attack takes place [5, 6].

The improvement of the corrosion performances of metal substrates coated with hard PVD coatings is of importance as increasingly demand for corrosion resistance from these coatings are required to enhance their tribological lifetime in aggressive working environments.
In this context, the high versatility of plasma processes allows also the deposition of multifunctional layers by combining PECVD and sputtering processes in order to increase both the corrosion and tribological behaviour of coated systems.
Aim of this study is to discuss the preliminary results concerning a comparison between the corrosion behaviour of SiO_x and SiN_x films deposited in RF plasmas with emphasis on the correlation of deposition parameters and their corrosion and tribological behaviour.
Moreover the use of amorphous SiO_x to interrupt the growth of TiN and CrN, deposited by magnetron sputtering in order to suppress their columnar structure, has been investigated, too.

2. Experimental

Low carbon and stainless steel substrates have been chosen for this study. Substrates were polished and cleaned with ethanol in ultrasonic cleaner for 15 min.
The coatings have been deposited in plasmas fed with different organosilicon precursors in mixture with argon and/or oxygen in different experimental conditions: SiO_x films have been obtained starting from hexamethyldisiloxane (HMDSO), tetraethoxysilane (TEOS), tetramethoxysilane (TMOS), hexamethyldixylazane (HMDSN), while SiN_x coatings have been deposited from bis(dimethylamino)dimethylsilane (BIS). SiOx coatings have been deposited by feeding the plasma with the monomer in mixture with O_2 and Ar with a O_2/monomer flow rate ratio higher than 10. On the other hand SiNx-like films have been deposited by addition of Ar.
Experiments have been carried out in two reactors with two different configurations: a capacitive coupled (CC) parallel-plate reactor and an inductively coupled reactor (IC). The capacitive coupled reactor has been extensively described elsewhere [7]. The IC reactor is a home made reactor consisting of a 20 cm diameter copper coil separated from the plasma by a quartz window 5 mm thick. The source is mounted over a stainless steel chamber of 30 cm in diameter. Both reactors are pumped down by a turbomolecular apparatus and pressure and gas flow rates are controlled by means of MKS baratron and mass flow meters.
Before the deposition a O_2-plasma treatment (500 mTorr, 50 W, 12 sccm O_2) has been performed. The pre-treatment increases the oxidation degree of the metal surface, reduces the porosity of the coating and improves its adhesion to the substrate [8].
TiN and CrN films have been deposited by magnetron sputtering, using Ti and Cr targets at 200°C, $3{,}0 \cdot 10^{-2}$ Torr and input power ranging from 150 to 300W; N_2 and Ar gases were used as a reactive source and a sputtering gas, respectively in an apparatus describe elsewhere [9].
The chemical and morphological characterisation of the coatings has been carried out by means of Infrared Spectroscopy (FT-IR) and Scanning Electron Microscopy (SEM).
The corrosion protective properties of deposited films have been assessed by means of Electrochemical Impedance Spectroscopy (EIS). The measurements are performed by applying an alternating potential of 10 mV amplitude in the frequency range 100 kHz -10 mHz to the coated substrate exposed to an aerated 0.1 M NaCl solution at room temperature. Impedance spectra recorded at the open circuit potential have been interpreted on the basis of a suitable equivalent circuit model [10, 11] in order to evaluate the value of the charge transfer resistance, R_{ct}, which can be directly related to the protective properties of the coatings.
Vickers microhardness measurements (ASTM E 384 Standard Method) and sliding wear resistance tests (pin-on-disc) have been also carried out in order to evaluate the mechanical and tribological behaviour of the layers. The film thickness has been evaluated by means of an α-step Tencor Profilometer.

3. Results and discussion

3.1 Corrosion and tribological behaviour of SiO_x and SiN_x coatings

The values of the charge transfer resistance, R_{ct}, obtained on low carbon steel samples coated with SiO_x and SiN_x films deposited starting from the monomers under study are shown in the plot of Fig. 1a.

Among the various monomers tested it has been shown that TMOS is not suitable to deposit SiO_x coatings characterised by a good protective effectiveness against corrosion, as confirmed by the R_{ct} value of about 2800 $\Omega \cdot cm^2$. On the contrary, high protective effectiveness has been observed for SiO_x and SiN_x coatings deposited in plasma fed with TEOS/O_2/Ar and BIS/Ar mixtures: the highest impedance modulus obtained are $7.5 \cdot 10^6$ $\Omega \cdot cm^2$ and $2.3 \cdot 10^7$ $\Omega \cdot cm^2$ for SiO_x and SiN_x films, respectively.

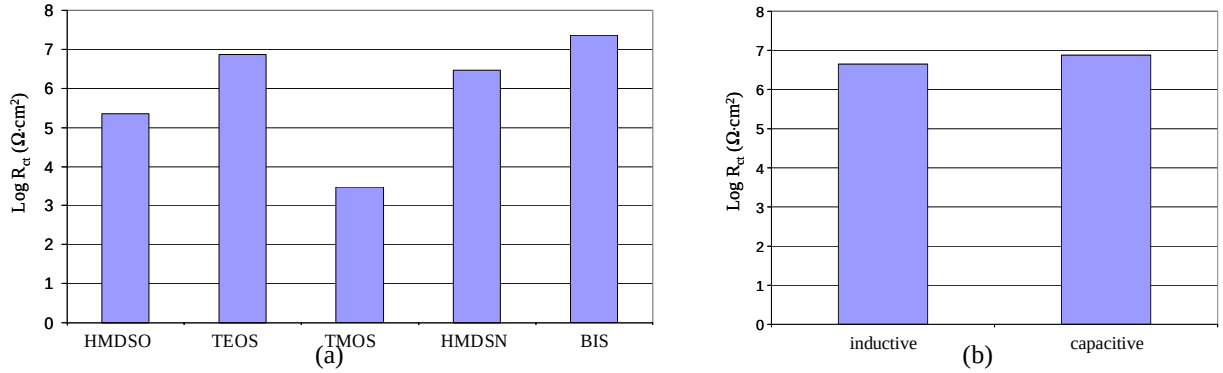

Fig. 1 – R_{ct} values obtained after 24h immersion in 0.1M NaCl solution on low carbon steel substrates coated with: SiO_x and SiN_x films deposited from different organosilicon precursors (a); SiO_x film deposited from TEOS in the capacitive and inductive coupled reactor (b). Coatings thickness is 2 μm.

The poor corrosion properties of coatings deposited in plasma fed with TMOS can be correlated to the low compactness of the film (Fig. 2a), while coatings deposited from TEOS and BIS precursors show a very low defects density and a good adhesion to the metal substrate (Fig. 2b, 2c).

(a) (b) (c)

Fig. 2 – SEM images of: SiO_x films deposited from TMOS (a) and TEOS precursor (b); SiN_x film deposited from BIS (c).

Moreover, the comparison of the R_{ct} values obtained for coatings deposited in the experimental conditions optimised for the two reactors, the capacitive and the inductively coupled one, shows that independently from the reactor geometry utilised, if the experimental conditions are adjusted in the proper way it is possible to deposit coatings with the same corrosion performances (Fig. 1b).

It this context, it is important to take into account that one of the experimental parameter that mainly affects the coating chemistry and, consequently, its corrosion and mechanical properties is the RF power. Best corrosion performances have been obtained for SiO_x and SiN_x thin films deposited on low carbon and stainless steel substrates by increasing the input power (Fig. 3). On the contrary, in the case of SiN_x films high Vickers micro-hardness values, about 1100-1150 Hv (kgf/mm^2), have been obtained for coatings deposited at 100W of input power. From the chemical point of view it has been shown [1, 2, 7] that the SiOx coatings deposited at high input power and at high O_2/monomer ratio are carbon and silanol free. FTIR has been used to analyse the chemistry of SiNx coatings and an absorption spectrum is reported in fig 4. The absorption band characteristic of

SiN stretching can be observed. However NH, CH and SiH bands can be easily recognised. These bands highlight that in the investigated conditions the coating is not a stoichiometric Si_3N_4.

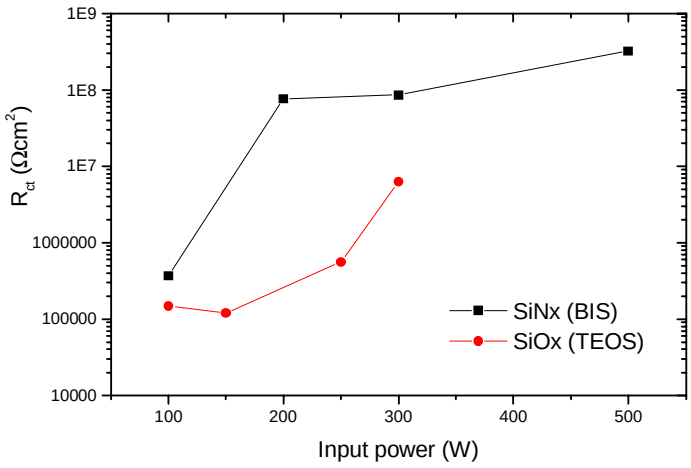

Fig. 3 – R_{ct} values as a function of the RF power for SiO_x film deposited on low carbon steel and SiN_x films deposited on stainless steel substrates. The R_{ct} values have been obtained after 24h of immersion in the 0.1M NaCl solution.

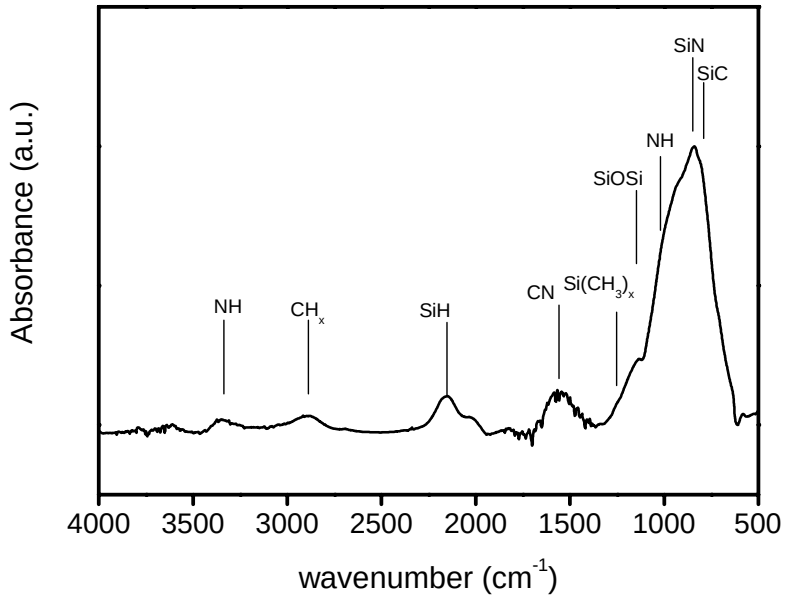

Fig. 4 – FT-IR spectrum of a coating deposited from a BIS/Ar gas feed at 300W in the CC reactor.

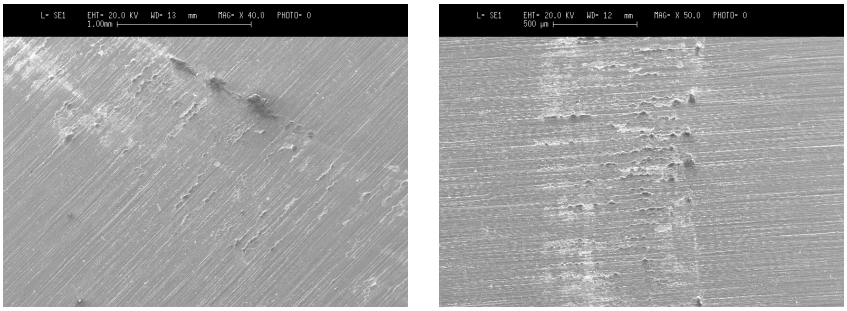
3.2 Corrosion behaviour of TiN/SiO_x and CrN/SiO_x multilayers

The good barrier properties against corrosive electrolytes and the amorphous structure of SiO_x thin films deposited from TEOS at high input power allow also to increase the corrosion behaviour of TiN and CrN hard coatings deposited by magnetron sputtering.

Table 1 - R_{ct} values obtained on low carbon steel substrate coated with TiN/SiO_x and CrN/SiO_x after 24h of immersion in 0.1M NaCl solution

Coating	**R_{ct} ($\Omega \cdot cm^2$)**
TiN	$1.5 \cdot 10^4$
CrN	$3.0 \cdot 10^3$
TiN/SiO_x	$1.5 \cdot 10^8$
CrN/SiO_x	$1.7 \cdot 10^7$



(a) (b)

Fig. 5 – SEM images of the surface of low carbon steel substrates coated with: TiN/SiO_x (a) and CrN/SiO_x after the sliding wear resistance test

Sliding wear resistance tests allow to confirm that the presence of the SiO_x layers doesn't affect the tribological behaviour of the coated systems as it is possible to observe in SEM images of Fig. 5. As a matter of facts, non significative weight lost has been determined after the pin-on-disc tests.

4. Conclusions

It can be concluded that coatings plasma deposited from organosilicon sources can be effectively used for protecting metals from corrosion. Furthermore coatings have not detrimental effects onto the tribological properties of the samples.

Abstract
We performed an experimental study of nitric oxide decomposition by an atmospheric-pressure DC hollow-needle to plate electrical discharge in N_2-NO mixtures. A needle electrode was biased negatively, mass flow through the needle and energy density ranged between 2.5-10 l/min and 0-250 kJ/m^3, respectively. Decomposition of NO and production of NO_2 species was monitored for several initial NO concentrations (20-200 ppm). We conclude that the transformation of NO is controlled by the production of atomic nitrogen.
Keywords: nitric oxide, DC discharge, atmospheric pressure

1. Introduction

Nitrogen oxides are formed when fuel is burned in combustion processes. They are toxic and cause serious health problems. The development of the NO_x control technologies is therefore an important challenge. Non-thermal plasma produced by electrical discharges is an efficient means for NO decomposition [1,2,3]. The principle of non-thermal plasma de-NO_x technologies is to produce an environment in which a majority of energy supplied to the discharge goes into the production of free energetic electrons rather than into gas heating. Even though these free electrons are short-lived under atmospheric pressure conditions and rarely collide with pollutant molecules, they undergo many collisions with dominant background gas molecules, thereby producing reactive species through electron impact excitation, dissociation and ionization processes. Chemically active species can, in turn, reduce and/or oxidize NO_x molecules.

In connection with N_2 + NO mixtures and for NO concentrations that do not exceed a few hundreds parts per million (ppm), the NO conversion is primarily controlled by ground state nitrogen atoms N(^{4}S). Molecular nitrogen N_2 is dissociated due to the presence of free electrons either through the direct electron impact or through the sequence of e-V, V-V and V-D processes [4]. Nitric oxide is then reduced by nitrogen atoms via a very fast process ($k_1 = 3.1\times10^{-11}$ cm^{3}s^{-1} [2]) with a subsequent formation of oxygen atoms:

$$N + NO \rightarrow N_2 + O. \qquad (1)$$

Additionally, free oxygen radicals created by (1) can react further with remaining NO species through an oxidative process ($k_2 = 9\times10^{-32}$ cm^{6}s^{-1} [5]) producing NO_2:

$$O + NO + N_2 \rightarrow NO_2 + N_2. \qquad (2)$$

Therefore, any removal of NO in the N_2+NO mixture which is induced by N(^{4}S) atoms created by electrical discharge should in general, be accompanied by formation of NO_2 species. The rate of NO removal and NO_2 formation then gives an indirect measure of N(^{4}S) production by a given type of discharge. In this connection we performed an experimental study of nitric oxide decomposition by a DC hollow-needle to plate electrical discharge in N_2-NO mixtures of a dilute amount of NO. All presented results were obtained with a needle electrode biased negatively.

An advantage of the hollow-needle to plate electrode arrangement with a supply of the mixture through the needle electrode is that all the mixture passes through the discharge zone and therefore is affected by plasma chemical processes. This idea was recently confirmed in a study of volatile organic compounds

decomposition [6]. We compared two different ways of the mixture supply to the discharge region. In the first case the mixture of air with VOC was supplied externally perpendicular to the needle electrode and in the second case the mixture was supplied through the needle electrode. The decomposition efficiency was about four times higher if the mixture of VOC with air had been supplied through the needle electrode.
Chemical reactivity of the same type of the discharge with the supply of dry synthetic air through the needle electrode was investigated through a comparative evaluation of ozone production efficiency [7]. Subsequently, it was discovered that the interaction of an ultrasound field with hollow needle to plate discharge substantially increases ozone production [8].

2. Experimental arrangement

Non-thermal plasma chemical decomposition of nitric oxide was studied in a DC-driven atmospheric pressure negative corona discharge. The experimental set-up is shown schematically in Fig. 1. A stainless steel needle *N*, (Terumo, Belgium) having an outer diameter of 1.2 mm and inner diameter of 0.7 mm was placed in a stainless steel discharge chamber. The needle was used as a cathode. A stainless steel disc anode was situated

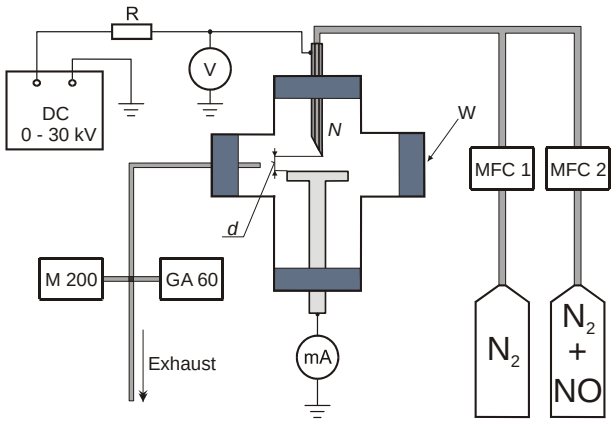

Figure 1. Experimental arrangement

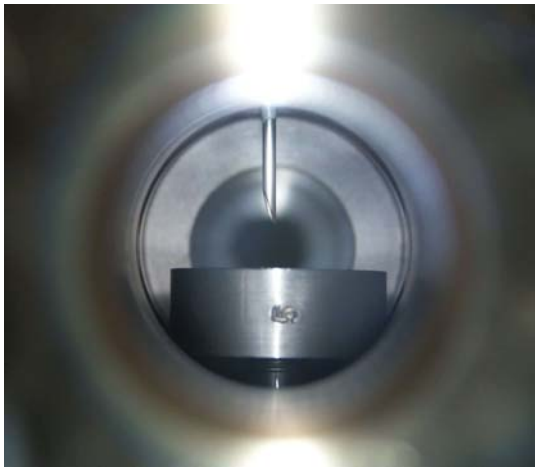

Figure 2. Photograph of the electrode system taken through the diagnostic window W.

perpendicular to the needle. The distance between the tip of the needle and the anode surface was *d*=4 mm. A digital photograph of the electrode arrangement is shown in Fig. 2.
The DC high voltage power supply, Technix, provided voltage up to 30 kV. The needle cathode was ballasted by a resistor R=0.889 MΩ. A stable flow of high-purity nitrogen with a defined quantity of NO was

maintained through the reactor. The gas pressure in the discharge chamber was fixed at 1.01×10^5 Pa and controlled by a pressure gauge. Nitrogen (99.9999) (Messer Austria, with certified impurities H_2O<0.5 ppm, O_2<0.5 ppm, CO/CO_2<0.1 ppm, HC<0.1 ppm and Ar<1 ppm) was delivered through Bronkhorst HI-TEC model mass flow controllers MFC. Quantified traces of NO (20, 100, 200 ppm) were added by the controlled flux of N_2+NO mixture (Pulmonix® forte, Messer Austria, 900 ppm NO in N_2, with main impurities H_2O< 3 ppm, O_2<1 ppm and NO_2<1 ppm). The GA-60 flue gas analyzer (Madur Electronics) equipped with electrochemical cells (O_2, CO, SO_2, NO, NO_2) and chemiluminiscence NO_x analyzer API 200EM (Teledyne Instruments) were used to monitor volumetric concentration of nitrogen oxides. Both instruments were used to verify a gas feed composition (N_2+NO) prepared by mass flow controllers and to analyze the discharge products ($NO+NO_2$) as well.

For a given electrode arrangement, stable discharge occurs for a wide range of the two most important external parameters: a) mass flow through the needle >2 l/min and b) DC driving high voltage >2.5 kV. We explored various combinations of the mass flow and DC driving voltage; however we observed only two basic discharge modes (shown in Fig. 3). At low energy dissipated between electrodes (usually obtained by combining a high

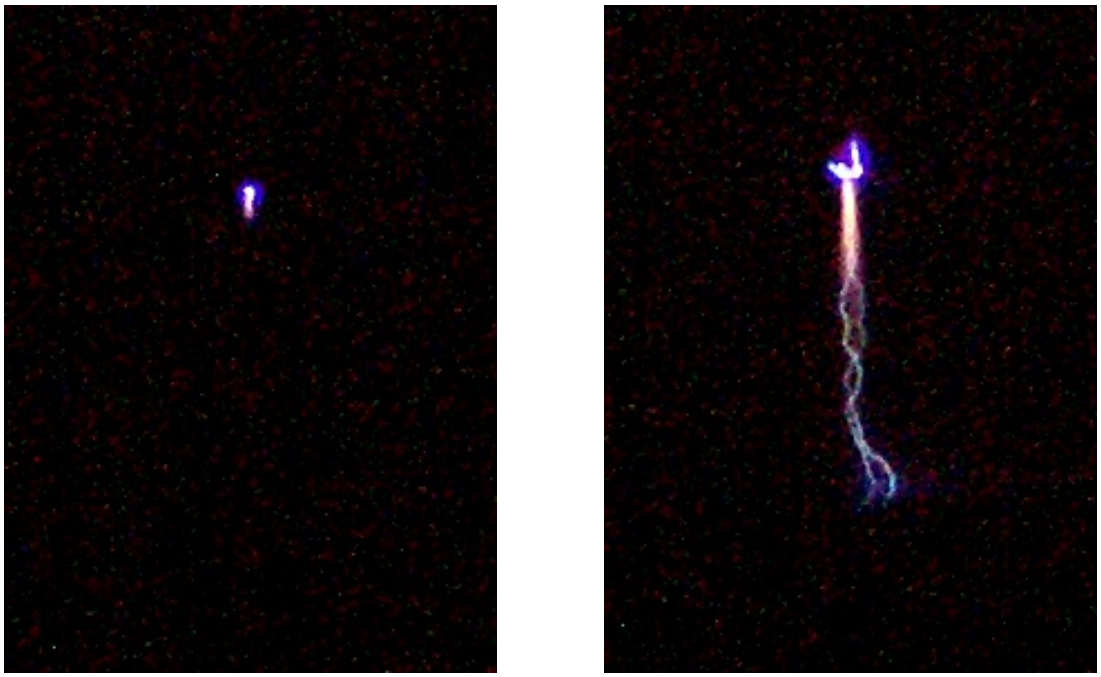

Figure 3. Two basic discharge regimes observed at low energy (left photo) and high energy (right photo) dissipated between electrodes.

mass flow with low driving DC voltage), the discharge is restricted to the small area surrounding the needle cathode. It takes the shape of a short luminous continuous jet, which is directed towards anode (see left photograph in Fig. 3). At higher energy dissipated between electrodes (usually obtained by combining a low-intermediate mass flow with a high driving DC voltage), the discharge is much more complex. The luminous jet directed towards the anode becomes longer (by 1-2 mm) and, simultaneously, the gap between the tip of the jet and the anode surface is frequently bridged by very thin filamentary discharges (see right photograph in Fig. 3). Our experimental results are presented as functions of energy density, which is defined as a ratio of power delivered to the discharge and flow of the mixture through the needle electrode. It is well known that depending on the nature of the feeding gas and polarity of the coronating electrode, the corona discharges

sometimes operate in the form of periodic pulses of different frequencies even at constant voltage conditions. For the purpose of this paper we determined the power delivered to the discharge as a product of discharge voltage and current. The discharge current was measured by milliamp-meter with a magnetoelectric system.

3. Experimental results

The experimental results concerning nitric monoxide transformation as a function of energy density for various initial NO concentrations obtained for constant flow rates through the needle 2.5, 5 and 10 slm are summarized in Figs. 4 - 6. The dependence of nitric monoxide concentration versus energy density delivered to the discharge for three different initial concentrations of nitrogen monoxide $[NO]_{in}$ = 20, 100 and 200 ppm is shown in Figs. labeled *a*. Equivalent dependence in the case of nitrogen dioxide is shown in Figs. *b*. Resulting NO removal rate is shown in Figs. *c* and, finally, the ratio of NO/NO_x concentration is shown in Figs. labeled *d*.

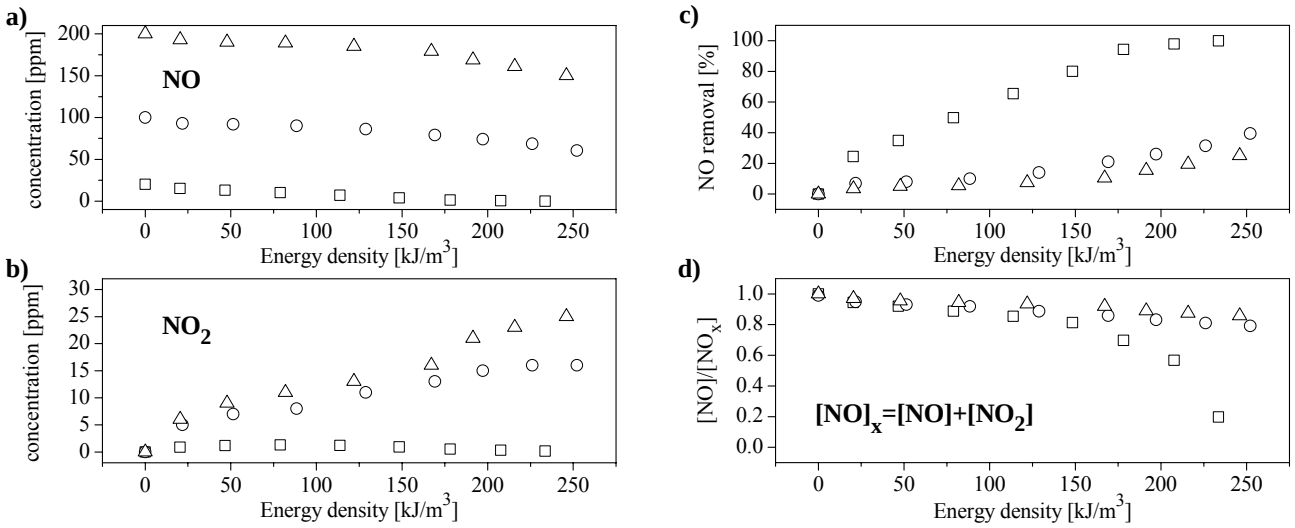

Figure 4. Nitric monoxide transformation as a function of energy density for various initial NO concentrations (□ =20 ppm O =100 ppm and Δ =200 ppm) and for a constant flow rate through the needle 2.5 slm.

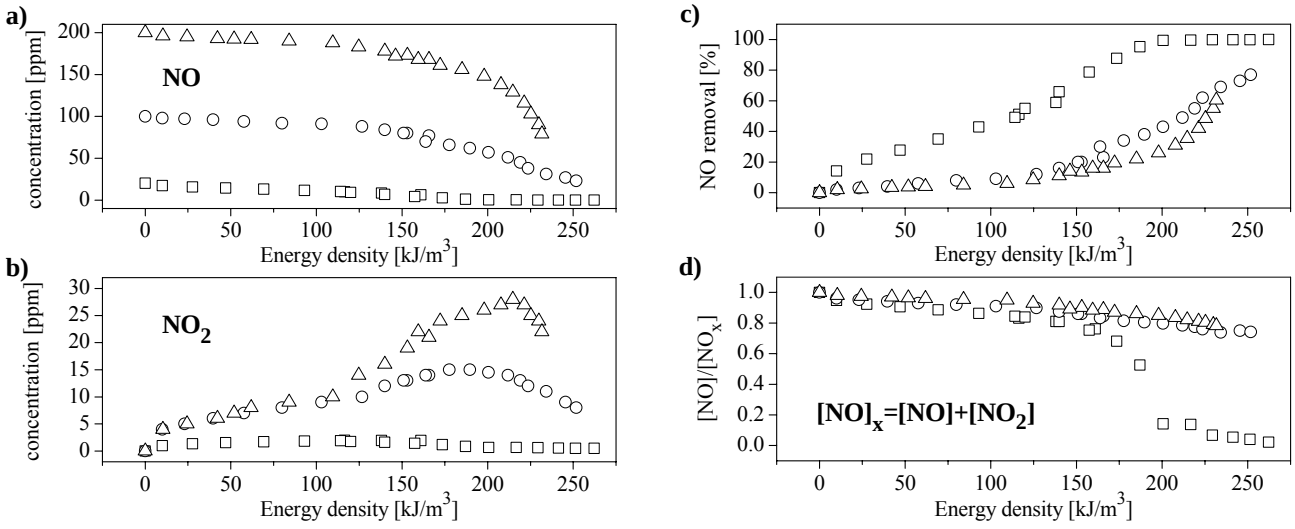

Figure 5. Nitric monoxide transformation as a function of energy density for various initial NO concentrations (□ =20 ppm O =100 ppm and Δ =200 ppm) and for a constant flow rate through the needle 5 slm.

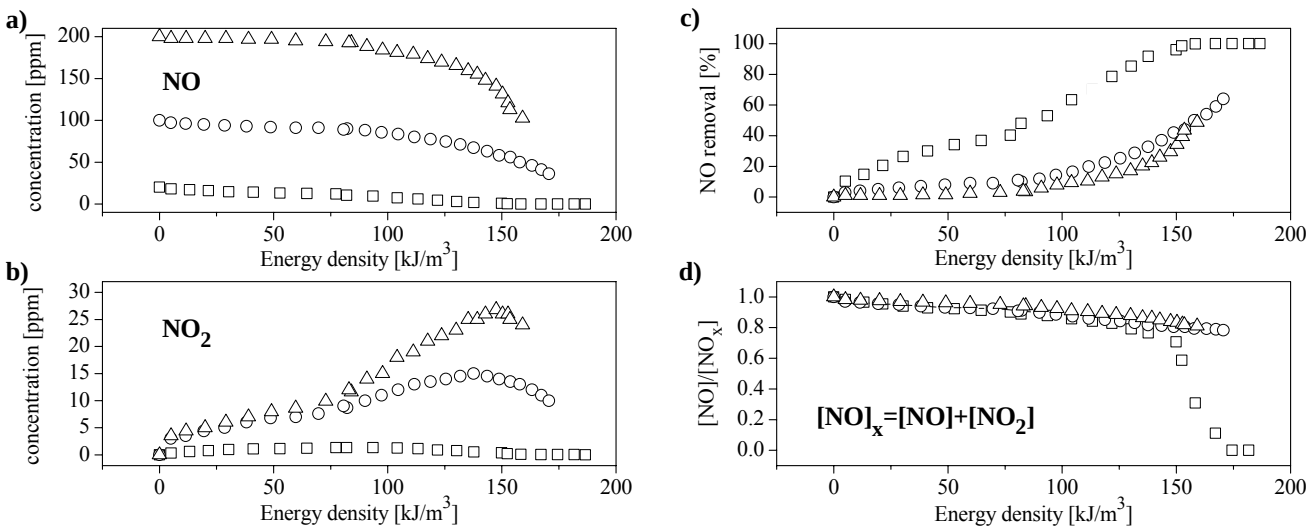

Figure 6. Nitric monoxide transformation as a function of energy density for various initial NO concentrations (□ =20 ppm O =100 ppm and Δ =200 ppm) for a constant flow rate through the needle 10 slm.

4. Discussion and conclusions

We have conducted experiments using the diluted mixtures of NO in N_2 to examine rigorously how various parameters affect the efficiency of N_2 dissociation and subsequent reduction of NO by N radicals. In our experimental arrangement the electric, energetic, hydrodynamic and chemical processes occurring in the discharge are strongly coupled. The mixture leaving the needle electrode expands and consequently the chemical kinetics is necessarily affected by this expansion. Furthermore a fraction of input energy in the discharge relaxes into thermal energy. The resulting change in the temperature induces perturbation on the chemical kinetics. The NO decomposition is therefore a result of many processes, which in a complex way depend on many factors such as:

- Reduced electric field - *E/N*
- Gas heating
- Polarity of the needle electrode
- Mixture composition
- Energy density
- Flow of the mixture through the needle electrode.

In our experiments we focused namely on the role of the last three parameters on NO decomposition. To summarize experimental results, the following findings can be highlighted:

- The NO decomposition in the discharge strongly depends on energy density for all three investigated initial NO concentrations.
- Complete NO removal can be more easily achieved for lower initial NO concentrations.
- The production of NO_2 increases with increasing the removal of NO. This result is in agreement with previous findings published in [9]. However we found that the production of nitrogen dioxide versus energy density exhibits a certain maximum. The position of this maximum depends on initial NO concentration and with increasing initial NO concentration is shifted towards higher energy densities.
- NO removal efficiency depends on initial NO concentration; complete NO removal is obtained for lower initial NO concentrations with lower energy density.

- The ratio of nitric oxide to the sum of nitric oxide and nitrogen dioxide decreases with increasing energy density. The sharp decrease of this ratio for initial NO concentration $[NO]_{in}$=20 ppm depends on the energy density and on the flow of the mixture through the needle electrode.

In conclusion, all experimental findings indicate that the transformation of nitric oxide in a negative hollow needle to plane HV discharge is controlled by the production of atomic nitrogen. The production of atomic nitrogen probably increases monotonously with increasing energy density as reflected by increasing NO removal efficiency (throughout all the 0-250 kJ/m^3 range inspected in this study) and by increasing NO_2 production as well (to a certain energy density level). In a low energy density range certainly both (1) and (2) processes strongly influence the NO removal. When the production of atomic nitrogen reaches a certain level, then subsequent production of atomic oxygen through (1) allows efficient production of NO_2 through (2) which is reflected by a peak NO_2 value. With a further increase of N^I production, the majority of NO species are removed in (1) and, consequently, the NO_2 concentration curve shows a declining trend.

STUDY ON THE ATMOSPHERIC-PRESSURE NON-THERMAL SURFACE-DISCHARGE PLASMA TORCH

Shin-ichi Kuroda, Kazuyuki Tamura, Tomoe Goto, Wataru Tobe and Hitoshi Kubota

Department of Chemistry, Faculty of Engineering, Gunma University, Tenjin-cho 1-5-1, Kiryu, Gunma 376-8515, Japan

Abstract

A cylindrical plasma torch composed of a stainless steel tube, a silicone tube and an aluminum ring belt was developed to generate an atmospheric-pressure non-thermal plasma jet. The plasma jet was obtained by applying pulse-modulated power under He gas flow. The electric current and the plasma jet length were found to depend on the input power frequency leading to the variation of active species concentration in the jet. Polymer films were effectively treated in the plasma jet resulting in the hydrophilic surfaces.

1. INTRODUCTION

There has been lately growing interests in low-temperature plasma sources working at atmospheric pressure[(1)]. Corona and dielectric barrier discharges (DBD) are traditional sources of atmospheric-pressure plasma that produce non-equilibrium plasmas with gas temperatures between 5-400 °C. However, since these discharges take place non-uniformly in a narrow gap of electrodes, their use in material processing is limited.

Recently, several plasma torch systems employing low-temperature flowing plasma jets have been developed, which seem promising for the surface treatment of large substrates with complex shape on the surface[(2-5)]. If a plasma jet with an adequate length is generated expanding out of the torch, more various and useful chemical reactions would be expected. In the previous study, we have developed a double cylindrical barrier discharge plasma torch and examined the effects of positioning of inner and outer electrodes on the generated plasma jet[(6)]. It was found that a stable He plasma jet was generated when the inner electrode was earthed and withdrawn back into the outer electrode.

In this paper, we developed another type of non-thermal plasma torch working at an atmospheric pressure. The torch consists with two coaxial cylindrical electrodes with different length and the plasma is generated by the surface discharge along the silicone tube that is inserted between the electrodes. The effects of applied voltage and helium gas flow rate on the plasma jet length are examined. The surface treatment of polypropylene film is carried out and the results are discussed in relation to the emission spectra observed for the plasma jet.

2. EXPERIMENTAL

The plasma torch used in this paper is illustrated in Fig.1. A stainless steel cylindrical tube of 6 mm diameter was used as the inner electrode and 20 mm length aluminum ring was located at the distance 5 mm from the tip of inner electrode. Silicone tube of 10 mm diameter was inserted coaxially between the electrodes for insulation. Helium gas was supplied to flow in the inner electrode at various rates. The input power was pulse-modulated bipolar sine wave with a pulse width of ca. 5 μs and applied by an impulse source (Haiden Laboratory, PHF-2K). The excitation frequency

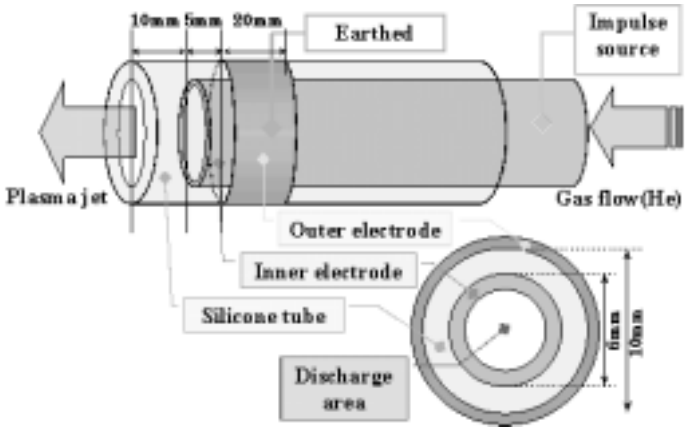

Fig.1 Scheme of plasma torch.

of discharge was varied from 2 to 100 kHz. The plasma was generated by applying the power to the inner electrode (A connection) or the outer electrode (B connection).

The plasma jet generated by the plasma torch was monitored by a CCD camera (SONY, DCR-TRV7) and recorded on a digital tape. The plasma jet length was evaluated on the recorded picture. In order to estimate the active species in the plasma jet, emission spectra were observed by using a plasma process monitor (Hamamatsu Photonics, C7460). The spectra were collected through an optical fiber for the plasma jet region out of the torch.

Polystyrene (PS) films were treated by the plasma torch for 10 s at the positions of 5-40 mm away from the torch end. XPS measurements were carried out after the treatment on the film surface by using Perkin Elmer ESCA 5600.

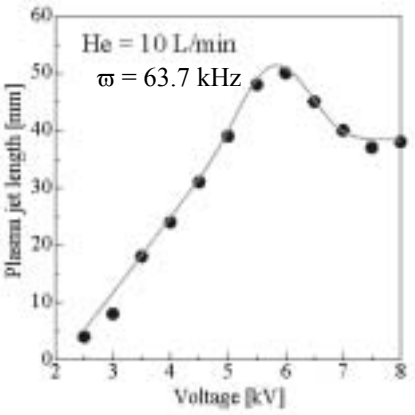

Fig.2 Effect of applied voltage on plasma jet length.

3. RESULTS AND DISCUSSION

The plasma jet was successfully generated both in the A connection and B connection.

The applied voltage and the flow rate of helium had a big influence on the length of plasma jet generated. The dependency of plasma jet length on the applied voltage and the helium flow rate is shown in Fig.2 and Fig.3, respectively for the case of A connection i.e. the outer electrode was earthed. The plasma jet length increases with the applied voltage up to 6 kV, which seems reasonable as the length should correspond to the amount of charged particles generated by the applied field. On the other hands, as the flow rate of helium increases, the plasma jet length increases till the flow rate of 30 L/min then turns into decrease. Too high fluid velocity seems to reduce the contact time of helium gas and inner electrode leading to the less generation of charged particles.

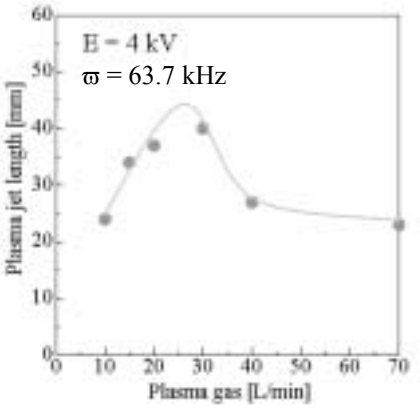

Fig.3 Effect of He gas flow rate on plasma jet length.

The input power frequency also affected the plasma generateon behavior. The electric current and plasma jet length were monitored with changing the frequency and plotted in Fig. 4 for the A connection as well as B connection. A similar dependency of current on the frequency is observed both in A and B connections, however that of plasma jet length is very different from each other in those two connections. The A connection leads to the consistent dependency of electric current and plasma jet length. On the contrary, the B connection shows almost opposite dependency. It is thus clear that the plasma jet length is not determined only by the electric current.

The raw emission spectra from the plasma jet region out of the torch are shown in Fig. 5. They were collected at 10 mm away from the torch end for the plasma jet generated under the frequency of 40 kHz. They exhibited prominent two nitrogen molecular band systems, i.e., N_2 second positive system (N_2 2+ ; 296, 316, 337, 358, 380 and 406 nm) and N_2^+ first negative system (N_2^+ 1– ; 391, 428 and 471 nm). The relatively weak bands due to oxygen neutral atoms (777 and 845 nm) and helium neutrals (588, 668, 706 and 728 nm) were also observed. It is considered that the energy transfer from the metastable helium species to the molecular nitrogen and oxygen take place very rapidly in the plasma jet. It is should be noted that the N_2

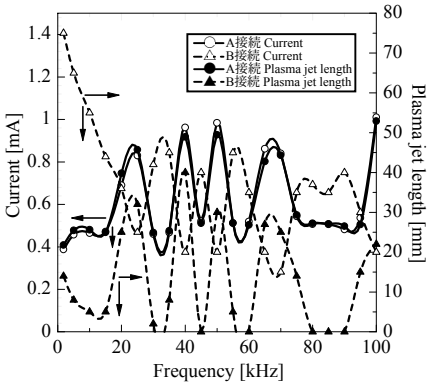

Fig.4 Effect of input power frequency on electric current and plasma jet length.

2+ emission is emphasized in A connection while the emission is weak in B connection though the emission intensity of N_2^+ 1– is close to the intensity in the A connection. In the similar manner, the intensity of O emission is about four times stronger in A connection than that in B connection while those of He are similar in A ad B connections.

The surface treatment of PS films was performed as one of applications of the present plasma torch. No fusion of polymer films was observed during the treatment indicating the gas temperature of the plasma jet was adequately low. The surface atomic concentrations of oxygen on the PS films estimated by XPS measurements are shown in Fig.4. It is obvious that the PS films are oxidized by the treatment. The O/C ratio keeps over 0.3 and changes little while the distance is less than 30 mm, i.e. the films are set in the plasma jet. On the other hand, the concentration drops down rapidly with increasing the distance when the films are treated at the outside of plasma jet. It is clear that the larger effect can be achieved when treated in the plasma jet than in the afterglow region.

TIME-DEPENDENT D.C. PLASMA FLOW MODELING

E. Meillot, D. Guenadou, A. Saget

C.E.A. LE RIPAULT, B.P. 16, 37260 MONTS, France
Erick.Meillot@cea.fr

Abstract: The main problem in D.C. plasma flow modeling concerns the taking-into-account of the time-dependent arc root movements in the anode. These movements are responsible of high fluctuations of the flow outside the torch. From a simple numerical model based on the gas acceleration and heating by JOULE effect in the anode, realistic flow behavior is reproduced, in particular, the mechanisms of air engulfment into the plasma plume, such as it was described by PFENDER and al [1]. Moreover, the centerline velocities and temperatures of the gas are compared with experimental values: the comparison shows good agreement.

1. Introduction. D.C. plasma torches are commonly used in industrial fields such as plasma spraying, waste destruction and so on. These guns based on electrical energy transformation to kinetic and thermal energies need high electrode cooling and rapid arc root movements on the anode wall on pain of destruction. These movements are responsible of high fluctuations of the plasma plume outside the torch and so of air engulfment in the flow. These interactions are not without consequence in the particle treatment in the case of plasma spraying. Depending on the in-flight time of the particles in the jet, their thermo-kinetic state at impact varies in a large range and so the coating structure can present different morphologies. This paper, first step of the global plasma spraying process modeling, is devoted to a simple time-dependent numerical model based on the gas heating and acceleration by JOULE effect inside the torch. The aim is to reproduce the behavior of the plasma flow outside the torch interacting with the air atmosphere from the only main operating parameters opened by the operators. The problem of the D.C. arc generation is not new. Literature is rich of simulation models but not yet including time instabilities. PFENDER et al. [1] have proposed a steady 3 D. model including the LORENTZ forces and the JOULE heating. CHEN et al. [2] have implemented a 3-D no-time-dependent model including LORENTZ and JOULE heating.

2. CFD code. The governing equations, the Reynolds average NAVIER-STOKES and heat equations, are solved using FLUENT commercial code. The turbulent model is the REYNOLDS STRESS MODEL (RSM) provided by FLUENT without any modification. In [3], k-ε model has been used for turbulence simulating. The results have showed that the plasma jet length was too short outside the torch. That is why RSM tests are performed in this paper. The mass, momentum conservative equations are standard provided by FLUENT. The only heat equation is modified by integrating a source term SE representing the electric power inside the torch. The conduction and radiation losses are also considered. The FLUENT Code is in its commercial way. No MAXWELL equations and no electromagnetic phenomena in relation with the electric arc (LORENTZ forces, electrode phenomena…) are implemented in it. The code has been only adapted to plasma spraying conditions by the way of user-defined-functions (plasma gas and atmosphere transport and thermodynamic properties, calculation of mixed gas properties, simple JOULE effect model).

3. Basic assumptions. The plasma, considered like a Newtonian mono-fluid, is supposed to be in the local thermodynamic equilibrium, optically thin and chemically inert; the mono-fluid assumption integrates, at high temperature, the interactions between ionic and electronic species through global transport coefficients and thermodynamic properties. The properties of the mixture between plasma gas and surrounding atmosphere at lower temperatures are calculated by the formula of WILKE and MASSON [4], [5] from the data of pure gases or the plasma mono fluid [6]. The enthalpy temperature tabulation is also introduced. No magnetic or electric effects are taken into account.

4. Simple model. The gas heating and acceleration are simulated by introducing an energy source in the torch (Fig. 1). This zone, which spreads from the cathode tip to the anode, is divided in two volumes V1 and V2. The area V_1 near the cathode tip depends on the radius r(x) with a constant length l_1. The volume V_2 inside the anode has a length l_2 depending on the movement of the electric arc root on the anode wall and so

is a function of time t. In these two volumes, the electric power transferred to the fluid is defined respectively by: $P_1 = P_m/L_m * l_1$ (Eq. 1) $P_2 = P_m/L_m * l_2(t)$ (Eq. 2)

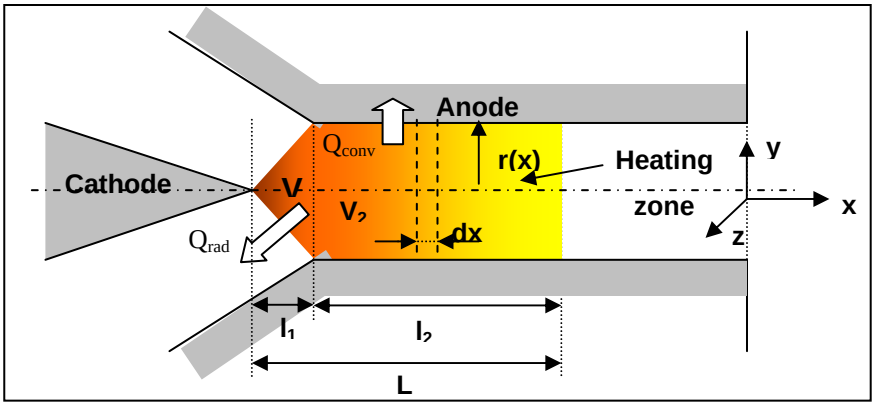

Figure 1: Different heating zones inside the gun.

where P_m is the time-average input power, P_m = U.I. (U and I are the mean arc voltage and intensity) and L_m is the plasma column length corresponding to P_m. l_1 is always constant while l_2 (t) is linked to the fluctuation of the arc voltage due to the arc root movement. The local volume energy density ∅(x) can be defined by:

$$\varnothing(x) = \frac{P_m}{r_{(x)}^2 . \pi . L_m} \qquad \text{(Eq. 3)}$$

with $r(x) = a.x^n + r_0$ (r0 is the cathode radius)

And so the electric power fluctuations depending on time can be written as:

$$P(t) = U(t).I = \int_o^l \varnothing(x)\, dx \qquad \text{(Eq. 4)}$$

With conduction and radiation losses, respectively written Q_{conv} and Q_{rad}, the thermal efficiency η is calculated as:

$$\eta = 1 - \left(\frac{Qconv + Qrad,}{P_m}\right) \quad \text{(Eq. 5)}$$

The first step of the model validation procedure consists in getting the stationary-state thermal efficiency by adjusting the function r(x) and the length l_2.

5. Operating plasma conditions. SULZER-METCO F4VB plasma gun, working with Argon/Hydrogen (75/25 %vol.) mixture flowing in standard air atmosphere, has been simulated with a 6 mm diameter anode. The other parameters are in Table 1. These conditions lead to voltage-vs- time evolution (Fig. 2).

Table 1: Operating parameters

Total gas flow rate	60 slpm
Total input power	32.5 kW
Arc intensity	500 A
Average arc voltage	65 V
Thermal efficiency	50 %

Figure 2 shows the fitted fluctuations of arc voltage from oscilloscope measurements. The arc voltage fluctuates from 55 V to nearly 90 V at the frequency of 4.3 kHz, which is in accordance with [7].

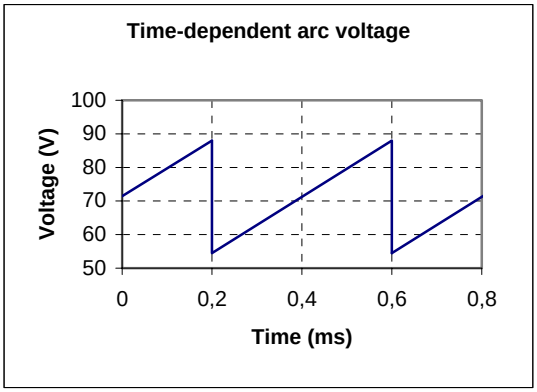

Figure 2: Time-dependent fitted arc voltage fluctuations.

6. Grid and boundary conditions.

A 2-D axis-symmetry grid has been performed. Near the wall and in the first millimeters outside the torch, the grid presents highest mesh number because of the high temperature and velocity gradients. The boundary conditions for turbulence input data are the turbulence intensity, the hydraulic diameter or the length scale. The engaged values are those proposed by FLUENT user guide [8].

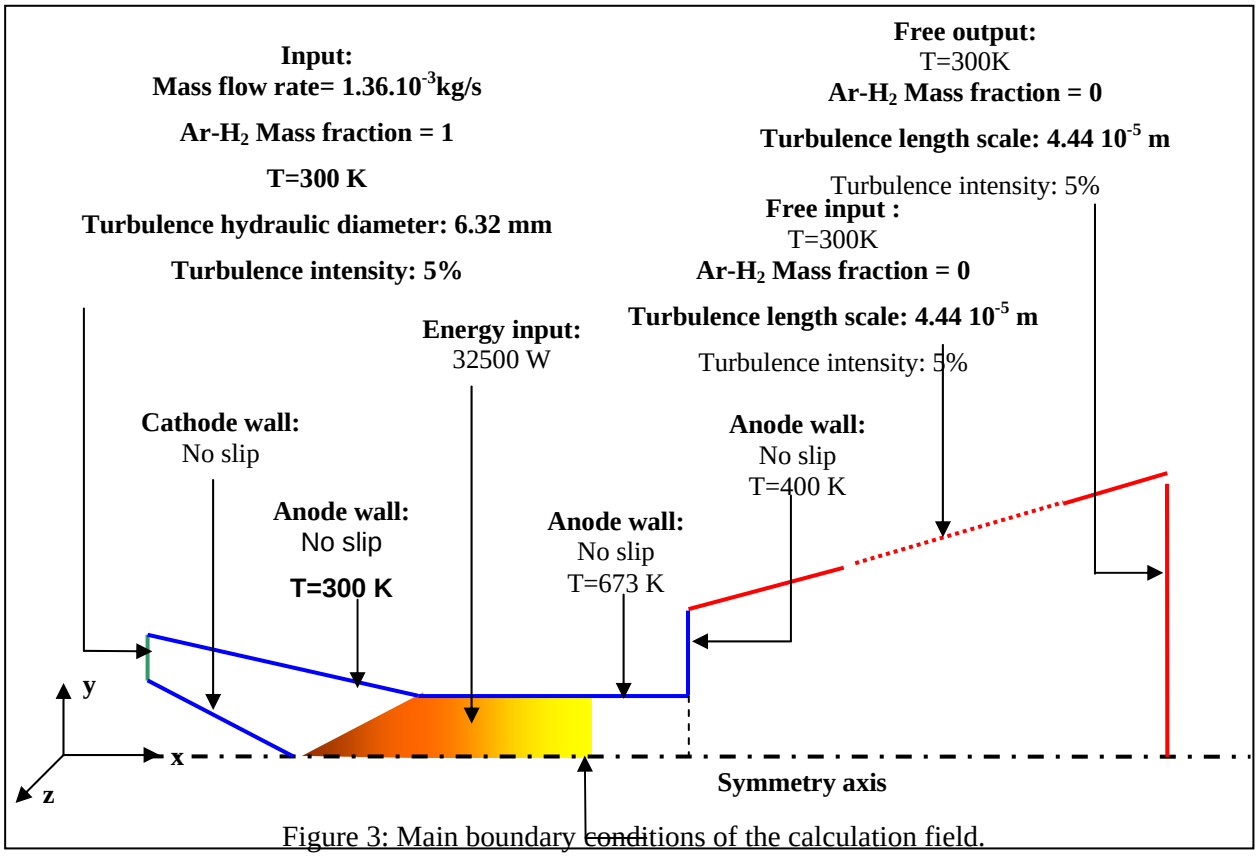

Figure 3: Main boundary conditions of the calculation field.

7. Results.

7.1 Stationary case. First of all, in no-dependent-time state, the two areas V_1 and V_2 have to be defined to get correct thermal efficiency. The V_1-defined-function is assumed such as $r(x) = a.x^n + r_0$ where r_0 is the cathode arc root radius. According to [9], [10], r_0 is fixed at 0.5 mm. x moves from 0 to l_1 = 7 mm. Three values (n=1, n=4, n= 12) have been tested. The V_2 area is defined by l_2 varying from 7 to 21 mm (torch exit position) while r_2 is constant at the anode radius 3 mm. Adjustment of thermal efficiency presents rather good correlation when n=1, l_2=15 mm (global volume= 487 mm^3) as shown in Figure 4.

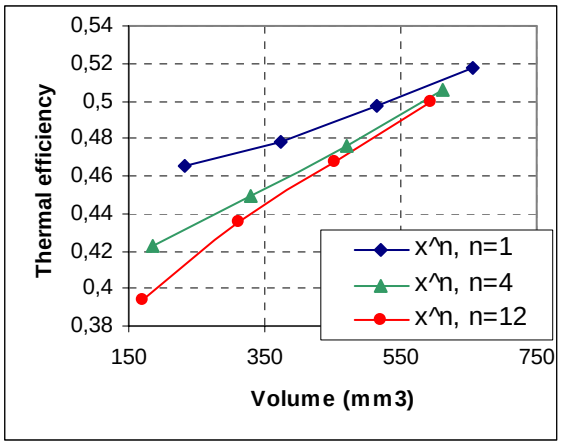

Figure 4: Thermal efficiency versus global heating zone volume.

The thermal efficiency η results from radiation and convection loss contributions. In V_1, convection is null due to no-direct contact between this zone and the walls. Radiation loss contribution ranks 90% in V_1 zone and 10% in V_2 due to different temperatures. On one side, expecting longest V_2 zone will tend to increasing in η (cf. Figure 4): the electrical power is diluted in a largest volume with lowest temperature and so conduction losses are diminished. On the other side, n modification leads to changing the constriction of V1 and so, mainly, the radiation loss level due to higher temperature near the cathode. That is why η decreasing when n increasing. Figure 5 shows the evolutions of velocity, temperature and molar air fraction on x centerline axis. Velocity values have been multiplied by 10 and air molar fraction by 10 000 to visualization in the same scale then that of temperature, point 0 corresponding to the torch exit.

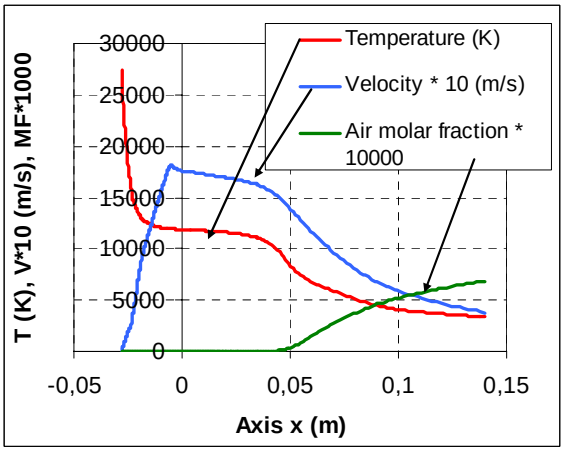

Figure 5: Evolution of temperature, velocity and molar air fraction on the x centreline axis.

First comments can be advanced about the general evolution of the velocity and temperature curves. If they are quite different inside the anode, they follow the same look after the anode exit, decreasing together faster and faster in a similar way when moving away from the torch. In particular, the two curves decrease strongly around 40 mm when turbulence becomes principal. If temperature values are in similar range than measurements near the torch exit [11], velocity gets 200 m/s too high at the torch exit [12]. Assumptions can be done about the theoretical arc root position which could be too near the torch exit. Previous works [3] have shown that the velocity increases when the electrical arc root comes near the front torch. As no cathode cooling has been taken into account, this could be the reason of this discrepancy. The same reason could be assumed for the delay of the air introduction which implies a too low molar air fraction at 80 mm (40% in place of 70% [13]). The cold atmosphere dilution absence leads to a too high temperature far from the front gun. Turbulence model can be charged: first tests with k ε model have shown similar behavior.

7.2 Time-dependent case. In figures 6 to 11, the mixing of the two fluids (air and plasma) is represented by their density at different times. In spite of the axis symmetry, air engulfment is well visualized with high constrictions and swirl developments of the plasma plume. Because of starting with stationary initial

conditions, the surface instability generation presents a delay as seen in figure 6. At time=0.84 ms (figure 6), the interactions between the two fluids become visualizing from the plasma surface which deteriorates to form arrows (figure 7). Then, acceleration of plasma gas, due to longer electrical arc in the anode, tends to develop again the plasma plume (figures 8 and 9): the arrows are smaller and smaller and a big puff of gas flows into the atmosphere. Then the cycle starts again (figure 10) with a lower constriction of the plasma and again generation of the arrows (figure 11). The surface instabilities are typically KELVIN HELMOLTZ. Unfortunately, their generation is not strong enough: as seen before, the air molar fraction is lower than the experiment measured one. Several reasons could be proposed to explain that phenomenon.

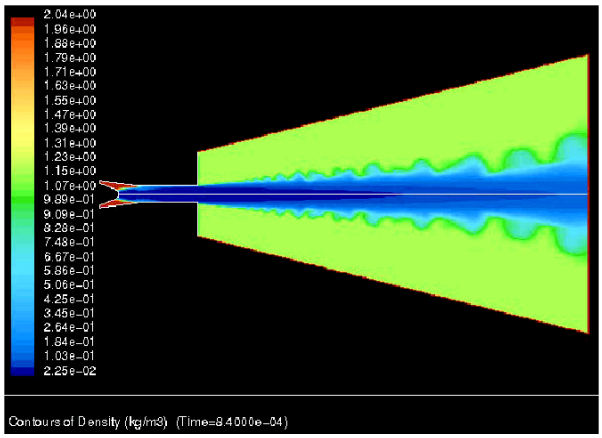

Figure 6: density of the two fluids at t=0.84 ms.

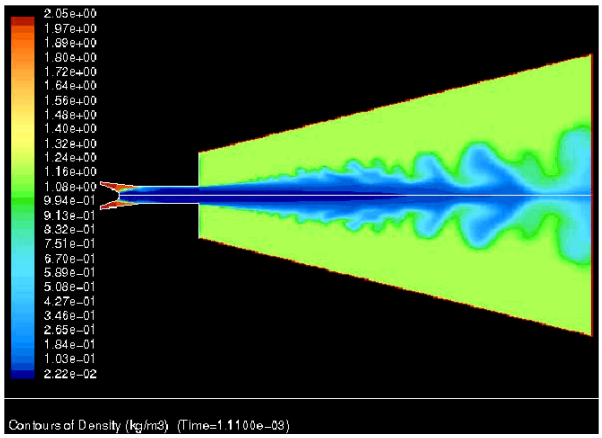

Figure 7: density of the two fluids at t=1.11 ms.

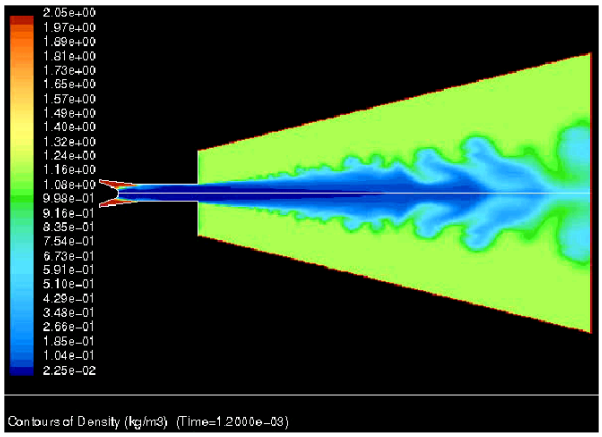

Figure 8: density of the two fluids at t=1.20 ms.

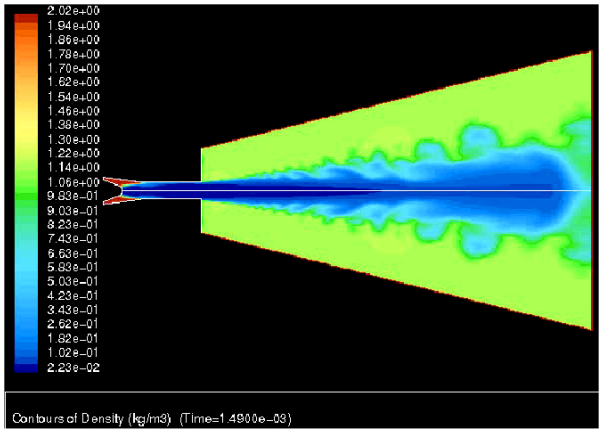

Figure 9: density of the two fluids at t=1.49 ms.

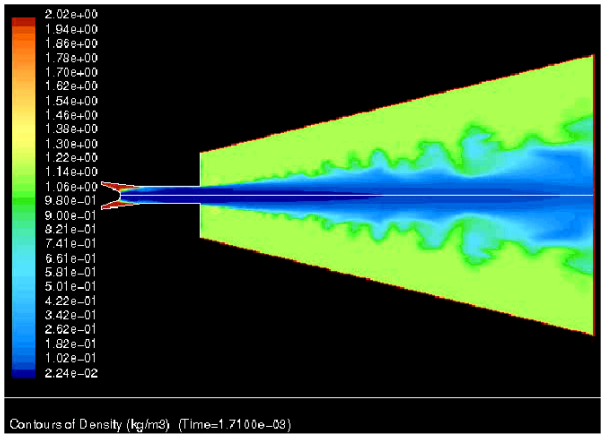

Figure 10: density pf the two fluids at t=1.71 ms.

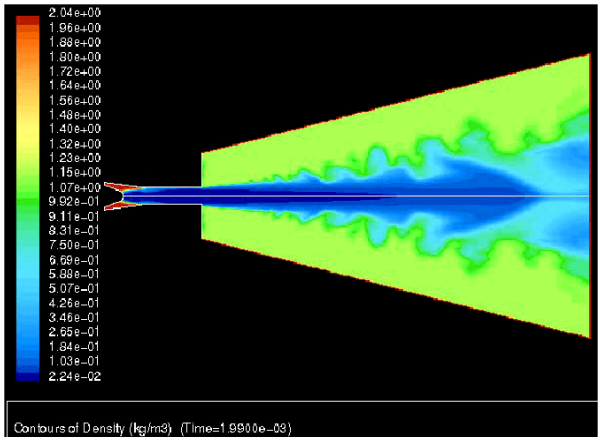

Figure 11: density of the two fluids at t=1.99 ms.

Due to convergence problem, mainly at the initial state, calculations have not been performed in 3-D but in 2-D axis-symmetry design: yet, electrical arc movement fluctuations are typically 3-D phenomena. Moreover, the preliminary initial conditions of the time-dependent case are from the average stationary solution. So, the complete development of air engulfment needs perhaps more time than 2.7 ms to forget the initial conditions and to penetrate completely the plume (stand-off position is on the centerline).

8. Conclusion. From a simple model based mainly upon JOULE effect, the operating parameters and the torch design, the plasma flow behavior outside the plasma spraying torch has been reproduced in time dependent simulations. The average results, temperature velocity and air fraction engulfment, in steady state, are a lit bit too high in comparison with experiments. Nevertheless, in dynamic simulation, plasma constrictions and puffs are well observed. Several correcting assumptions will be integrated in further works: the first one will improve the heating model by adding cathode cooling and modifying the heating zone with a casual and fast movement of the arc root all along the anode wall perimeter, the second one concerns the turbulence model to advance the laminar-turbulence transition. This movement will simulate the taking-into-account of the anode wall surface state but will imply 3-D simulations. The third proposes to start the calculation without stationary solution but, for the moment, this was unsuccessful due to convergence problem.

Three-Dimensional Modeling of Non-Equilibrium Effects in a Transferred DC Arc Plasma with Lateral Gas Blowing

He-Ping Li[1, 2], J. Heberlein[1], and E. Pfender[1]

[1] *Department of Mechanical Engineering, University of Minnesota, Minneapolis, MN 55455, USA*

[2] *Present address: Department of Engineering Physics, Tsinghua University, Beijing 100084, P. R. China*

Abstract

In this paper, three-dimensional, non-equilibrium physical/mathematical models of transferred DC arc plasmas with lateral cold gas blowing are described, and the modeling results under typical operation conditions are presented. The predicted deflections of the anode arc-root attachments in the direction of the lateral cold gas flow for different lateral gas flow rates are in reasonable agreement with measurements.

Keywords Three-dimensional modeling, Non-equilibrium effects, Arc plasmas

1. Introduction

Thermal plasmas have been widely used in industrial applications, such as plasma spraying, welding, cutting, etc., because they can provide high fluxes of charged species and other useful radicals, usually coupled with high heat fluxes. However, the high heat fluxes also lead to erosion of electrodes, and such plasmas are not suitable for processing of low melting point and/or thin film materials. In many applications, large plasma volumes, with high electron densities and higher electron temperatures compared to heavy-particle temperatures, and operation at relatively high pressures ($p \geq 0.1$ atm) are desirable as an ideal plasma processing environment.

Previous numerical [1-3] and experimental [4, 5] investigations on plasma arcs showed that the non-equilibrium effects were pronounced near the electrodes, near cold walls or in the fringes of arc plasmas, even though deviations from local thermodynamic equilibrium (LTE) in the arc core were insignificant for high-intensity arcs. However, these non-equilibrium regions are very small, and in general, not suitable for plasma processing applications. Recently, experimental studies on arc-anode attachment instabilities in this laboratory have shown that a stable form of an arc attachment with a relatively large non-equilibrium region in front of the anode can exist when a cold gas is injected laterally along the anode surface [6, 7]. A schematic diagram of the experimental setup of a transferred DC arc plasma with lateral cold gas flow, used in the experimental studies [6, 7], is shown in Figure 1.

Associated with the combinations of different arc currents, working gas flow rates and lateral gas flow rates, different anode attachment modes, including a steady deflected anode root, a randomly fluctuating attachment, and a periodically fluctuating attachment, have been observed in experiments [7]. But up to now, the understanding to this non-equilibrium effect is still very limited. Few papers [8, 9] were published describing this three-dimensional (3D), non-equilibrium effect numerically and comparing it with measurements. In this paper, a 3D, non-equilibrium model of transferred DC arc plasmas with lateral cold gas flow, as shown in Figure 1, is described. The 3D modeling results with constant plasma working gas flow rate, arc current and variable lateral cold gas flow rates are presented and compared with experimental measurements. The predicted arc

deflections in the direction of the lateral gas flow for different cold gas flow rates are in reasonable agreement with experimental data.

2. Descriptions of the 3D, non-equilibrium model

A schematic diagram of the calculation domain (indicated by the dashed lines in Figure 1), as a simplification of the real apparatus, is shown in Figure 2 with geometrical dimensions. Because the actual flow patterns and heat transfer in the region outside the constrictor tube are symmetrical about the plane passing through the constrictor tube axis and perpendicular to the injection frontal plane (plane ABCD as shown in Figure 2, which is called injection plane hereafter), only half of the 3D space is adopted as the calculation domain (formed by the points ABCDEFGH) in this modeling work. The inner diameter of the constrictor tube is 10 mm. In this paper, a part of the constrictor tube (10 mm in length) is included in the calculation domain, because the flow patterns at the exit of the nozzle are not completely axi-symmetrical due to the 3D behavior of the deflected arc with larger lateral cold gas blowing. And this non-axi-symmetrical behavior will, to some extent, influence the local characteristics of the deflected arc near the exit of the nozzle. In addition, the solid anode region with the thickness of 5 mm is also considered in this study, which is convenient for specifying the boundary conditions for heavy-particle temperatures [10, 11].

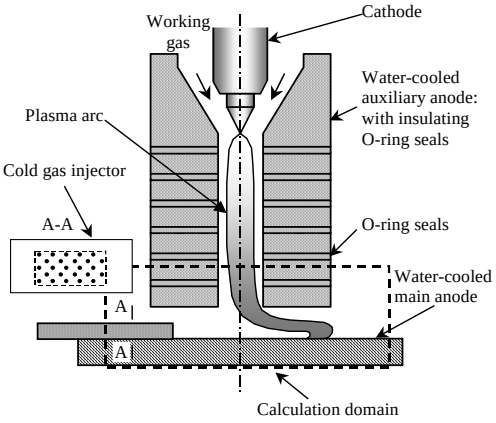

Figure 1. Schematic diagram of a transferred arc

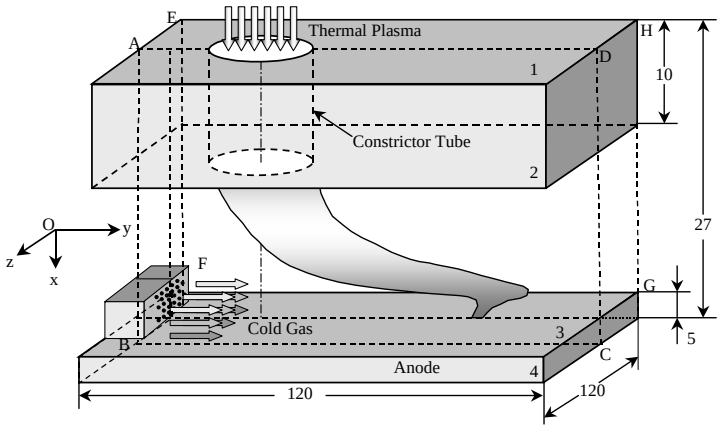

Figure 2. The schematic diagram of the computational domain

In this paper, we assume that: (1) the plasma flow is 3D, quasi-steady and laminar; (2) the plasma is in kinetic and chemical non-equilibrium state, i.e., the electron temperature is very different from the heavy-particle temperature, indicated with T_e and T_h, respectively, and separate Maxwellian distributions of electrons and heavy particles are postulated; (3) the plasma is optically thin; (4) argon is used as the plasma working gas and the transversely injected cold gas; (5) the plasma system is composed of three components, i.e., atoms (Ar), singly-ionized ions (Ar^+) and electrons (e), with only one ionization-recombination reaction as $Ar + e \Leftrightarrow Ar^+ + e + e$, with charge neutrality sustained in this system; (6) the thermodynamic and transport properties of the argon plasmas are a function of the species number densities (n_e) and the temperatures (T_e and T_h); (7) the gravity, viscous dissipation and the pressure work terms are neglected in the momentum equation and energy equations, respectively.

Based on the foregoing assumptions, the governing equations for the 3D, quasi-steady numerical simulations can be written in Cartesian coordinates as follows:

Species Continuity Equation:

$$\nabla \cdot \left(n_e \vec{v} \right) = -\nabla \cdot \vec{\psi}_e + \dot{S}_e^c \tag{1}$$

where n_e and $\vec{\psi}_e$ are the number density and number flux of electrons, respectively. $\vec{v}$ is the mass-averaged velocity of plasmas. $\dot{S}_e^c$ is the source term of chemical reactions for electrons, and can be calculated as [12a]

$$\dot{S}_e^c = \alpha n_a \left[S(T_e) - \frac{{n_e}^2}{n_a} \right] \tag{2}$$

where α is recombination coefficient ($\alpha = 8.72 \times 10^{-22} n_e T_e^{-9/2}$ is used in this study [13]). In Equation (2), $S(T_e) = \left({n_e}^2 / n_a \right)^*$ is the ratio of number densities for chemical equilibrium [14].

Mass-Averaged Momentum Conservation Equation:

$$\nabla \cdot \left(\rho \vec{v} \vec{v} \right) = -\nabla p - \nabla \cdot \vec{\vec{\tau}} + \vec{j} \times \vec{B} \tag{3}$$

where $\vec{\vec{\tau}}$ is the shear stress tensor, $\vec{j}$ and $\vec{B}$ are the total current density vector and the self-induced magnetic induction.

Electron Energy Conservation Equation:

$$\nabla \cdot \left(\frac{5}{2} n_e k_B \vec{v} T_e \right) = \nabla \cdot \left(k_e \nabla T_e \right) - \nabla \cdot \left(\rho_e h_e \vec{V}_e \right) + \vec{j} \cdot \vec{E} + \dot{Q}_{eh}^{el} + \dot{Q}_{e,ch} - \dot{Q}_r \tag{4}$$

Total Heavy-Particle Energy Conservation Equation:

$$\nabla \cdot \left[\left(\frac{5}{2} n_h k_B + \frac{n_i E_i}{T_h} \right) \cdot \vec{v} T_h \right] = \nabla \cdot \left(k_h \nabla T_h \right) - \nabla \cdot \left(\rho_a h_a \vec{V}_a \right) - \nabla \cdot \left(\rho_i h_i \vec{V}_i \right) - \dot{Q}_{eh}^{el} - \dot{Q}_{e,ch} \tag{5}$$

In Equations (4) and (5), n_j, ρ_j, h_j and k_j are the number density, mass density, specific enthalpy and thermal conductivity of species j, while $\vec{V}_j$ is the diffusion velocity of species j, which can be calculated using the formulas presented in Ref. [15]. The subscripts a, i, e and h represent atoms, ions, electrons and heavy particles, respectively. k_B and E_i are the Boltzmann constant and the ionization energy of argon atoms. $\vec{E}$ is the total electric field. $\dot{Q}_r$ is radiation power per unit volume. The rate of energy exchange per unit volume during elastic collisions between electrons and heavy particles can be calculated as

$$\dot{Q}_{eh}^{el} = -\frac{3 m_e}{m_i} n_e \left(\bar{\nu}_{ei} + \bar{\nu}_{ea} \right) k_B \left(T_e - T_h \right) \tag{6}$$

where $\bar{\nu}_{ei}$ and $\bar{\nu}_{ea}$ are the average collision frequency between electrons and ions [12b], and between electrons and atoms [16], respectively. The chemical energy source term $\dot{Q}_{e,ch}$ is calculated by

$$\dot{Q}_{e,ch} = -\dot{S}_e^c E_i \tag{7}$$

Electric Potential Equation:

$$\nabla \cdot \left(\sigma \nabla \phi_{eff} \right) = 0 \tag{8}$$

where σ is the electric conductivity of argon plasmas, ϕ_{eff} is the effective electric potential written as

$$\vec{E}_{eff} = -\nabla \phi_{eff} \tag{9}$$

where $\vec{E}_{eff}$ is the effective electric field, which relates to the total electric field $\vec{E}$ as $\vec{E}_{eff} \cong \left(\vec{E} + \nabla p_e / e n_e \right)$.

And thus, the current density $\vec{j}$ can be calculated by $\vec{j} = \sigma \vec{E}^e$.

Magnetic Vector Potential Equation:

$$\nabla^2 \vec{A} = -\mu_0 \vec{j} \tag{10}$$

where μ_0 is the permeability in vacuum. The three-dimensional, self-induced magnetic induction $\vec{B}$ is defined as $\vec{B} = \nabla \times \vec{A}$.

For obtaining converged solutions, appropriate boundary conditions for the foregoing dependent variables are necessary. On the injection plane (ABCD), symmetry conditions are employed. At the outer edges of the calculation domain (Plane ABFE, DCGH, EFGH), free boundary conditions are used. Two-dimensional modeling results are employed as the boundary conditions of the variables to be solved in the 3D case at the inlet of the calculation domain. At the rear surface of the anode, a uniform temperature (T=300 K) and electric potential (ϕ=0) are specified. The modeling results are very sensitive to the boundary conditions of electron temperature and electron number density along the inner surface of the anode. In this study, the (2^3-1) extrapolation rule [17] is employed to specify the values of the electron number density and electron temperature along the anode inner surface. In the actual experimental setup, the injector is composed of 25 1 mm-in-diameter circular holes as shown in Figure 1. For simplicity in this study, these circular holes are replaced by the 1×1 mm^2 rectangular holes because the rectangular mesh is employed in this modeling work. The velocity of the injected cold gas issued from each injection port is calculated based on the actual lateral gas flow rate and injection port cross-sectional area. The boundary conditions for the magnetic vector potential are specified using the analytical solutions of Equation (10) [11].

3. Modeling results and discussion

3.1. Discussion on the typical modeling results

In this study, the foregoing 3D governing equations are solved simultaneously with appropriate boundary conditions. For a typical experimental operation condition (arc current I=100 A, working gas flow rate Q_1=5 slpm, lateral gas flow rate Q_2=18 slpm, and the distance between the frontal surface of the constrictor tube and the anode inner surface L=12 mm), the calculated distributions of heavy-particle temperature, electron temperature and number density, and velocity vectors in the injection plane are shown in Figures 3(a)~(d), respectively. It can be seen that the anode arc-root attachment moves downstream in the direction of the cold gas flow due to the blowing of the lateral cold gas along the anode inner surface. The calculated heavy-particle temperature and velocity distributions in the plane parallel to the anode surface and located 0.05 mm away from the anode inner surface are shown in Figure 4. It can be seen that a large part of the injected cold gas flows around the core region of the arc instead of passing through it, and the center of the anode arc root also deviates from the constrictor tube geometrical axis.

3.2. Comparisons with measurements

Under the same operation condition as those discussed in Section 3.1, the experimental charged-coupled device (CCD) image of the deflected arc is shown in Figure 5 [7]. By comparing Figures 3 and 5, the predicted deflection of the anode arc attachment in the direction of the lateral gas flow is ~6.7 mm, which is almost the same as the value derived from the experimentally obtained image (Figure 5) [7]. By varying the flow rate of the lateral gas from 0.0~20.0 slpm, the predicted deflections of the anode arc root attachments in the direction of the lateral cold gas flow are shown in Figure 6, compared with the corresponding derived values from the experimental images [7]. It can be seen that the calculated locations of the anode arc root attachments are in reasonable agreement with the experimental observations for different lateral cold gas flow rates. The maximum

relative discrepancy between the calculated and measured arc deflection length is ~25% at Q_2=17 slpm.

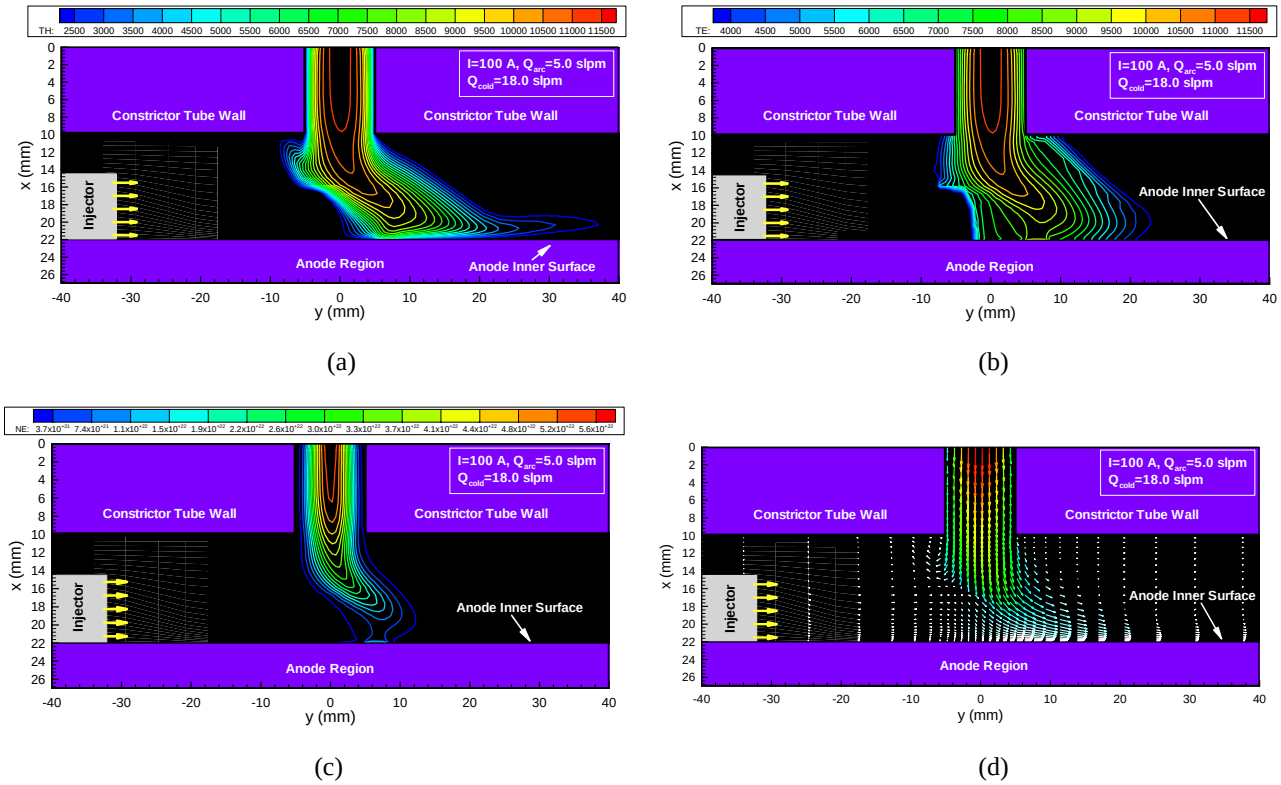

Figure 3. Distributions of heavy-particle temperature (a), electron temperature (b) and number density (c), and velocity vectors (d) in the injection plane

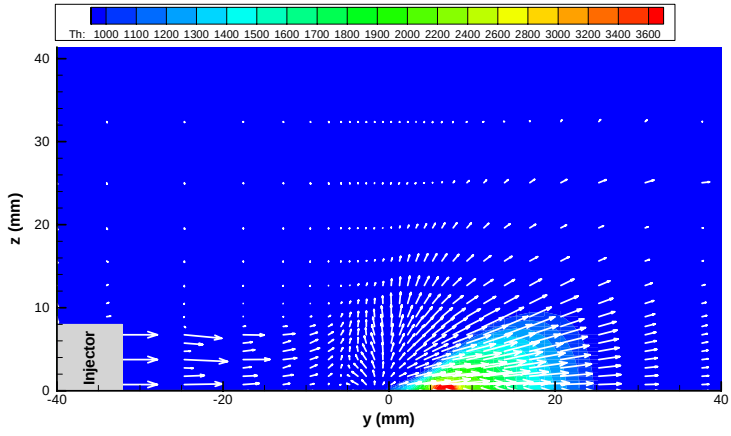

Figure 4. Distributions of the heavy-particle temperature and velocity in a plane 0.05 mm away from the anode inner surface

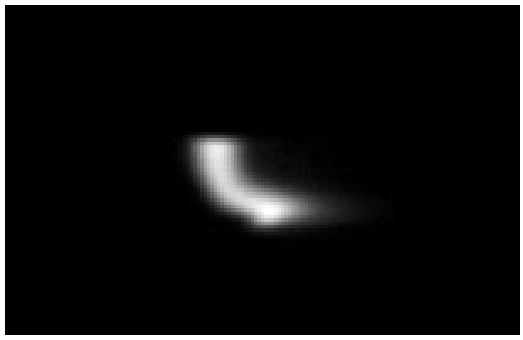

Figure 5. Picture of a deflected argon arc [7]

4. Conclusions

In this paper, the 3D, non-equilibrium effects of transferred DC arc plasmas with lateral cold gas blowing along the

anode inner surface are simulated. The physical/mathematical models are described and the modeling results are presented for typical operation conditions. The predicted arc deflection lengths are in reasonable agreement with experimental observations for different lateral cold gas flow rates.

Continuous Optical Discharge in Gas Flow

E.B. Kulumbaev[1], V.M. Lelevkin[1]

[1]*Kyrgyz-Russian Slavic University, Bishkek, Kyrgyz Republic*

Abstract

Theoretical model of continuous optical discharge burning in air at atmospheric pressure is used to carry out numerical analysis of optical radiation power input, wind speed at optical discharge localization in Earth's gravitation field, influencing the characteristics of optical discharge.

Introduction

The continuous optical discharge (COP) obtained a series of unique features in comparison with other electric discharge sources [1]: high temperature (~18000 K in atmospheric air), spectral purity of plasma (maintenance in free space), small spatial sizes (sizes of the discharge in a cross direction toward a laser beam ~ 1 mm), a possibility of re-localization in space et al. The COP, realized in practice, differs by length of the wave and focus of the laser radiation, by structure and exterior gas flows direction.

In experimental COP researches the discharge burning special temperature distributions in the atmospheric air free space, in a channel with forced gas pumping (in laser plasmatron regime) depending on gas flow were measured; the area of steady burning depending on a type and pressure of plasma-generating gas, wave length and a laser beam intensity, velocity and direction of blowing flow, focal distance and available target was established [2-4].

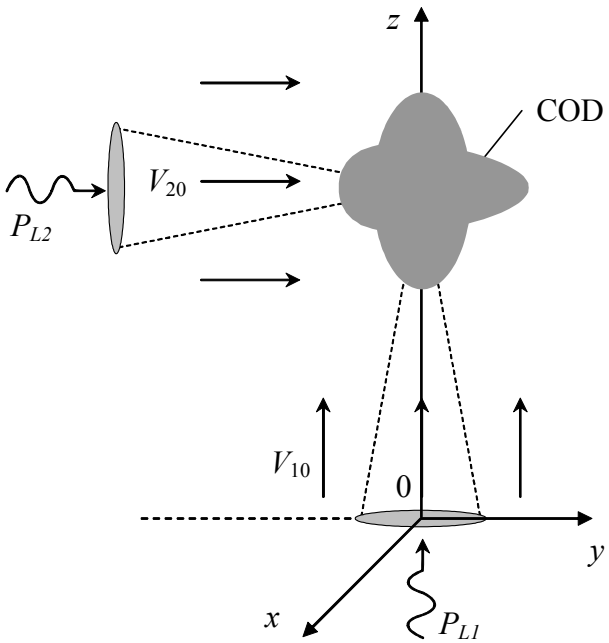

Figure 1. Schematic of a COD: P_{L1}, P_{L2} – intensities of vertical and respective horizontal laser beams; V_{10}, V_{20} – velocities of external gas flows.

Model

We consider a continuous optical discharge burning maintained by adsorption of power, supplied by CO_2-laser beams in airflow at atmospheric pressure. (fig.1). We guess that the flow is laminar, subsonic; plasma is balanced; the refraction of laser light is negligible; laser beams are Gaussian in shape.

Characteristics of the COD are found by solving a set of continuity equations, Navies-Stokes equation, energy balance equation, equation for selective radiation transport in multi-group diffusion approximation, and transport equation for laser radiation along optical beams axes:

$$\frac{\partial\rho}{\partial t}+\nabla\cdot\left(\rho\vec{V}\right)=0;\qquad \rho\left[\frac{\partial\vec{V}}{\partial t}+\left(\vec{V}\cdot\nabla\right)\vec{V}\right]=-\nabla\left(p+\frac{2}{3}\eta\nabla\cdot\vec{V}\right)+2\nabla\cdot\left(\eta\dot{S}\right)-\left(\rho_0-\rho\right)\vec{g};$$

$$\rho C_p\left[\frac{\partial T}{\partial t}+\left(\vec{V}\cdot\nabla\right)T\right]=\nabla\cdot\left(\lambda\nabla T\right)+Q_L-Q_R+\vec{V}\cdot\nabla p+2\eta\dot{S}^2-\frac{2}{3}\eta\left(\nabla\cdot\vec{V}\right)^2;$$

$$\nabla\cdot\left(\frac{1}{3\chi_k}\nabla U_k\right)=\chi_k\left(U_k-U_{kp}\right),\quad k=1,2,...,N_k;\qquad Q_R\approx\sum_{k=1}^{N_k}c\chi_k\left(U_{kp}-U_k\right);$$

$$Q_L=\frac{\mu P_{L1}}{\pi R_{L1}^2}\exp\left(-\frac{x^2+y^2}{R_{L1}^2}\right)\exp\left(-\int_{z_0}^{z}\mu dz\right)+\frac{\mu P_{L2}}{\pi R_{L2}^2}\exp\left(-\frac{x^2+\left(z-z_1\right)^2}{R_{L2}^2}\right)\exp\left(-\int_{y_0}^{y}\mu dy\right).$$

Notation: $\vec{V}$ - average-mass velocity; p - the pressure difference relative to the atmospheric pressure $p_0 = 10^5$ Pa; T - temperature; $\dot{S}$ - the tensor of velocities deformations; $\rho, C_p, \eta, \lambda, \mu$ - density, thermal capacity, viscosity, heat conductivity, the laser radiation absorption factor; χ_k, U_k, U_{kp} - group values of the absorption factor, density of the radiation of ambience and black body, averaged in each N_k spectral intervals; c -velocity of light; ρ_0 - density of a cold gas; $\vec{g}(0, 0, g_z = -g)$ - gravity acceleration; P_{L1}, P_{L2} - laser beams power with the radius $R_{L1}(z)$ and $R_{L2}(y)$; x, y, z - Cartesian coordinates; the optical laser beams axes are in parallel with the axes z and y (fig.1).

A numerical solution of a set of equations in physical variables is carried out by the method SIMPLE [5] in air at atmospheric pressure with thermal-physic, transport and optical (N_k =10) properties on data [6].

Results

It was found (fig. 2) that the COD high temperature core is located near the focus of a single laser beam or in area of crossed laser beams [7].

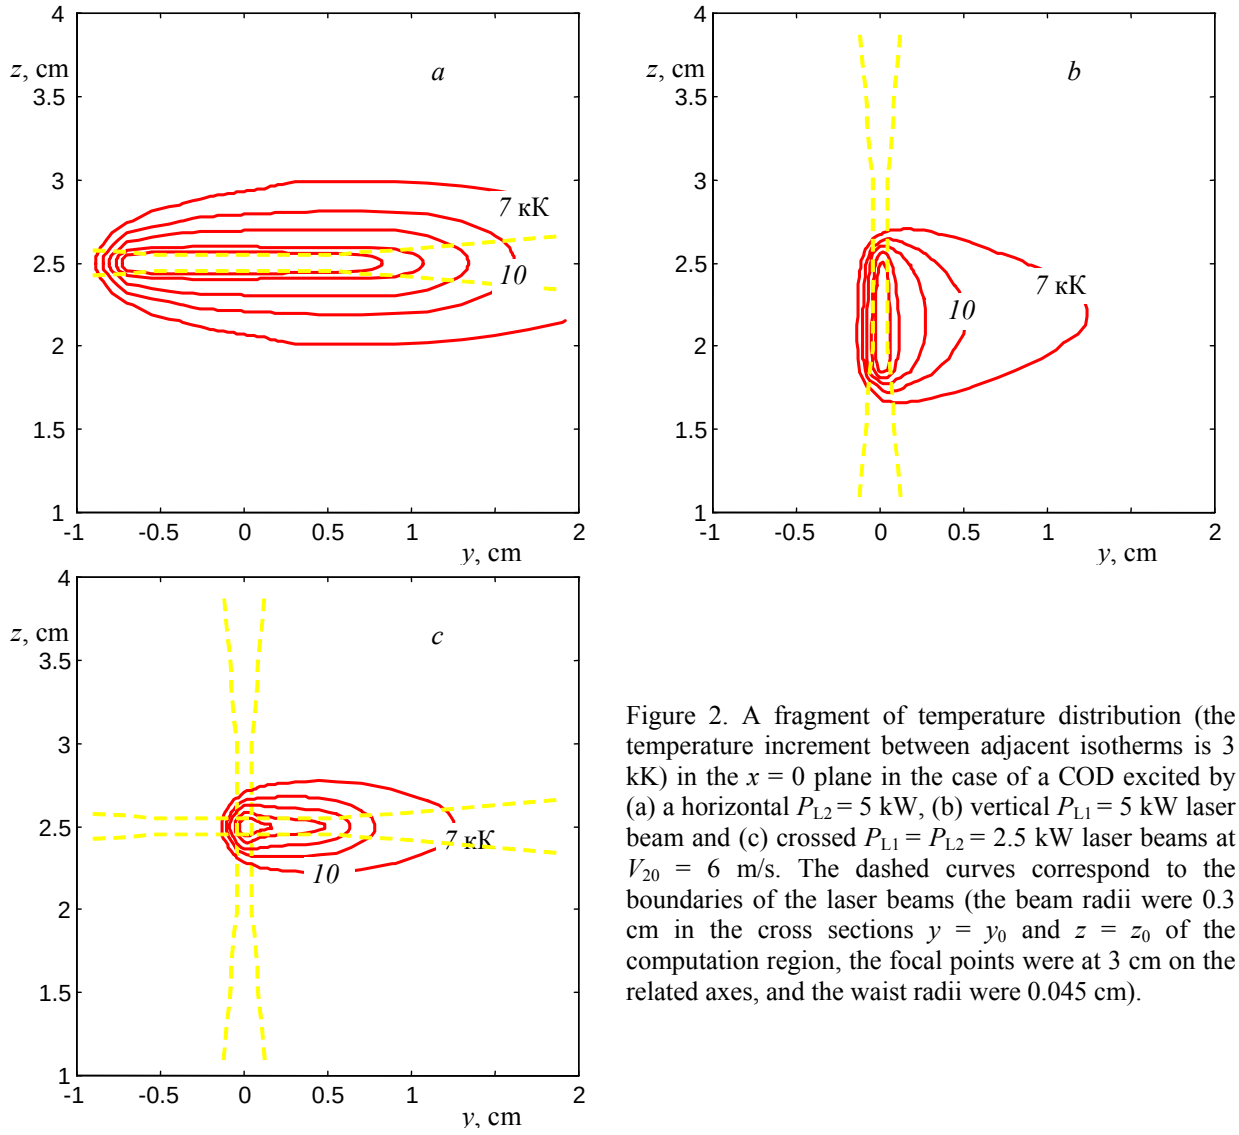

Figure 2. A fragment of temperature distribution (the temperature increment between adjacent isotherms is 3 kK) in the x = 0 plane in the case of a COD excited by (a) a horizontal P_{L2} = 5 kW, (b) vertical P_{L1} = 5 kW laser beam and (c) crossed $P_{L1} = P_{L2}$ = 2.5 kW laser beams at V_{20} = 6 m/s. The dashed curves correspond to the boundaries of the laser beams (the beam radii were 0.3 cm in the cross sections $y = y_0$ and $z = z_0$ of the computation region, the focal points were at 3 cm on the related axes, and the waist radii were 0.045 cm).

Independently of the direction of exterior gas flow, the gas deceleration is observed on the directed to it front of discharge, where a zone of increased pressure is formed and preferential gas flow around the high-temperature area of COD without vortex structures formation is realized (fig.3).

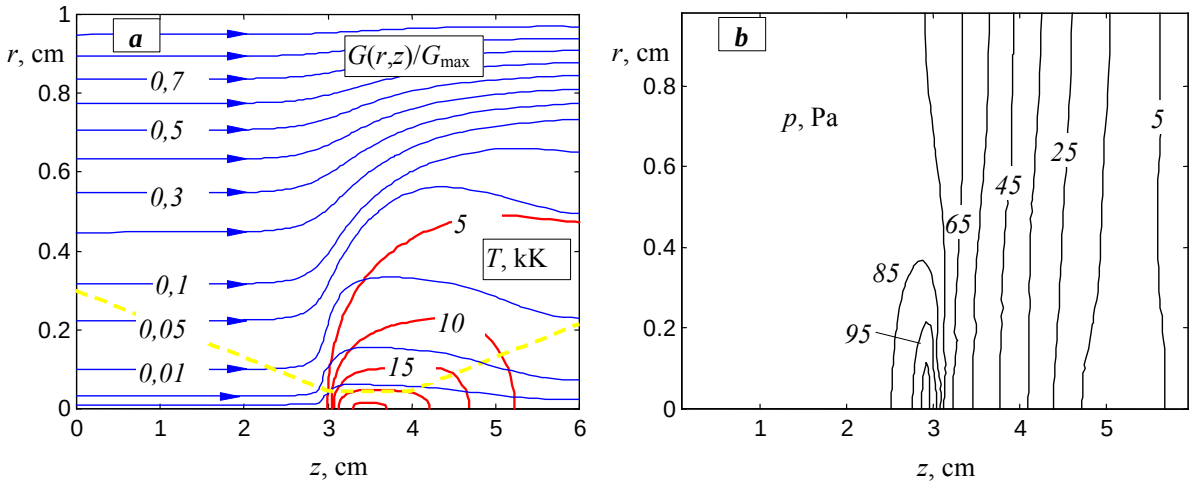

Figure 3. (a) Temperature distribution and the lines of the gas flow and (b) the distribution of the excessive gas pressure for P_L =5 кW, V_{20}=8 m/s, G_{max}=2.9 g/s (the dashed curve corresponds to the conditional boundary of the laser beam).

In variables "laser power – flow rate" the area of existed continuous optical discharge in the cross gas flow (relative to direction of the laser radiation propagation) an amount of gas is less than in the longitudinal flow.

As a result of calculation the optical discharge steady burning in area of the laser beams crossing, where power of each beam is insufficient to maintain the discharge, was established.

A possibility to run a shape and sizes of the discharge depending on flow rate, power and direction of laser beams is shown.

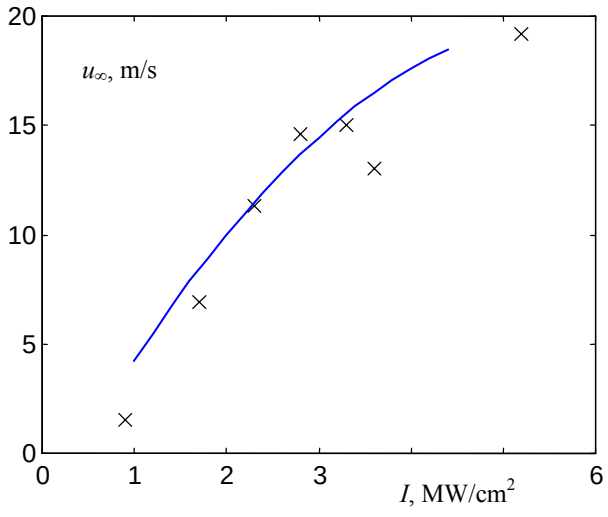

Figure 4. Front velocity of the discharge versus the laser intensity (crosses correspond to the experimental values).

The outcomes are in accord with experimental data (fig.4). The optical gas-dynamic structure of the discharge is interpreted in frames of a model problem of motion of a slow burning front. [8] We write down the Bernoulli equation in accordance with computation results along a normal to the front (zero) line of the gas flow: $u_1^2 + 2\delta p_1 / \rho_\infty = u_\infty^2$. The index "1" marks parameters before the discharge front; δp_1 - pressure excess, arising as a result of the velocity drop at a motion toward the front. After the flow passes through the discharge front, the gas is heated, and the gas flow becomes quasi-uniform and is characterized by a temperature close to maximum value T_0 and a density ρ_0, the viscosity forces and pressure gradients being insignificant. The thickness of hot and gas dynamic layers are small compared to the cross dimensions of the region in which the gas flow is quasi-uniform and the layers themselves are similar to gas-dynamic discontinuity surfaces on which the flow structure changes. At the front of the discharge the conditions of the mass fluxes density and impulse are conserved: $\rho_\infty u_1 = \rho_0 u_0$; $\rho_\infty u_1^2 + \delta p_1 = \rho_0 u_0^2$. The above equations allow us to determine the gas–dynamic characteristics of the discharge plasma from prescribed parameters of the incident flow of a cold gas:

$$u_0 = \frac{\rho_\infty / \rho_0}{\sqrt{2\rho_\infty / \rho_0 - 1}} u_\infty, \quad u_1 = \frac{1}{\sqrt{2\rho_\infty / \rho_0 - 1}} u_\infty, \quad \delta p_1 = \frac{2(\rho_\infty / \rho_0 - 1)}{2\rho_\infty / \rho_0 - 1} \frac{\rho_\infty u_\infty^2}{2}.$$

If the parameters of the gas state on both side of the front and the velocity u_1 with which a cold gas enters the front (this velocity has the meaning of the normal velocity of burning) are known, then we arrive to classical statement of a gas-dynamic problem of slow burning. In this case at $\rho_0 << \rho_\infty$, yields the following expression for the propagation velocity of the discharge: $u_\infty \approx u_1\sqrt{2\rho_\infty / \rho_0}$. The parameters of the problem are weakly sensitive to the properties of the cold gas flow around the discharge because a hot discharge region is filled by gas from a narrow paraxial tube of current. The gas parameters in the tube and both sides of the front determine main discharge characteristics.

The rotary gas flow results in pressure reduction around the axis, the COD as though rises along the lines of symmetry axis, influencing qualitative change of the pressure propagation versus the non-swirling flow and reducing of a value around the axis near the discharge front (fig.5). The area of increased pressure shifts toward the laser beam. A cold flow deceleration begins long before its flowing on COD. A dynamic gas pressure impacting the discharge front reduces, and an amount of gas in the discharge high-temperature region (isotherm ~10 kK) remains practically constant. The COD shifts noticeably toward the gas flow. Maximum temperature is realized near the laser beam focusing as in a case without gas swirling. Near the discharge front a region of vortex toroid gas flow appears, promoting heat transference on axes from the discharge region toward incident flow. With increase of the gas swirling we observe pulsations or crushing of a vortex cell, gas current lines and absence of stationary COD burning regimes.

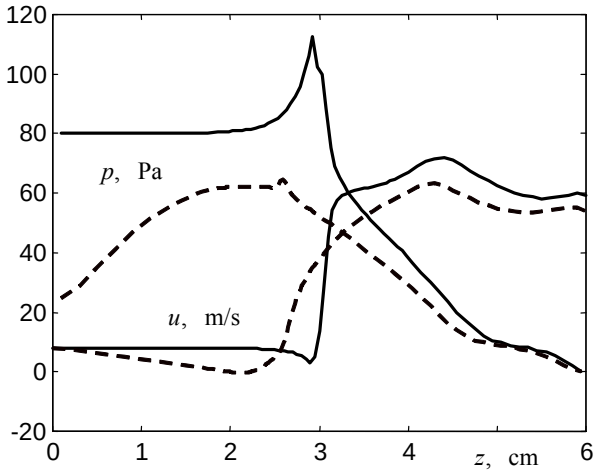

Figure 5. Longitudinal profiles of the velocity and pressure at the discharge axis for P_{L1} = 5 kW, V_{10} = 8 m/s, ω = 0 (solid curves), and ω = 1800 s^{-1} (dashed curves).

By decreasing the laser power the axis parameters, core temperature, and dissipated in COD power of the laser radiation (P_d = 4; 1.6; 0.9 kWt for P_{L1}=5; 3; 2.4 kWt accordingly) decrease, the pressure variation (surplus) on the front and gas, flowing through the front, increase (fig.6). The pressure and mass velocity in the core practically do not change. The constant is a negative depressed pressure behind the front, which ″ensures″ a reverse gas motion of the same gas quantity from a zone of the laser radiation dissipation toward trailing edge of the discharge. Both fronts shift toward each another. The fronts as though come together in beam-convergence cross section (z = 4 cm) at the supplied power 2.4 kWt. It is minimum (threshold) value of the laser radiation power, when the iteration came to a non-trivial solution. At power of 2.3 kWt and less the discharge in iterations “went out”.

The available power threshold and two stationary regimes of burning are observed in accounts (fig.5b) in a shape of two branches (with a “low” and a “high” temperatures) of maximum temperature $T_m(P_L)$ depending on the supplied laser radiation power. When the supplied power is higher than the threshold power, two stationary burning regimes are realized: with a low and a high temperature (fig.6). The low-temperature state is unsteady regard to temperature fluctuations, and any small temperature growth results in increase of the actual power value, necessary for maintaining a regime with a new temperature. As a consequence, the plasma heats up to reaching a steady high temperature state.

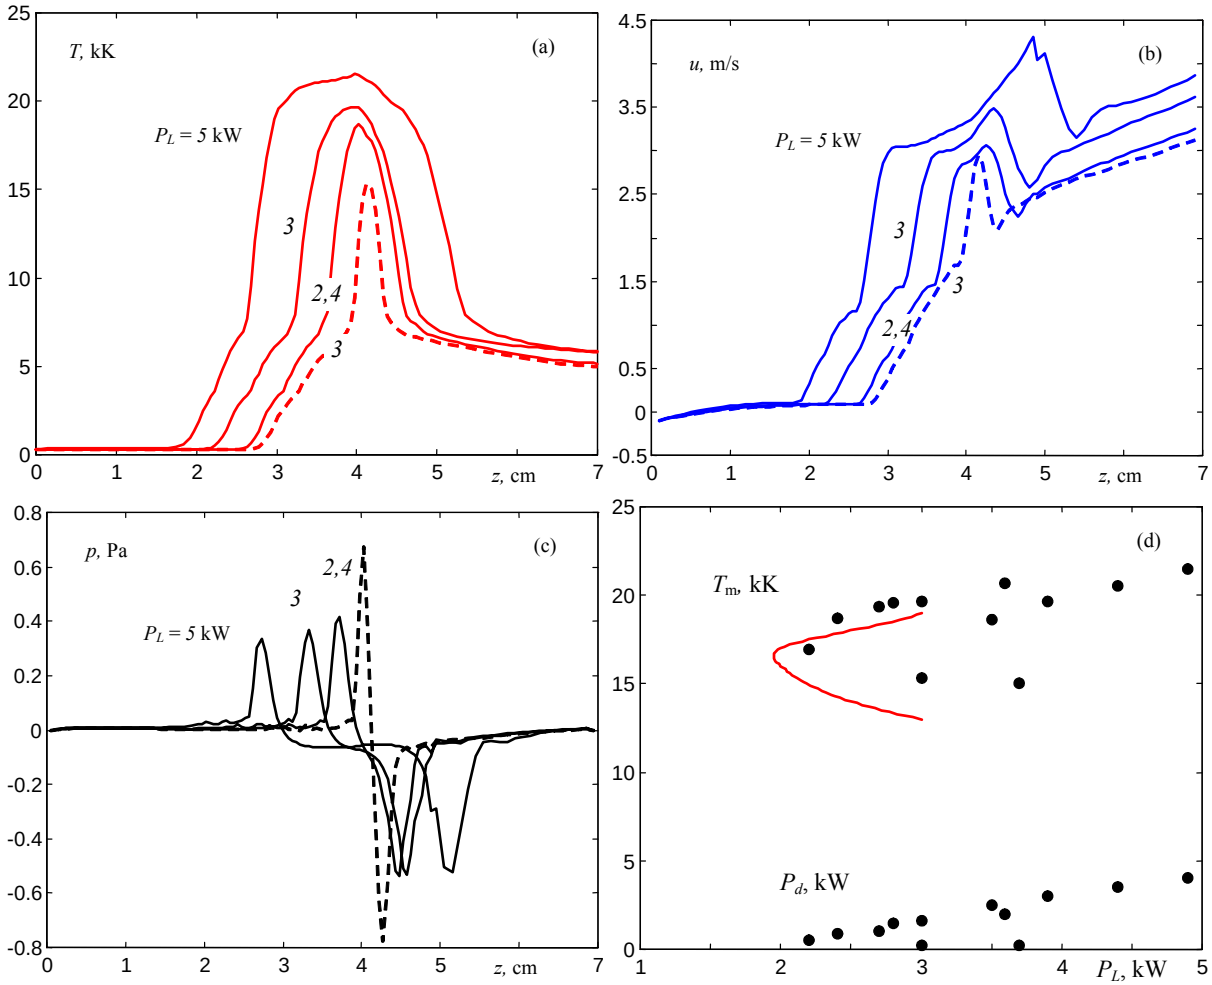

Figure 6. Distributions of the (a) temperature, (b) velocity, (c) pressure along the COD-axis at different laser power (the dashed curves correspond to the unstable regime) and (d) the maximum temperature and the fraction of the laser power dissipated in the discharge plasma as functions of the laser power (the solid curves illustrate the results of calculations based on the analytical model of a spherical COD).

Ultra-dispersed silicon powder combustion activation by corona discharge plasma

Lelevkin V.M.[1], Kanygina O.N.[1], Petrenko N.L.[1], Tokarev A.V.[1]

[1] *Kyrgyz-Russian Slavic University, Bishkek, Kyrgyz Republic*

Abstract

Self-distributed high-temperature synthesis of silicon powder in air at high pressures was studied. A new method of obtaining ultra-low-dense structure by creation of ultra-dispersed silicon powder suspension at electrical deposition on the base plate was developed. The content of silicon nitride in combustion products, dependences of increase in mass and combustion rate on air pressure were defined.

Introduction

The synthesis by combustion is one of the most modern directions in science of materials [1]. To control a process of silicon synthesis by combustion chemical reactions between powder mixture particles and gaseous environment are needed. At self-distributed high-temperature synthesis (SHS) complex phenomena connected with mass-transport (diffusion component, exothermal reaction energy liberation and distribution, temperature variation etc.) occur.

When burning silicon with use of gaseous nitrogen, one obtain nitride ceramic materials, and when burning in oxygen or air - obtained is oxide ceramics. The combustion of ultra-dispersed silicon powder in air or nitrogen at normal conditions does not occur because of insufficient oxidizing agent. In order to conduct similar reaction, high pressures of reacting gas are needed. One of the ways for reaching the ignition limit at normal pressures is a reaction realized in liquid nitrogen, or SHS realized with silicon powders of ultra-low density. Pursuant to assessments, the necessary relative density of silicon powder should be around 4% that corresponds to bulk density of 100 kg/m^3.

The purpose of this work is to obtain silicon nitride by realization of self-distributed high-temperature synthesis, occurred in ultra-dispersed silicon powder in air at different pressures.

Experiment

Experiments on combustion of silicon powder in air are carried out as follows:

- Feedstock is washed by hydrochloric acid solution for removing iron admixtures;
- Monocrystalline silicon is grinded in a ball mill;
- From obtained silicon powder the ultra-dispersed powder of ultra-low density forms with use of electrostatic method;
- With help of electric discharge at different pressures initiated was SHS, the results of which were compositions of silicon oxide, dioxide and nitride;
- Silicon nitride selection from compositions mixture realized by chemical leaching.

Air suspensions of ultra-dispersed silicon powder creation

Silicon powder after grinding represents a dense conglomerate. It is very difficult to organize SHS in air at normal conditions because of densely inter-linked silicon powder particles. Therefore a preliminary turbulent air current with suspended silicon particles is provoked. At supply of air through the tangential integrated fitting, a turbulent gas movement entraining silicon powder arises in camera. At rotating, the large conglomerates of the powder strike on the camera walls and split into the smaller ones. As a result of friction on walls the particles are charged and due to coulomb (electrostatic) forces push off the basic mass, forming a homogenous two-phase medium (silicon-air).

Silicon powder deposition on base plate

Ultra-dispersed low-dense silicon powder is obtained with help of a process installation (fig.1). The installation consists of camera 1 inside of which there are corona-forming electrodes 2, base plate 3 on the camera floor is the cathode. At high positive polarity voltage supply the corona discharge appears between corona electrode and the base plate. Silicon powder particles are supplied into the camera together with air current, get in the field of corona discharge and are charged positively due to positive ions sticking on them. Positive silicon particles drift under coulomb forces towards the base plate and deposit on it. A bit later rather a thick layer of low-dense silicon powder forms on the base plate.

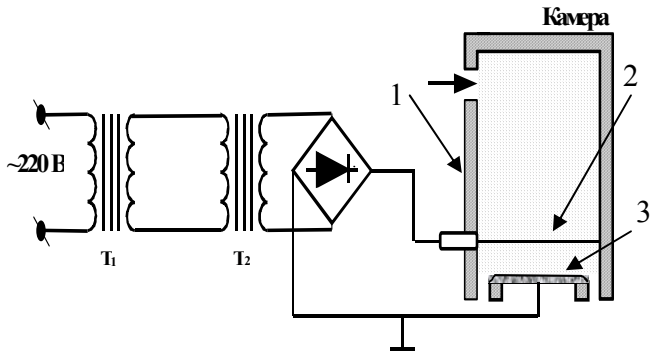

Figure 1. Scheme of silicon powder deposition:
1 – camera; 2 – corona electrodes;
3 – base plate (cathode); T_1 – autotransformer;
T_2 – high-voltage transformer.

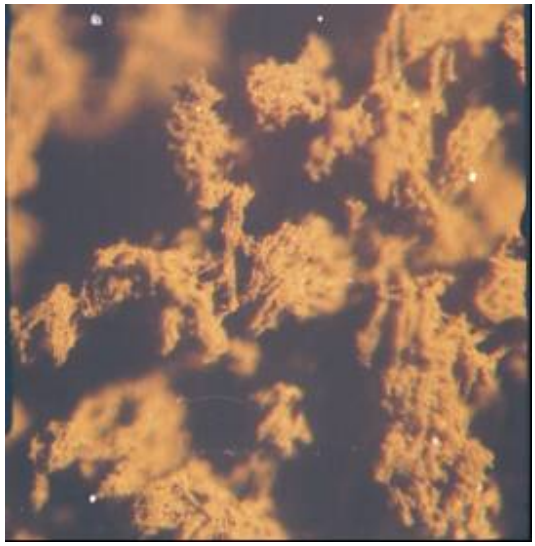

Figure 2. Deposited silicon structure (image magnification in 56 times)

The layer structure is loose with a large amount of pores and spasmodic thread-like silicon particles (fig.2). Similar structure contains a lot of reacting gas and easily lets oxidizers into deposited silicon powder and promotes SHS occurring. By measuring a volume of deposited layer and its mass one define a density of silicon powder, which is equal to ~100 kg/m^3 (by one order less than [2]).

Initiating of a process of deposited powders burning

The installation given in fig. 3 is proposed for silicon combustion. Base plate with deposited silicon 2 is placed in camera 1 with a given air pressure. The electrode is introduces in the camera above base plate through insulator. The second electrode is the camera itself and base plate. The electrode system connects to the high-voltage transformer T. The voltage of 2kV is supplied in the electrode system; the electric discharge is ignited between electrode and base plate, as a result of that the surface of deposited silicon heats up to the temperature sufficient for SHS progress.

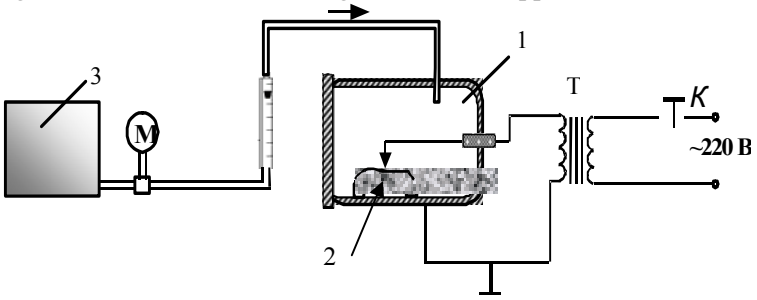

Figure 3. Scheme of the installation for silicon powder combustion:
1 – camera; 2 – base plate; 3 – compressor; M – manometer;
T – transformer; K – key.

After the ignition a zone of preliminary heating forms in ultra-dispersed silicon powder; the zone defines a character of burning wave (astable mode of burning) [3,4]. Combustion temperature in a volume of the ultra-dispersed powder occasionally varies, consequently a

typical “spasmodic” astable mode of layer-by-layer combustion of silicon happens. The heat, emitted in a zone of reaction comes in a zone of preliminary heating that ensures the process’s high rate. If the material diffusion progresses slower then the thermo-diffusion, then in a zone of reaction more surplus energy is emitted than in stationary wave of combustion [5].

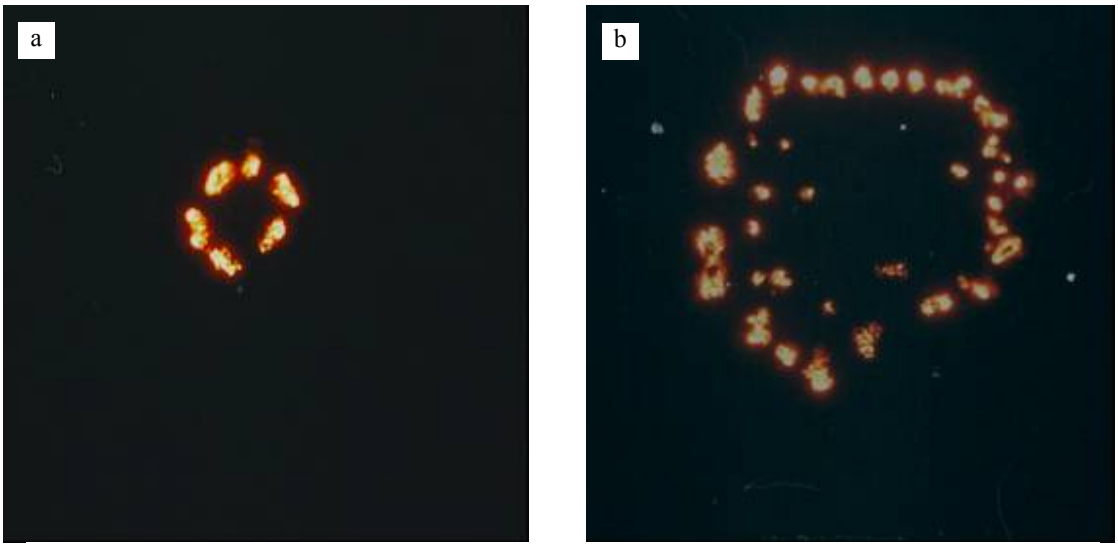

Figure 4. Ultra-dispersed silicon powder combustion in air (image magnification in 1.5 times):
a) combustion time - 5 sec. b) combustion time – 60 sec.

In the course of the study it was established that ultra-low-dense silicon powder burns both in an astable and a spin mode. The mode of spin burning is characterized by available large quantity of burning fronts inside of the pattern and on its surface. From figure 4a it is viewed that after SHS forming high-temperature local areas of combustion waves in a shape of bright luminous spots, which migrate on the pattern, appear. Due to heterogeneity of heat losses the front of combustion wave distorts (fig. 4b). With the mixture density growth

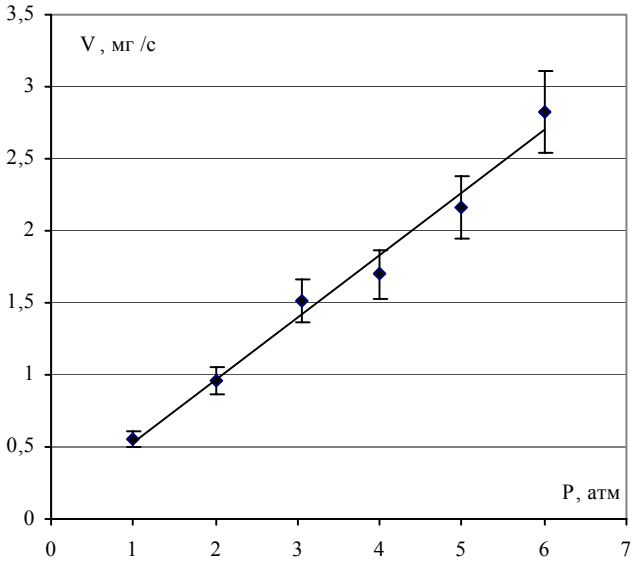

Figure 5. Dependence of silicon combustion rate on pressure

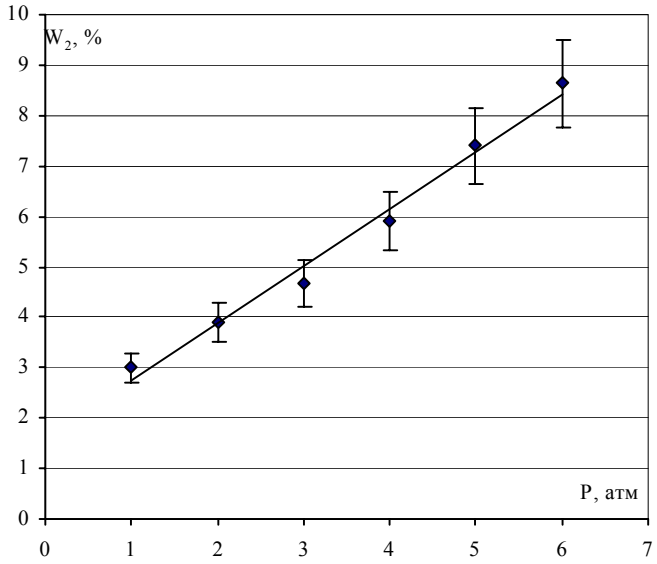

Figure 6. Dependence of output of silicon nitride on pressure

the distribution of combustion wave decelerates, relative share of heat losses from the surface decreases, and the front of combustion wave becomes flat. The time of existed high-temperature area over combustion wave increases that ensure greater degree of the initial silicon transformation.

At combustion of silicon powder the structured, laminated materials of SiO, SiO_2, Si_3O_4 as well as residuals of the burnt silicon are formed. With increase of pressure the rate of combustion front linearly grows (fig.5). At pressure increase from 1 to 6 atm. combustion rate increases from 0.5 to 2.7 mg/s that is connected with air concentration increase in the system's pores, and because of oxidized silicon mass increase a higher temperature develops, that promotes chemical reactions accelerated progressing. The mass of obtained compositions grows. The conditions for greater junction of O_2 and N_2 molecules with molecules of Si appear depending on pressure.

Output of silicon nitride

With pressure growth from 1 to 6 atm the pattern's increase in weight grows from 47 to 68%. Maximum increase in weight of silicon nitride at pressure 6 atm makes around 70% that corresponds to increase of the pattern mass in 1.7 times.

For quantitative determination of silicon nitride a chemical method of treatment by alkaline solution was applied:

$$SiO_2 + H_2O + 2NaOH \rightarrow Na_2SiO_3 + 2H_2O,$$

$$SiO + 2NaOH \rightarrow Na_2SiO_3 + H_2,$$

$$Si + 4NaOH \rightarrow Na_4SiO_4 + 2H_2$$

Silicon nitride (Si_3N_4) does not interact with alkaline at temperature close to normal and precipitates as gray sediment. X-ray structural analysis shows that the obtained material is a coarse-grained silicon nitride of β-structure.

It is visible from fig.6 that with pressure growth a percentage of silicon nitride linearly grows towards the initial pattern in the product of reaction. Minimum concentration of silicon nitride makes 3.1% at pressure of 1 atm. At pressure of 6 atm. the percentage increases up to 8.5% that is explained by increase of reacting components concentration in porous space between silicon particles. At SHS wave passage a greater mass of the material chemically reacts, emitting energy. A high temperature develops in SHS wave, which enhance the chemical reactions rate.

The initial material reacts in several reaction channels, but the reaction, which has lowest activation energy, prevails: it begins at lower temperatures accompanied by great energy liberation and has greater dependence of the reaction rate on temperature. If end product of any reactions channel results from several intermediate ones, then the channel with minimum intermediate reactions and maximum rate of each reaction prevails. For obtaining Si_3N_4 atomic nitrogen is needed which concentration in SHS grows pro rata to temperature. Besides, the SHS is a fast process, therefore slow reactions have no time for termination. That is why a higher temperature emerged at silicon combustion with high pressures results in slow cooling of a system and promotes full course of slow reactions with Si_3N_4 formation. On the basis of the analysis of end products enthalpy formation a channel with energy-liberation process can be determined.

$$Si + O_2 \rightarrow SiO_2 + 912\ \ kJ/mol = 32{,}571\ \ MJ/kg$$

$$2Si + O_2 \rightarrow 2SiO + 100\ \ kJ/mol = 1{,}786\ \ MJ/kg$$

$$Si + N_2 \rightarrow Si_3N_4 + 759\ \ kJ/mol = 9{,}378\ \ MJ/kg$$

It is viewed that the most favorable reaction will be in a channel of SiO_2 formation, then Si_3N_4, and SiO forms most weakly.

Conclusions

1. The method of ultra-dispersed silicon powder obtaining is developed;
2. A new way of ultra-low-dense structure of ultra-dispersed silicon powder creation by electrostatic deposition on base plate in corona discharge plasma is offered;
3. The conditions of SHS synthesis course in the system silicon-air at high pressures are determined;
4. Linear growth of silicon combustion rate in air, and silicon nitride output with pressure growing are defined.

Surface barrier discharge with a plasma electrode

V.M. Lelevkin [1], A.V. Tokarev[1].

[1] *Kyrgyz-Russian Slavic university, 44 Kievskaya str., Bishkek, the Kyrgyz Republic*

Abstract

The researches of statistical and dynamic volt-ampere and volt-coulomb characteristics of the surface barrier discharge (SBD) with a plasma inductive electrode were carried out. The dependences of current on gas pressure in a discharge electrode, of a corona electrode coil pitch and power factor on voltage, supplied to the discharge node are determined.

Introduction.

The surface barrier discharge (SBD) of alternating current with frequency less than 100 kHz is ignited between gas condenser plates, where both electrodes touch a dielectric. Corona forming electrodes are made in a shape of strip and in case of a flat configuration lay on the dielectric surface. An inductive (flat) electrode is located on the dielectric adverse side. The electrodes are supplied with alternating voltage of 10 kV. The discharge appears as a continuous luminous band, covering an end strip of the corona forming electrodes. The band consists of multiple luminous micro-discharges, which appear in every half a period of input voltage and are directed perpendicular to the electrode [1]. The micro-discharges number increases with the increase of voltage, promoting the luminescence intensity strengthening.

The surface barrier discharge (SBD) differs from the barrier discharge by dynamic capacitance, caused by the dielectric covered with plasma of the discharge [2-4]. It is possible to obtain record ozone concentrations in SBD (more than 200 g/m^3) at minimum power inputs (around 15 kV*h/kg) [5–6].

Here the SBD was carried out by substitution a plasma electrode for the metal inductive one [7]. By supplying power to a dielectric barrier with help of a plasma electrode it is possible to reduce power inputs for the ozone synthesis compared to the classical surface barrier discharge. The available two electric discharges located consequently on the electric circuit are an essential distinction of a surface barrier discharge with plasma inductive electrode (SDPE) against standard surface discharge.

Purpose of the work is to study features of the surface barrier discharge with a plasma inductive electrode: investigation of static and dynamic volt-ampere and volt-coulomb characteristics of the discharge; determination of pressure of plasma-generating gas inside the tube and the corona electrode coil pitch, influencing electric characteristics of SDPE.

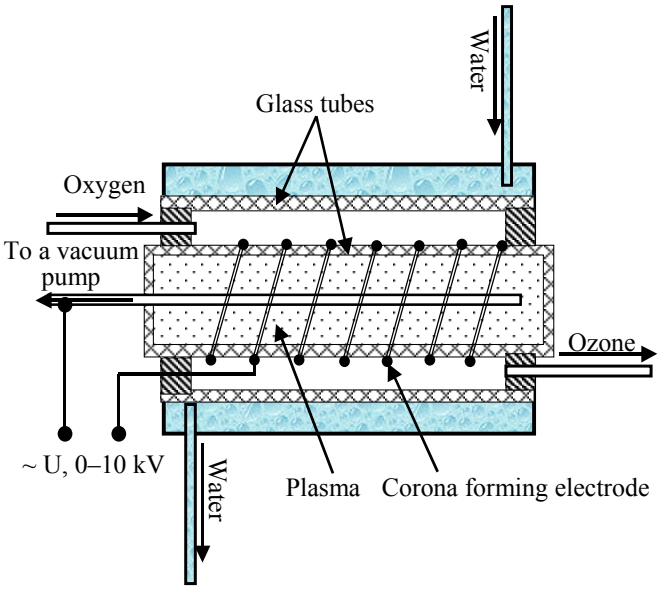

Fig. 1 The gas-discharge node

Experiment.

The experimental installation consists of a gas-discharge node (fig. 1) made of two glass tubes. Exterior diameter of the first (exterior) tube is 25 mm and interior diameter of this tube is 23 mm; exterior diameter of the second (interior) tube is 21 mm and interior diameter of this tube is 19 mm. A co-axial gap between two tubes is 1 mm, through which a dried by silicagel oxygen is pumped. A nichrome wire of diameter 250 mcm (corona electrode) is coiled with a certain specified pitch on exterior surface of the interior tube in 16 cm long. A metallic tube with exterior diameter 4 mm is a grounded electrode, which is hermetically introduced into

interior glass tube and serves for air exhaust and letting-to-air. The installation comprises a fore-vacuum pump for air exhausting from the tube to reaching pressure of 10^{-3} Torr, a device for vacuum registration, a tap for letting-to-air from atmosphere, a device for oxygen drying, and a rotameter for registration of oxygen consumption, flowing through the discharge node. Cooling of the discharge node is realized with help of water jacket, being on exterior glass tube. In order to prevent the ignition of a barrier discharge, in interval between glass tubes the installation is fixed on dielectrics, and the discharge node cooling system is equipped with input and output drop dielectric discontinuities. Alternating voltage under 10 kV and frequency 50 Hz is supplied to the corona electrode and metal tube.

The electric scheme contains the instruments for measuring average values of electric current (I_{avg}), voltage (U_{avg}), and devices for registering dynamic characteristics of electric discharge. According to instantaneous current, voltage, and discharge, flowing through the discharge gap, the parameters of SDPE are calculated: average current and voltage; full active and reactive power; power factor of the installation.

Output.

At critical voltage a volume barrier discharge is ignited on the discharge contour inside the tube. When pressure inside the tube is 10^{-3} Torr, the discharge burns, when glass dielectric is available, due to bias currents. The barrier discharge ignition is registered according to volt-ampere characteristics modification and weak lilac luminescence inside the tube. When increasing voltage, a surface barrier discharge is ignited between nichrome wire coils. For alternating current the SDPE first looks like a weak corona around the wire. With voltage increase the micro-discharges begin to appear and propagate from the wire. Their length increases with voltage growth. When the electric current increases, luminescence increases too, the discharge passes in a creepage form. Pulses – surges of active current appear on oscillograms of current as in case of a barrier discharge. On exterior luminescence it is viewed that the electric discharge snuggles up to the surface. According to data [1], an active form of the electric current is developed as micro-discharges, lasting ~ 10 ns, and following the magnitude order corresponds to the time needed for forming of channel in a barrier discharge.

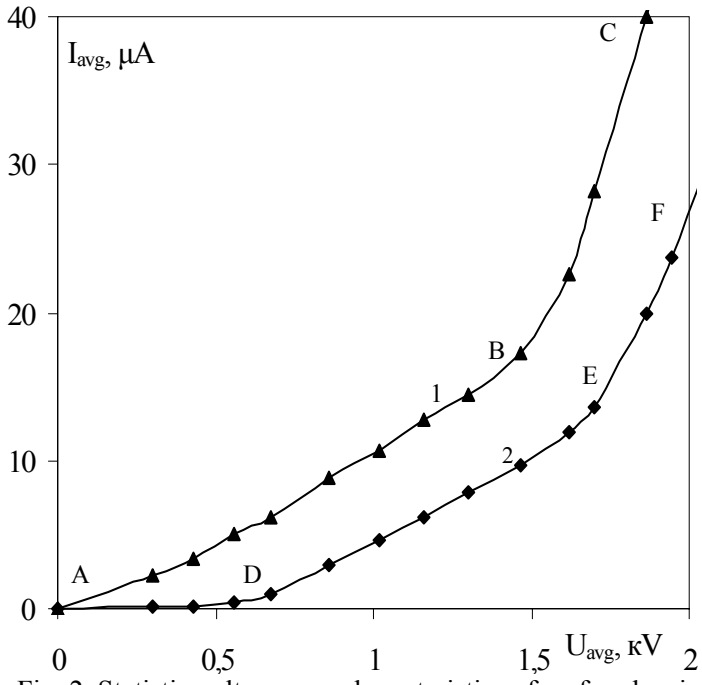

Fig. 2. Statistic volt-ampere characteristics of surface barrier discharges with a classical (1) and plasma (2) inductive electrodes.

Statistic and volt-ampere characteristics. The SBD's volt-ampere characteristics are similar to characteristics of the barrier discharge (BD) [8]. Traditional volt-ampere characteristics of the surface discharge were obtained on a discharge cell of similar construction (fig. 1.), but with a metallic internal electrode instead of plasma electrode. The area AB (fig.2. 1): corresponds to average electric current depending on effective stress at absence of electric discharge on the tube's surface. The slopping of this area is defined by general capacity of the discharge cell. At the SBD ignition and development a slope modifies (area BC), that is connected with increase of the discharge cell capacity. The continuation of the area BC is in a shape of a straight line up to the voltage on a discharge cell 10 kV.

Unlike SBD the volt-ampere characteristics for SDPE consists of three segments, each segment practically represents a straight line (fig.2): 1 – In interval to 500 V (segment AD) passes a current of

displacement, stipulated by a small capacity of electrodes of discharge; 2 – At voltage more than 500 V (segment DE) the current increases at the expense of the discharge gap general capacity growth at ignition of a volume barrier discharge; 3 – At voltage 2.7 kV (segment EF) a fracture of volt-ampere characteristics, connected with development of a surface barrier discharge with plasma inductive electrode is considered.

Dynamic characteristics of the discharge. Volt-coulomb characteristics of a barrier discharge have a shape of parallelogram [9]. The parallelogram's parallel sides point to that, that the barrier discharge burning voltage at steady ozone concentration in a discharge gap is constant during a half-period of current [10].

Volt-coulomb characteristics of SDPE for U_{avg} on the discharge contour 3 kV and 6 kV differ from characteristics of a barrier discharge (BD) (fig. 3). At U_{avg} on the discharge cell equal to 3 kV the cycle pattern is of a shape of ellipse, which is transformed in parallelogram at voltage growth to 6 kV. This can be explained that

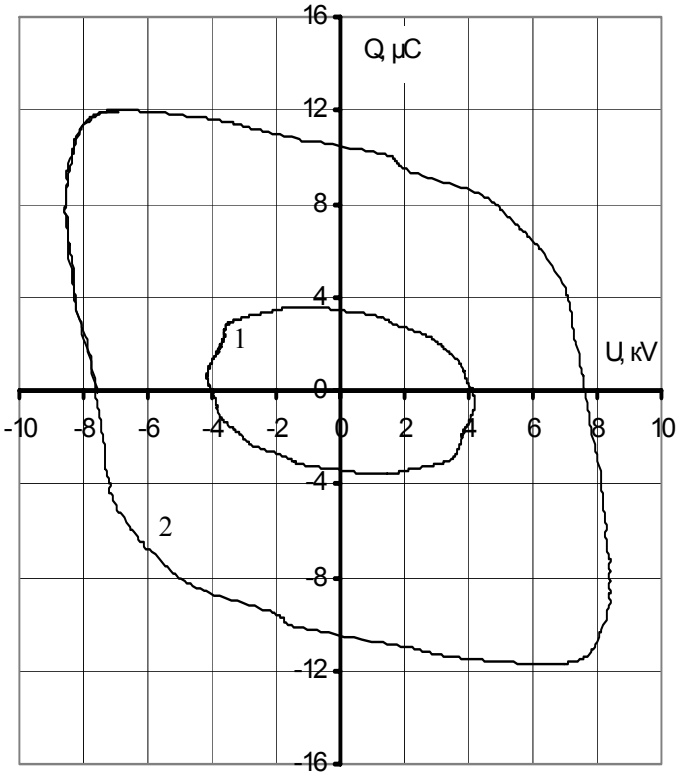

Fig. 3. Volt-coulomb characteristics of SDPE for effective voltages 3 (1) and 6 (2) kV.

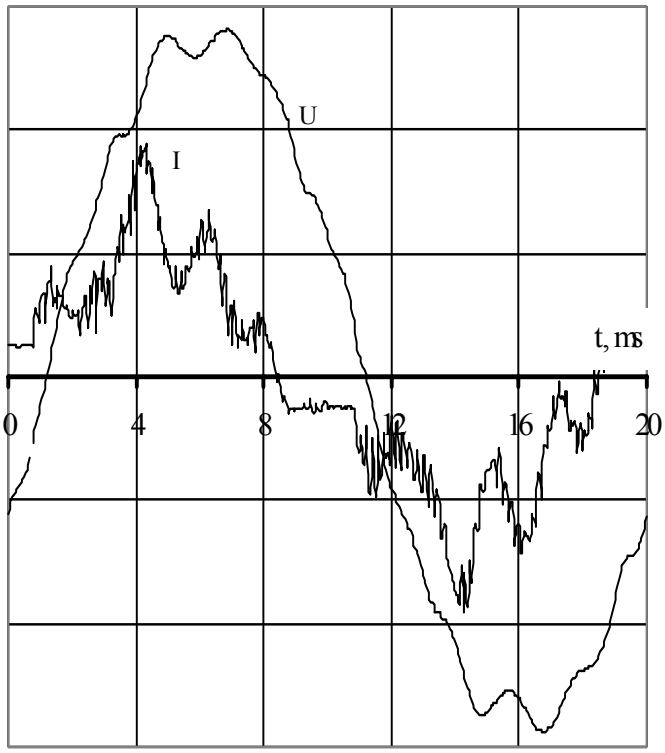

Fig.4.Oscilograms of the SDPE current and voltage. Amplitude values of current 3.1 mA, voltage 14 kV.

at voltage 3 kV a dynamic capacity, arising at plasma spreading on the dielectric surface by order of magnitude is comparable with electrodes own capacity. When increasing voltage, plasma fills a dielectric gap between wire coils, a dynamic capacitance stops to grow, and a cycle pattern gains a shape close to parallelogram.

Voltage of the discharge burning is a constant for classical BD. In case of SDPE volt-coulomb characteristics it follows, that voltage of burning depends not only on U_{avg}, but also on air consumption. When U_{avg} is higher than 8 kV, a burning voltage stops to change, because plasma of the surface discharge covers completely a free area of the dielectric. Influence of air consumption on voltage of burning is explained by ozone generation in the discharge.

Oscillograms of current and voltage on ozonizer are symmetrical for axis of abscissas (fig. 4.) with a cycle of vibration T=0.02 s. A lagging phase is insignificant between current and voltage, that is stipulated by

influence of the SDPE active capacity load. The forms of current and voltage differ from the sinusoid. Modification of a voltage form is defined by grand output resistance of the transformer. Distortion of an electric current form depends on the discharge ignition points and on appeared active component of current, that signifies a presence of an ohmic resistance in a chain of the barrier discharge [10]. A high-frequency component of electric current (separate pulses are hardly distinguished) are observed on oscillograms that is connected with forming of micro-discharges, sliding on the dielectric surface.

Parameters of a discharge contour and characteristics of the discharge. It was established (fig. 5, 6), that dependences of the electric current's discharge on pressure inside the inductive electrode tube and on the corona electrode coil pitch are of complex nonlinear nature. For the coil pitch d=1.1 mm and 2.2 mm at P=50 Torr minimum current is considered (fig. 5). At pressures 150 – 200 Torr and the same d there is an area of a small increase of current. At increasing d this area is gradually smoothed and for d=40÷80 mm the dependence is practically linear. The appeared minimums and maximums of current can be explained by modification of structure of both volume barrier and exterior (surface) discharges. This is well viewed at observation of a volume barrier discharge. At low pressures it fills all volume of a discharge tube, at increased pressures the

discharge structure modifies depending on a form of the wire coiled on a glass tube. Hereupon the discharge dynamic capacity changes, a resistance of the discharge node grows, and the electric current reduces.

Depending on a corona electrode coil pitch (fig.6), the area with sharply increased electric current is realized, that is explained by screening of the corona electrode neighboring coils. At a small pitch of coiling, neighboring coils of the corona electrode screen a horizontal component of the electric field strength, and the discharge cannot be distributed throughout a free surface of the tube. This brings about that the dynamic capacity and electric current reduce. When increasing d the screening reduces between coils, and at d=4–5 mm plasma of

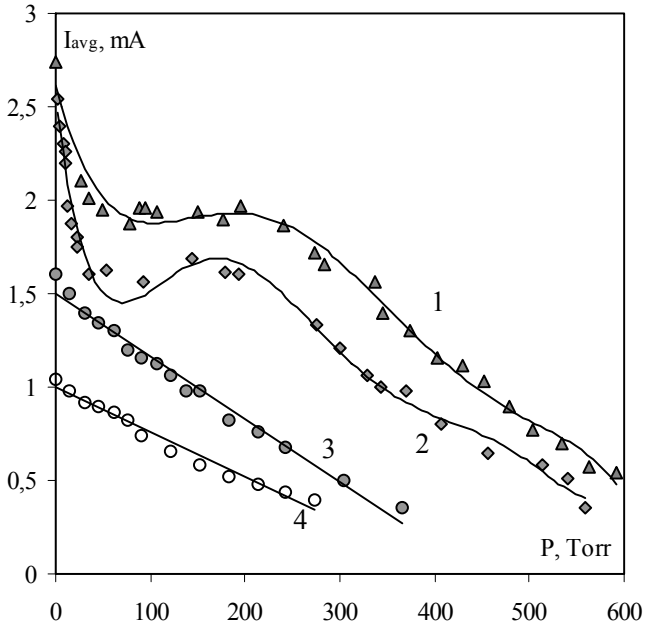

Fig. 5. Dependences of the discharge mid current on gas pressure in plasma electrode for the corona electrode coil pitch 1.1 (1), 2.2 (2), 25 (3) and 80 mm at voltage 10 kV.

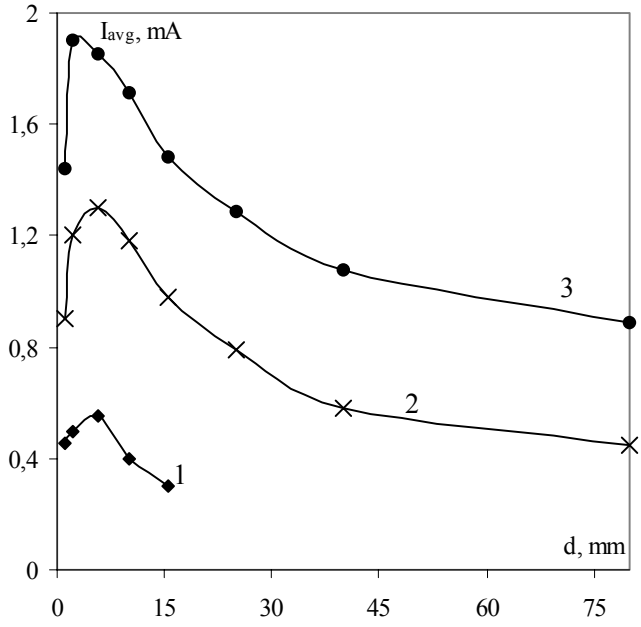

Fig. 6. Dependencies of mid SDPE current on the corona electrode coil pitch for the voltage effective values 5 (1), 8 (2) and 10 (3) kV.

the surface discharge covers in full the tube's area, that corresponds to maximum current. At further increase of d a value of horizontal component of the electric field strength reduces, and plasma cannot fill all space between

neighboring coils of the corona electrode. Therefore a dynamic capacity of the discharge node diminishes, a resistance increases and the discharge current reduces.

At increasing voltage on a discharge cell from 3 kV to 10 kV, power factor reduces linearly from 0.7 to 0.54. This means that with increase of U_{avg} the discharge active power decreases and reactive power increases. Therefore, for economic reason, the SDPE is effective in a range of voltages 3 – 5 kV, at further increase of voltage, power factor drops due to logging phases between amplitudes of current and voltage, and due to increase of the discharge node dynamic capacity.

Conclusions.

1. Volt-ampere characteristics of SDPE differ from a similar dependence for barrier and surface discharges because another fracture appears in region of 600 – 700 V, which corresponds to ignition of a volume barrier discharge in a vacuum tube. At voltage around 1.8 – 1.9 kV the investigated SDPE is ignited.
2. From dynamic characteristics follows, that around 70% of the discharge current accounts for a high-frequency component.
3. The power factor of SDPE is higher than at classical barrier and surface discharges due to a grand contribution of a high-frequency current in active power;
4. Complex dependences of current on pressure and on a corona electrode coil pitch are defined by the discharge basic adjustment depending on pressure and mutual screening of neighboring coils of a corona forming wire.

Abstract

A stable plasma can be generated in a sub-mm gap by using both VHF electric power and a cylindrical electrode at 10^5 Pa. The chemical vaporization machining (CVM) plasma uses a mixture of He, CF_4 and O_2 for an ultra precise polishing of silicon wafer. The plasma is diagnosed by an optical emission spectroscopy. Both fluorine and oxygen atom densities are measured by an actinometry technique. The gas temperature is estimated with electronic spectra of diatomic molecules. The results are compared with the etched patterns.

Keywords: atmospheric plasma, capacitively coupled plasma, chemical vaporization machining, actinometry, optical emission spectroscopy, molecular spectrum, rotational spectrum, rotational temperature

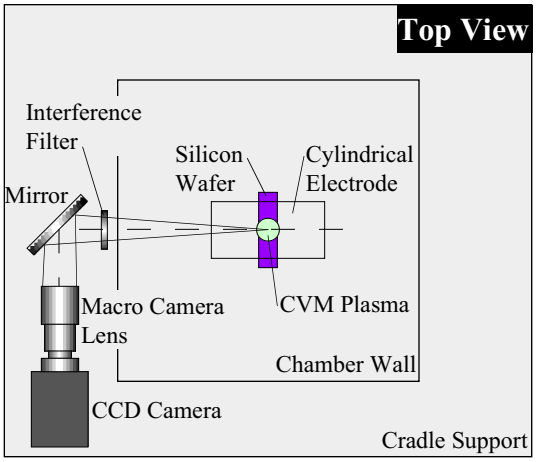
1. Introduction

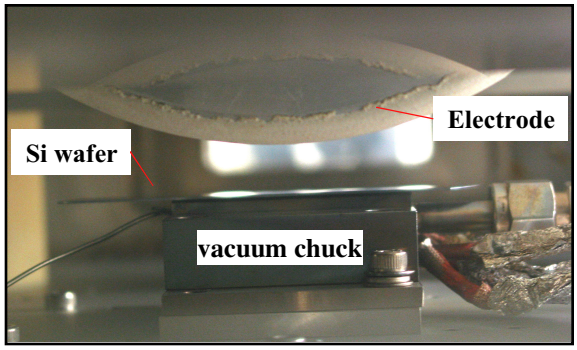
A stable capacitively coupled plasma in a narrow gap (~500 μm) at one atmosphere can be generated with both VHF (150 MHz) electric power and a rotating cylindrical electrode (ϕ160 mm) coated with alumina. When we use a diluted fluorocarbon gas, a mixture of He, CF_4 and O_2, for the plasma generation, this system is named the "Chemical Vaporization Machining; CVM [1-3]." The CVM process can polish a silicon wafer and glass surface very softly by a kind of plasma etching mechanism coupled with a high-speed shear flow in the plasma gap. Purpose of this paper is to diagnose an atomic density of both oxygen and fluorine by an optical emission spectroscopy (OES) [4-6]. For the plasma etching of silicon, both fluorine and oxygen atoms play important roles. Therefore we have tried to realize a visualization for spatial density distribution of both fluorine and oxygen atoms. The spatial distribution is observed by a simple technique based on an actinometry technique [7-9]. This major technique could determine a "relative density" by calculating a line emission intensity ratio between target atom and argon. The resultant density map is compared with a etched pattern on silicon wafer in four conditions for plasma generation. The CVM plasma is a kind of glow discharge at low gas temperature (T_{gas}). In such plasmas, chemical reactions in the gas may govern the etching mechanism. Therefore we concentrate on molecular spectra observed by OES to estimate rotational temperatures (T_{rot}) and vibrational temperatures (T_{vib}) [10-12]. T_{rot} normally relaxes to equilibrium much faster than T_{vib} (of the order of one collison as compared to 1000 collisions). T_{rot} of several diatomic molecules (CO [13], SiF [14], He_2 [15,16], O_2^+ [17], C_2 [18]) are determined by fitting calculated relative intensities to those observed experimentally. T_{vib} is estimated with a rotational spectrum of C_2. An Excitation temperature of the plasma is also estimated by rare gas OES technique [18].

2. Experiments and results

2-1 Two dimensional argon actinometry

Experimental setup for two dimensional argon actinometry is shown in figure 1 (a). In this study, a cooled CCD camera (C4880-10-12AU, 1018x1000 pixels; Hamamatsu) coupled with both a macro camera lens (180 mm F3.5 APO MACRO; SIGMA) and a 2x teleconverter (TELEPLUS PRO300; Kenko) was covered with an interference filter (Optical Coatings Japan) of very narrow bandpass (~1.5 nm FWHM) to record monochromatic images of each line emission. Magnification of the plasma image was unity on the CCD chip. The OES spectrum of plasma confirmed that the interference filter was enough to record monochromatic images with O. D. values of more than four at Ar I 750.4 nm (E_{th}; 13.48 eV), F I 739.9 nm (E_{th}; 14.37 eV), and O I 844.6 nm (E_{th}; 10.99 eV), respectively. We brought a center of the plasma into focus. Spatial resolution of the image was determined by a CCD pixel size of 12 μm. Ten consecutive frames were recorded and accumulated to produce the averaged





(b) Sideview of plasma gap w/o discharge.

(c) Typical monochromatic image.

Figure 1. (a) Experimental setup for actinometric measurement, (b) configuration of plasma gap, and (c) typical monochromatic image of plasma gap taken by CCD camera.

image of 14bit. Two dimensional density maps of both fluorine and oxygen were constructed by dividing each pixel value of the monochromatic images by corresponding each pixel value of the plasma image of argon. Dependence of the density maps on both VHF power (50, 100 W) and rotation speed of electrode (250, 1000 rpm) was studied. The plasma gas mixing ratio was fixed at $He/CF_4/O_2/Ar=99.89/0.1/0.01/0.05$. Specimen for the process was prepared by cutting off a 90*15 mm^2 strip from p-type, mirror-polished silicon wafer. Figure 1 (b) shows a widened plasma gap between electrode and wafer, and fig. 1 (c) is a typical monochromatic image of the plasma at 750.4 nm with the interference filter. The both of plasma sheaths are clearly resolved. Figure 2 shows a dependence of the monochromatic plasma image at 750.4 nm on both VHF electric power and rotation speed of the electrode. These images act as references of two dimensional distribution of fluorine and oxygen atom densities. Figure 3 shows a dependence of the plasma image at 844.6 nm (left) and 739.9 nm (right) on the condition of plasma generation, respectively. The emission patterns differ considerably between oxygen and fluorine. Two dimensional density maps of both fluorine and oxygen were finally constructed by dividing each pixel value of the monochromatic

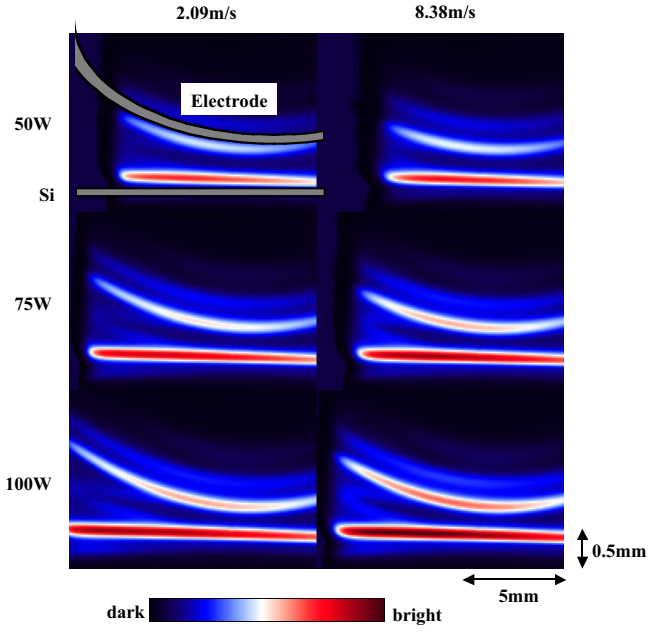

Figure 2. Dependence of argon monochromatic image on both VHF power and gas flow rate. The gas flows from left to right.

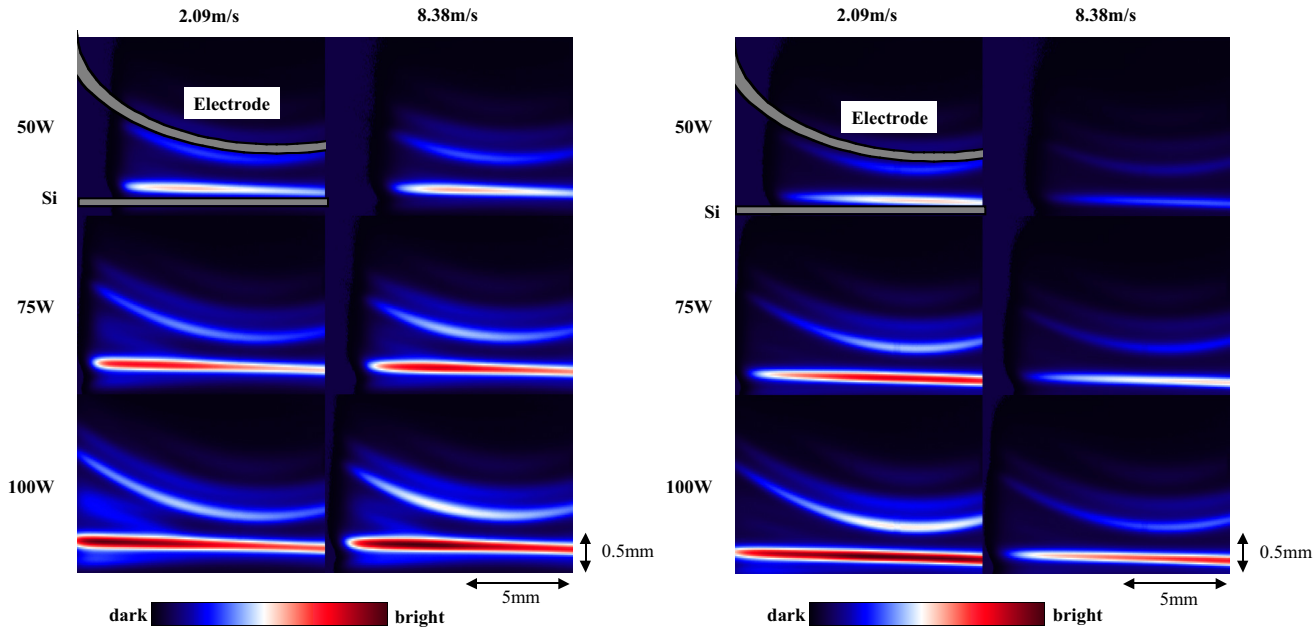

Figure 3. Dependence of oxygen (left) and fluorine (right) monochromatic images on both VHF power and gas flow rate. The emission patterns differ considerably between oxygen and fluorine. The gas flows from left to right.

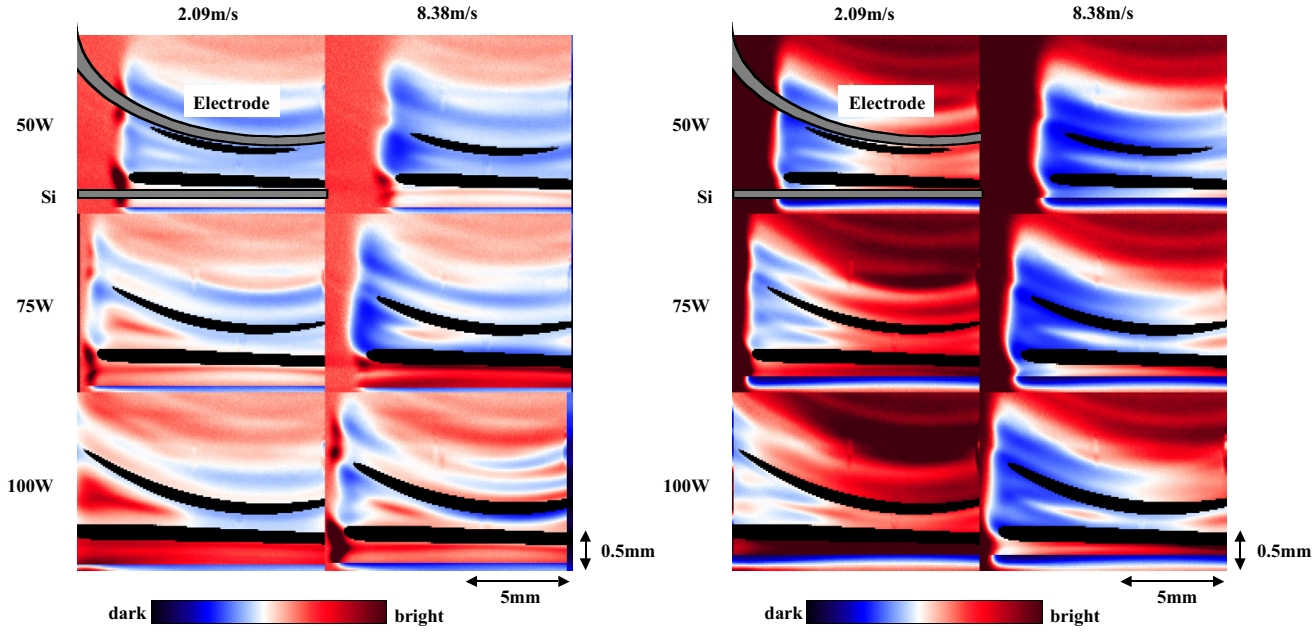

Figure 4. Dependence of oxygen (left) and fluorine (right) atom density maps on both VHF power and gas flow rate calculated with fig. 2 and fig. 3. The density maps differ considerbly.

images by corresponding each pixel value of argon image. The result is shown in figure 4. The density maps differ considerbly by changing both VHF power and gas flow rate, and the maps are quite different from fig. 3. These differences are reflected to the etched patterns on silicon specimens. Figure 5 summarizes the results of CVM process by changing both VHF power and rotation speed of electrode. As with the actinometric results differ, the etched patterns differ greatly.

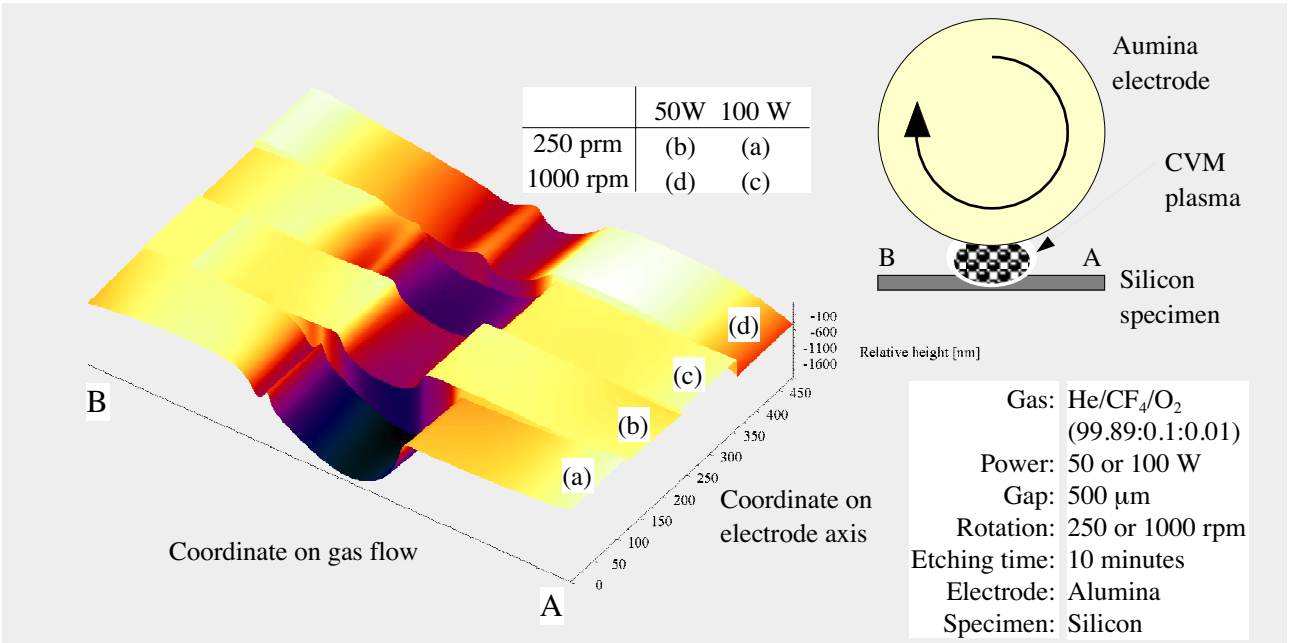

Figure 5. Dependence of the CVM plasma etching process on VHF power and rotation speed of electrode. Length and width of the plasma is about 15 mm, respectively. Specimen is made from Cz P-type Si (100) wafer. Etching condition is 250 rpm with (a) 100 W and (b) 50 W, 1000 rpm with (c) 100 W and (d) 50 W, respectively. The surface profile is measured with Zygo NewView.

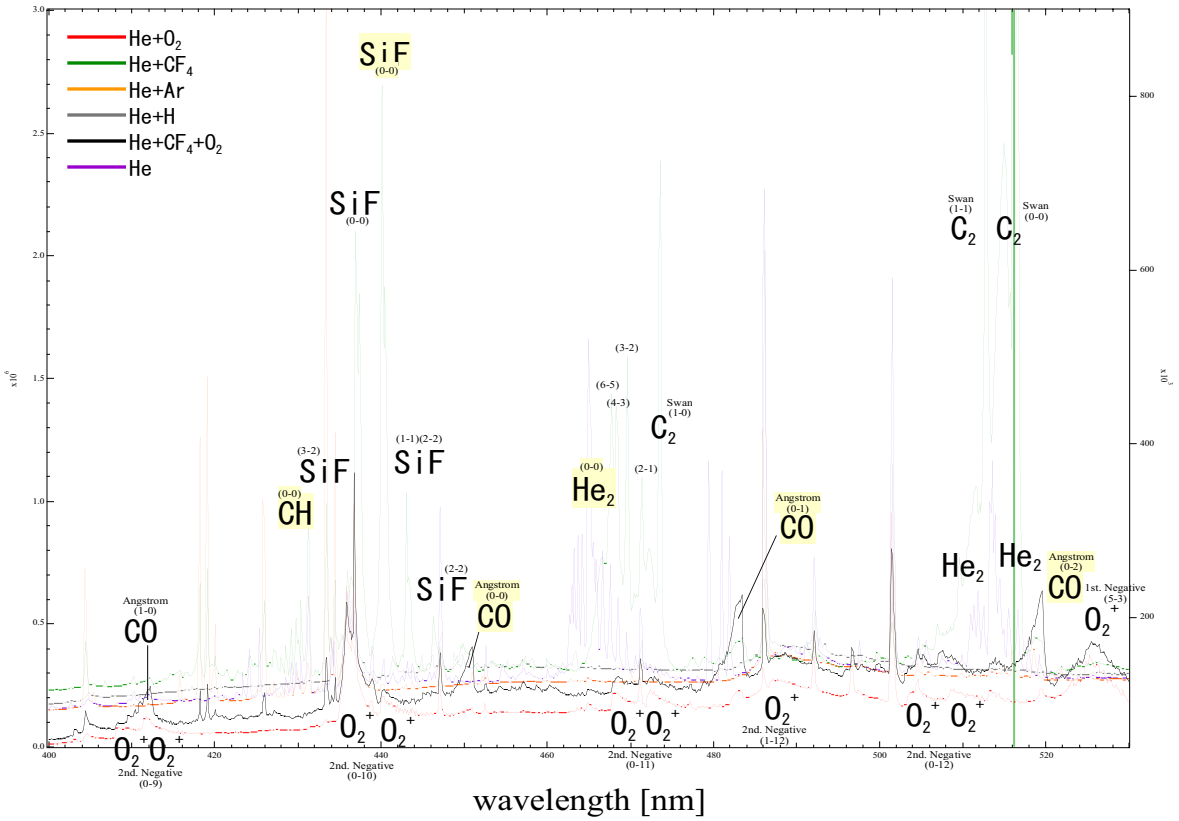

Figure 6. Electronic band spectra of diatomic molecules observed with several gas compositions based on an atmospheric helium. CH spectra appeared in several compositions because the chamber cleaning was not enough after the other CVD experiments. Pure helium plasma shows band spectra of He_2 excimers.

2-2 Electronic spectra of diatomic molecules in the CVM plasma

The electronic spectra of diatomic molecules as the plasma products were recorded with the MS257 spectrograph (ORIEL) coupled with the CCD camera used in the actinometry measurement. The MS257 is an F/3.9 instrument with a focal length of 257.4 mm, usable as a monochromator or true flat field imaging spectrograph because aspheric mirrors are installed. This instrument has three gratings of 300, 600 and 1200 lp/mm. For exmple, we can obtain spectral range of 38 nm on the CCD chip with 1200 lp/mm grating. An optical emission from the plasma was collected and focused onto the entrance slit of the spectrograph through L39 and L40 short cut filters (HOYA). Hence the OES spectrum was recorded at the wavelengths longer than 400 nm. The slit width was 10 μm. Ten consecutive images of spectrum were recorded and accumulated to produce the averaged spectrum of 14bit. A total spectral response of the spectrograph and the CCD camera was calibrated with a calibrated tungsten halogen light source LS-1-CAL (Ocean Optics). To understand roles of each gas component, OES spectrum was recorded with He, He/CF_4, He/O_2 and He/CF_4/O_2 plasma from 400 nm to 530 nm with both high and low resolution. The resultant spectra are superimposed in figure 6. Of couse, each gas composition emits different spectrum, but the spectra of both He atom and He_2 molecule were profoundly affected or suppressed by minor constituents. Sharp two peaks of C_2 (0-0) and (1-1) bands were saturated to record week tails of the bands. These electronic band spectra were numerically simulated, and one of the simulation parameters, T_{rot}, were estimated by a spectral simulation program "Pgopher" with NIST database [19]. The estimated rotational temperatures were from 400 to 600 K. On the other hand, the vibrational temperature of C_2 was estimated to be 10000 K with (0-0) and (1-1) bands.

2-3 Estimation of excitation temperature by OES of rare gases

We have taken a OES approach to determining electron excitation temperature in the CVM plasma. Emission is detected from multiple rare gases (Ar/Ne/Kr/Xe) that are added to a plasma at such low levels that they cause minimal perturbation to the plasma. Furthermore, their partial pressures are sufficiently low for their emissions to be under optically thin conditions. This trace rare gases OES (TRG-OES) method has been used to measure T_e and EEDF in several types of plasmas, and Donnelly recently reviewed the TRG-OES method and provided an updated model and recommendations for electron impact cross sections [20]. In our experiment, line emission spectra of the rare gases were recorded with MS257. After a spectral calibration of the spectroscopic system, the excitation temperature was estimated by drawing Boltzmann plot.

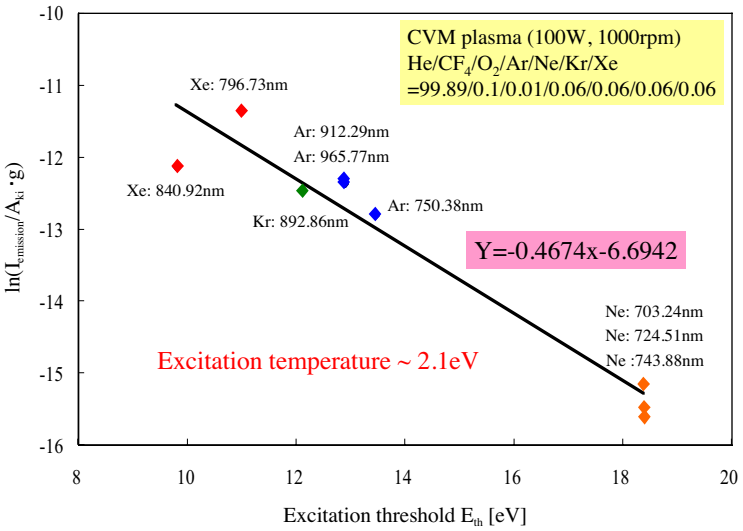

Figure 7. Excitation temperature estimated from rare gas OES spectrum of atomic line emissions.

3. Discussion

The sheath on sample is much brighter in all images in fig. 2and 3 because the sample is metal. Since sheaths in the images of fig. 2 are relatively homogeneous, the CVM plasma is basically uniform in the direction of gas flow, and only the height or the thickness of bulk plasma region changed. However in fig. 2, an interesting feature is observed in the left hand side or wider part of bulk plasma region. A weak emission bump in the bulk region seems to be splitted into two parts, and they seems to be drawn into the sheaths. This pattern might arise from a gradual decline in the plasma gap rather than an injection of laminar gas flow along the electrode surface. Narrawing of the plasma gap might changes a penetration of electric field into plasma bulk region. This bulk emission might be caused by a kind of stochastic heating beacuse of supplying VHF field at 150 MHz. In parallel plate CCP experiments, the same emission in bulk region has been observed more than one atmosphere. The resultant actinometric data are different from the plasma images. The actinometric data in fig. 4 emphasize a density maximum in the central region. In fig. 4, density maps of fluorine (right) has three density maxima

which might reflect an opposite pattern of argon emission. It is caused by that in fig. 3 (right), despite a threshold energy is almost same as the values of oxygen and argon, the bulk emission of fluorine is weak and nearly homogeneous. The position of density maximum is same as that of oxygen. Hence oxygen atoms might increase a dissociation of CF_X molecules. The whole bulk plasma region might contains both fluorine atoms and CF_X molecules homogeneously, and a small amount of oxygen atoms distributes inhomogeneously reflecting the bulk field and results in fluctuation of fluorine distribution.

The OES spectra shown in fig. 6 confirm that (1) CF_4 molecules are basically dissociated enough to couple with Si and O, (2) Si is etched with F atoms, (3) suppression of He_2 spectra may caused by reduction of He(2P) atom density because the excited states of He_2 are generated by He(2P) + 2He [16]. The rotational temperature or gas tempeature was very low because the room-temperature gas cools the plasma by its high speed shear flow. But the vibrational temperature was very high because the relaxation time long, and there may be a lot of population at higher vibrational level. Hence the dissociation of molecules may be governed by vibrational excitation in the CVM plasma.

The electron excitation temperature as shown in fig. 7 has reproducebility. But the temperature may not be a key parameter for the CVM proccess monitoring. Further discussion will presented in the conference.

Abstract

Energy-resolved mass spectroscopy was used to study differences in ion bombardment characteristics during conventional reactive magnetron sputtering and a grid-assisted magnetron sputtering proposed for deposition of films with a dense microstructure and smooth surface. An effect of the ion extraction grid potential, the total pressure and the argon-nitrogen gas mixture composition on energy distributions and integral fluxes of ions bombarding the growing Ti and TiN films was also investigated.

Keywords

Magnetron sputtering
Mass spectroscopy
Grid-assisted system
Ion bombardment effects

1. Introduction

It is well known that ion bombardment of growing films is of key importance for their structure and properties [1,2]. Recently, a novel grid-assisted magnetron sputtering system was developed in the CAPST laboratories at the Sungkyunkwan University in Suwon (Korea) making it possible to form high-quality films with a dense microstructure and smooth surface [3,4]. The main aim of this paper is to characterize energy and flux of ions bombarding growing films during their deposition using the grid-assisted magnetron sputtering. Reactive deposition of TiN films has served as a model system to illustrate differences between a conventional magnetron sputtering and the grid-assisted magnetron sputtering.

2. Experimental details

Figure 1 shows the new magnetron system with two mesh type Ti grids and a circular anode, electrically isolated from a chamber wall. A cylindrical vacuum chamber (diameter 160mm, length 220mm) was pumped down to a base pressure of 5×10^{-3}Pa by a diffusion pump backed with a rotary pump. An unbalanced

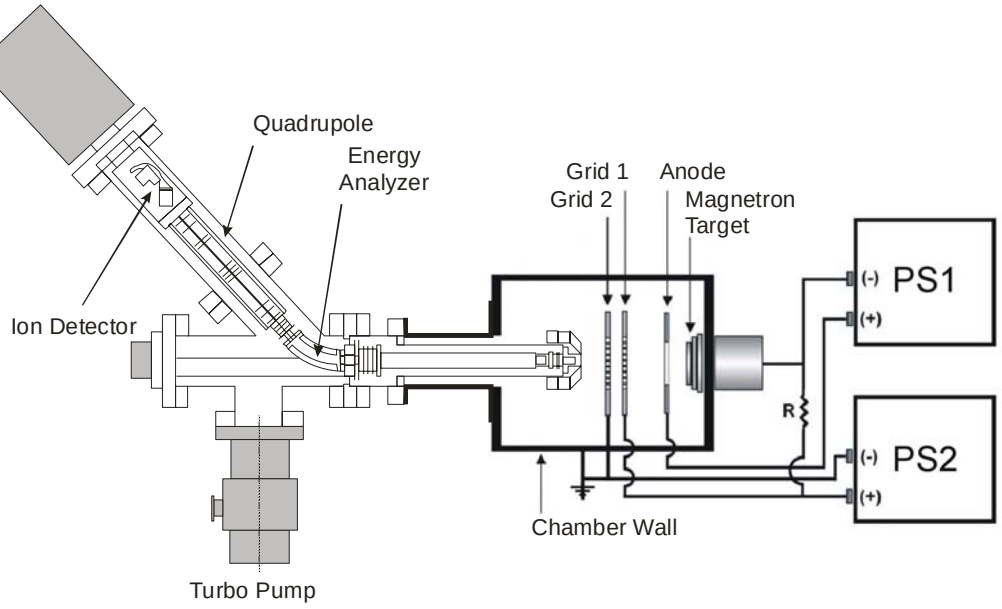

Fig. 1. Schematic illustration of the experimental set-up.

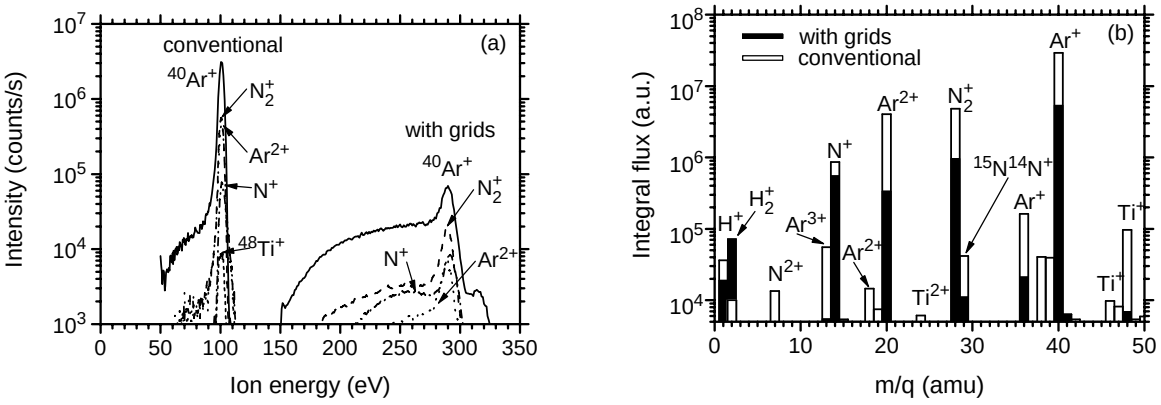

Fig. 2. Energy distributions (a) and integral fluxes (b) of the ions incident at a biased substrate (V_b=-100V) during conventional magnetron sputtering and at a grounded substrate during grid-assisted (V_g=+100V) magnetron sputtering.

circular planar magnetron equipped with a 45mm diameter Ti target was connected to the power supply PS1. An ion extraction potential V_g at the first grid was established by the power supply PS2. The films were deposited on silicon substrates located at the distance of 65mm from the target. The total pressures of argon-nitrogen gas mixtures were p=0.5 and 1Pa at the argon fraction ranging from 40 to 100%. The discharge current on the magnetron target was held constant at 0.9A. Microstructure and surface morphology of the as-deposited TiN films were investigated by FESEM (Philips XL30 ESEM-FEG) and AFM CP Research (Thermo-Microscope).

The energy-resolved mass spectrometer (EQP 300 Hiden Analytical) was placed at the substrate position in the center line of the discharge (see Fig. 1). We used a configuration, in which an extraction electrode with a 0.1mm diameter orifice in the center was located 5mm behind a grounded front electrode of the spectrometer with a central input aperture of 5mm in diameter. A negative extraction potential V_b=-100V, relative to ground potential of the chamber walls, was applied to simulate the same negative substrate bias used in the conventional magnetron sputtering. A low extraction potential of -10V, compensated at the output, was applied in measurements of the energy distributions of ions arriving at the grounded substrate during the grid-assisted magnetron sputtering with the first grid at a positive potential V_g in the range from 0 to 150V and the second grid at ground potential. The integral fluxes of individual ionic species were determined by a direct integration of the respective energy distributions.

3. Results and discussion

3.1. Comparison of conventional and grid-assisted magnetron sputtering of TiN films

Figure 2 provides information on energy distributions and integral fluxes of ions bombarding the growing TiN films during their conventional magnetron deposition on a biased substrate

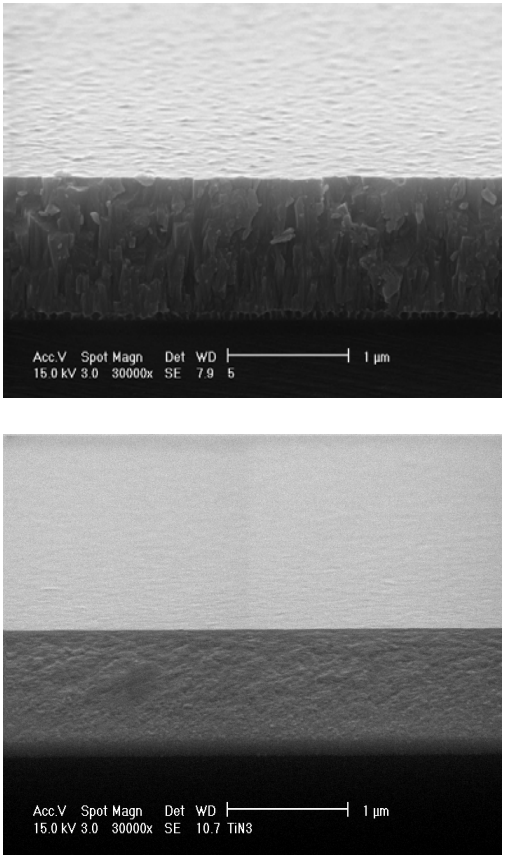

Fig. 4. Tilted cross-sectional SEM photographs of the TiN films deposited using conventional magnetron sputtering at V_b=-100V (top) and grid-assisted magnetron sputtering at V_g=+100V (bottom).

(V_b=-100V) and grid-assisted (V_g=+100V) magnetron deposition on a grounded substrate in an 80%Ar+20%N_2 gas mixture at the total pressure p=0.5Pa. The sputtered Ti target was at a cathode potential V_C=-445V with respect to the grounded chamber walls in the used conventional magnetron system. This value is in good agreement with a difference between the respective anode potential V_A=+318V and cathode potential V_C=-101V in the grid-assisted magnetron system with V_g=+100V. Figure 2(a) shows a progressive rise in the kinetic energy of ions bombarding the substrate in the grid-assisted magnetron system. This is mainly due to the high positive value of the anode potential resulting in a strong increase in the plasma potential V_p in the discharge, where ionization processes are realized (see the ion energies close to eV_A corresponding to maxima of the energy distributions). In addition, the used two-grid configuration is important for extraction and acceleration of the ions towards the grounded substrate. As expected, relatively narrow spectra with the maxima corresponding to the ion energy $e(V_p-V_b)$, where $V_p \approx 1$V, were obtained in the conventional magnetron discharge. As can be seen in Figs. 2(a) and 2(b), the ion flux to the substrate substantially decreases in the grid-assisted magnetron system under practically the same magnetron power. The main reason are large losses of the charged particles at grounded chamber walls. A total ion flux to the substrate decreases 5.4 times in the grid-assisted system compared to the conventional system at almost the same fractions of predominant Ar^+ (73 and 74%, respectively) and N_2^+ (13 and 12%, respectively) ions and the increased fraction of the N^+ ions from 2 to 7% [see Fig. 2(b)]. The enlarged dissociation degree of nitrogen ion flux towards the substrate, which could reflect an increase in the dissociation degree of neutral nitrogen molecules, might be caused by a substantial rise in the electron temperatures measured in the grid-assisted magnetron discharges [5]. As expected, the contributions of the Ti^+ and particularly the TiN^+ ions were very low in both the systems investigated. The respective fractions were 0.2 and 0.005% in the conventional system, whereas they decreased 2 and 5 times, respectively, in the grid-assisted system.

The AFM images proved a very smooth surface morphology of the TiN films (RMS=0.7nm) deposited using the grid-assisted magnetron sputtering at V_g=+100V, see Fig. 3. This can be explained by an increasing role of ion-induced effects (such as ion-induced knock-on subplantation of the film-forming particles leading to densification of the films, and resputtering) in film growth processes at the enlarged ion energies and low ion fluxes to the substrate. In Fig. 4, a significant increase in the density of the film deposited by grid-assisted magnetron sputtering is shown. It should be noted that the deposition rate of 67nm/min achieved for TiN films in the conventional magnetron system at V_b=-100V decreased to 25nm/min in the grid-assisted system at V_g=+100V [5], mainly due to resputtering of growing films at the enlarged ion energies.

Table 1. The cathode and anode potentials in the grid-assisted magnetron system during depositions in an 80%Ar+20%N_2 gas mixture at various values of the extraction potential V_g, and p=0.5Pa and V_b=0V.

Grid 1 potential V_g (V)	0	50	100	150
Cathode potential V_C (V)	-170	-130	-101	-67
Anode potential V_A (V)	254	290	318	348

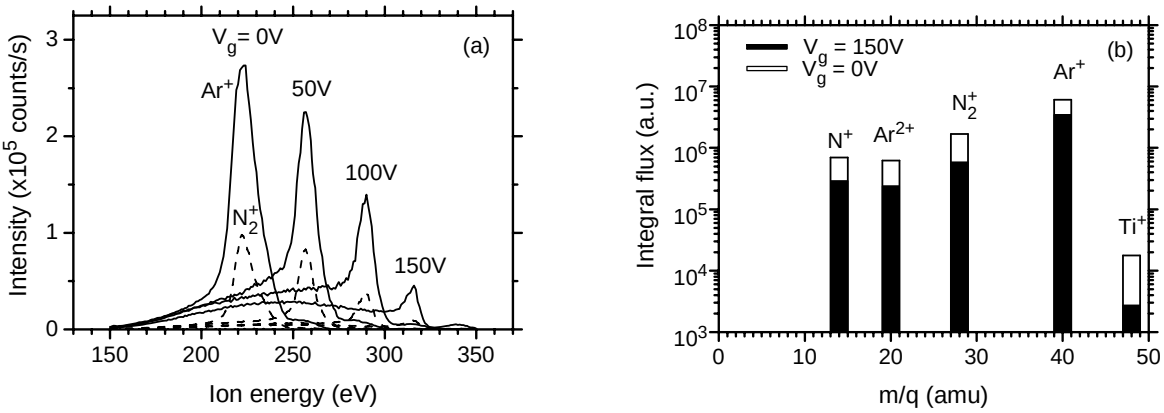

Fig. 5. Energy distributions (a) and integral fluxes (b) of the predominant ions incident at a grounded substrate during grid-assisted magnetron sputtering for various potentials V_g.

3.2. Effect of the process parameters on ion bombardment characteristics during grid-assisted sputtering

As can be seen in Figs. 5(a) and 5(b), an increase in the values of the potential V_g from 0 to 150V leads to a rise in the kinetic energy of ions and to the corresponding decrease of the ion fluxes to the substrate. These effects are natural consequences of a substantial increase in the plasma potential in the discharge due to the respective rise in the anode potential V_A from 254 to 348V (see Table 1). Let us recall that the V_A values increase as a result of the raising values of the cathode potential V_C from -170 to -67V (see Table 1 and a direct electrical connection between the cathode and the grid1 electrode in Fig. 1), as the potential difference V_A-V_C, keeping constant the discharge current on the magnetron target I=0.9A, is only slightly decreasing from 424 to 415V with the increase in the V_g values from 0 to 150V. This rise in the extraction potential V_g leads to almost 2 times lower total ion flux to the substrate at increasing fraction of Ar^+ ions (from 67 to 76%) and decreasing fractions of the N_2^+ ions (from 18 to 13%) and N^+ ions (from 8 to 6%). The N^+/N_2^+ ion flux ratio was in the range from 0.42 to 0.58. The corresponding deposition rate of films decreased from 46 to 20nm/min.

Figure 6 shows the effect of the total pressure and the argon-nitrogen gas mixture composition on ion bombardment characteristics during grid-assisted magnetron sputtering at a fixed extraction potential V_g=+100V. The obtained results can be explained on the basis of the data given in Table 2 if one takes into account that the values of the cathode potential V_C and the potential difference V_A-V_C are affected by a plasma conductivity determined by the total pressure and the gas mixture composition.

4. Conclusions

Energy-resolved mass spectroscopy was used to study differences in ion bombardment characteristics during conventional reactive magnetron sputtering and the grid-assisted magnetron sputtering proposed for deposition of films with a dense microstructure and smooth surface. It was found that the grid-assisted magnetron system makes it possible to increase substantially the values of the plasma potential in the discharge. As a result, the role of ion-induced effects (such as knock-on subplantation of the film-forming particles leading to densification of the films, and resputtering) is enhanced in film growth processes at the enlarged ion energies and low ion fluxes to the substrate. The effect of the ion extraction grid potential, the total pressure and the argon-nitrogen gas mixture composition on energy distributions and integral fluxes of ions bombarding the growing Ti and TiN films was shown.

Table 2. The cathode and anode potentials in the grid-assisted magnetron system during depositions in various argon-nitrogen gas mixtures at two total pressures, and V_g=+100V and V_b=0V.

Total pressure p (Pa)	0.5	0.5	1.0	1.0
Ar fraction (%)	80	100	40	100
Cathode potential V_C (V)	-101	-89	-105	-67
Anode potential V_A (V)	318	294	320	279

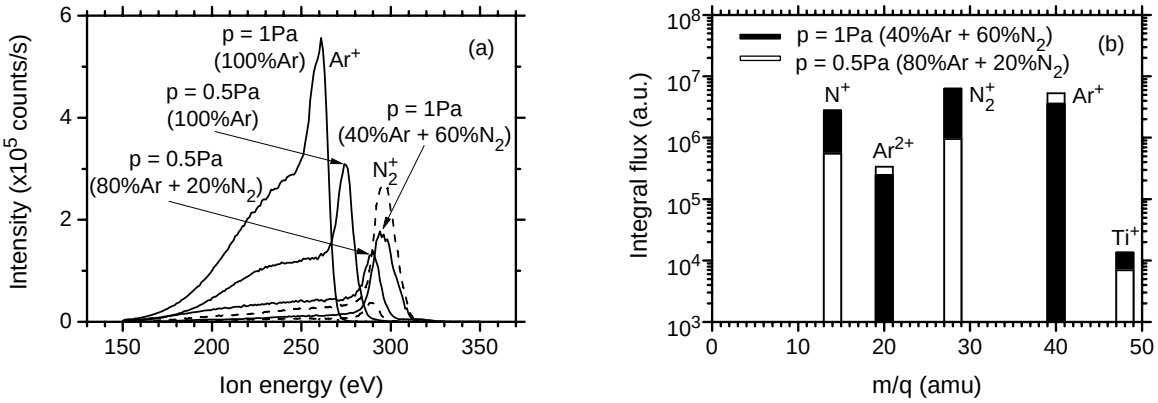

Fig. 6. Energy distributions (a) and integral fluxes (b) of the predominant ions incident at a grounded substrate during grid-assisted magnetron sputtering for various gas mixtures and total pressures.

Synthesis of carbon nanostructures by arc discharge in liquid

Shenli Jia, Gang Xing, Pu Yang, Zongqian Shi

Department of Electrical Engineering, Xi'an Jiaotong University, Xi'an China

Abstract

In this paper, we conducted serial experiments on synthesis of nanomaterials by arc discharge both in water and liquid nitrogen. The parameters of arc discharges such as arc current and electrodes size have been optimized, the products were analyzed and compared. In order to understand the mechanism of the formation of nanomaterials during the arc discharges, the cross magnetic field was introduced to disturb the arc plasma. The interesting result was got and tentative explanation was given.

1.Introduction

After the discovery of carbon nanotubes in 1991 [1], the synthetic methods of nanomaterials have been widely studied. At present, there are three kinds common methods to fabricate nanomaterials. They are arc discharges in protection gases [2-5], laser ablation [6-9] and chemical vapor deposition [10-13]. Most of those methods need complex vacuum system and the arc discharge in protection gas needs additional cooling for cathode and reaction container wall. So the cost is high and the nanomaterials yield is relatively low. Ishigami *et al* [14] proposed a method for fabrication multi-walled carbon nanotubes by arc discharge in liquid nitrogen. After that, due to its simple implementation, potential for high yield and low cost , synthesis nanomaterials by arc discharge in liquid has been studied more widely. Sano et al obtained nano-onions by arc discharge in water [15] and single wall nanohorns (SWNHs) in liquid nitrogen [16].

Although a lot of experimental research have been conducted on this field, the mechanism of nanomaterials formation in arc discharge in liquid is still not clear. Such as, the effects of different liquid medium on the products, why the nanotubes formed on the cathode surface but nanoparticles got from the liquid surface. In this paper, a tentative physical model was proposed to explain the nanomaterials synthesis process in liquid arc discharge. In order to study the effect of stability of arc discharge on the characteristics of products, a low frequency cross magnetic field was used to make the arc column swinging.

2.Experiments and results

DC arc discharge was used for the experiments. Two pure graphite electrodes were submerged in liquid, the arc was initiated by slowly detaching the moveable anode from the cathode. The arc gap should keep at the value that the continuous arc discharge can be obtained. Arc current scope is 30~100A.

For arc discharge in water, the cathode size is 20mm in diameter and anode 6mm in diameter. The arc current was selected from 30A to 100A. The anode was eroded during the arc discharge, most of carbon come from anode was reacted with water under the high temperature and turn into gases, part of carbon flow to cathode and deposit on cathode surface, some products float on the water surface and some products deposit at the bottom of liquid container. When the arc current was 60A, reaction gases production rate was 225cm^3 min-1. Analysis by chromatograph showed that the major content of gases produced during the arc discharge in water was CO and others were H2, CO2, C2H2, C2H4, C2H6 and CH4.The percentage of carbon coming from anode went to gases was about 79.66%, and deposition at container bottom was 10.85%, cathode deposition 9.377% and floating products 0.1145%. TEM investigation showed that multi-wall carbon nanotubes were the major content of cathode deposition and carbon-onion found in the floating product. The

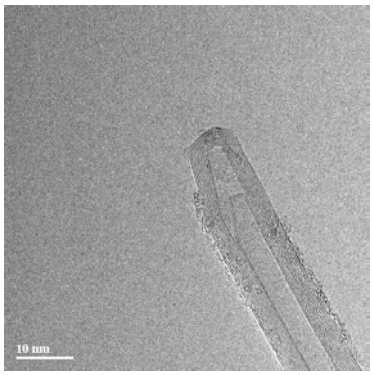

Figure 1. TEM image of multi-wall carbon nanotubes from the cathode deposition of arc discharge in water.

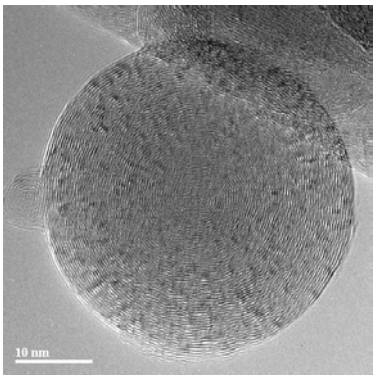

Figure 2. TEM image of carbon onion from floating products of arc discharge in water.

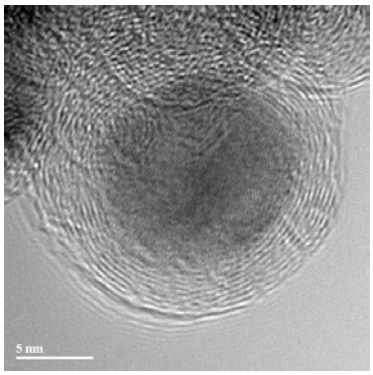

Figure 3. TEM image of cobalt encapsule carbon onion of arc discharge in water.

deposition at container bottom was amorphous carbon. The TEM images are shown in figure 1. and figure 2. The TEM was performed using a H-9000NAR microscope operated at 300 kV. The samples of TEM were prepared by decentralizing the dried powder in ethanol by supersonic, then drop the solution on copper grid.

The effect of catalyst metal was also tested. A hole of 2mm in diameter is drilled in the anode and filled with the mixed powder of cobalt and graphite. Then the arc discharge was conducted in water also. Comparing with pure graphite anode, the cobalt encapsule carbon onions was got from floating products as shown in figure 3.

When the liquid changed to liquid nitrogen, the arc discharge will be more “quiet” compared with that in water and the anode vaporization rate was also lower. If the arc discharge parameters do not change, no nanoparticles could be found in the surface floating products such as carbon onions produced in water. It could be expained that since liquid nitrogen could provide a much stronger cooling effect to the graphite electrodes than water, which made the anode temperature keeping lower and the anode vaporization rate decreased, the nanoparticles could not be formed around the arc column if the density of carbon species were low. So we decreased the anode to 3mm in diameter as the arc current maintained at 60A. The floating products were collected by adding water into the liquid nitrogen after arcing and then collected the floating materials on the water surface after liquid nitrogen completely vaporized. The major content of cathode deposition was multi-wall nanotubes same as arc discharge in water. But the major content of floating product were not carbon onion like in water, it was carbon nanohorns, spherical agglomerate composed of single- wall graphene sheets. The TEM images of carbon nanohorns produced by arc discharge in liquid nitrogen were shown in figure 4.

Besides the temperature gradient, the density of carbon species (carbon atoms or ions) is also the very important parameter for the carbon nanoparticles formation. In order to disturb the carbon species flow come from the anode, the cross magnetic field was introduced for the arc discharges in water, the direction of magnetic field were arranged perpendicular to the arc column and alternate at 5 Hz. The magnetic strength was chosen to get maximum arc swing but not blow out the arc. The density of carbon species from arc plasma became unstable at a certain place out of arc column where the carbon onions being produced. Under this condition, the major products formed in the bubble were some 2 or 3 layers defective carbon nanostuctures as shown in figure 5. The formation of this new structure may be caused by the carbon species (carbon atoms and ions) diffusing out of the arc column become unstable due to the disturb of magnetic field, and the disturb of the magnetic field and the disturb is fast than the carbon-onions formation time.

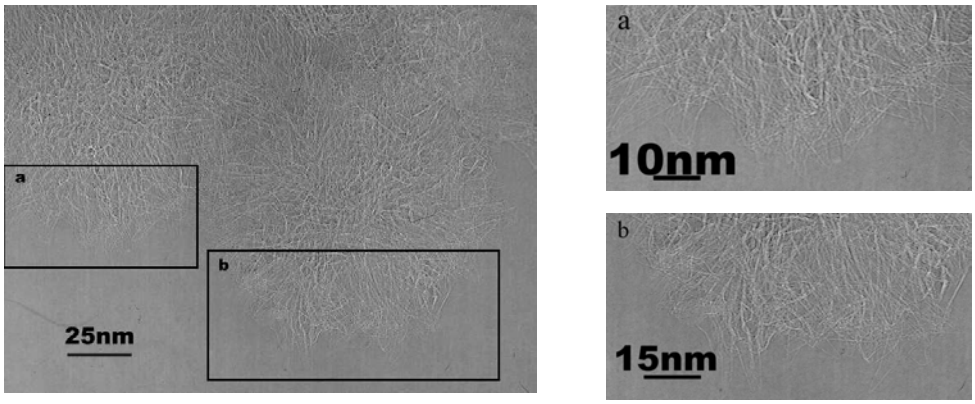

Figure 4. Carbon nanohorns produced by arc discharge in liquid nitrogen

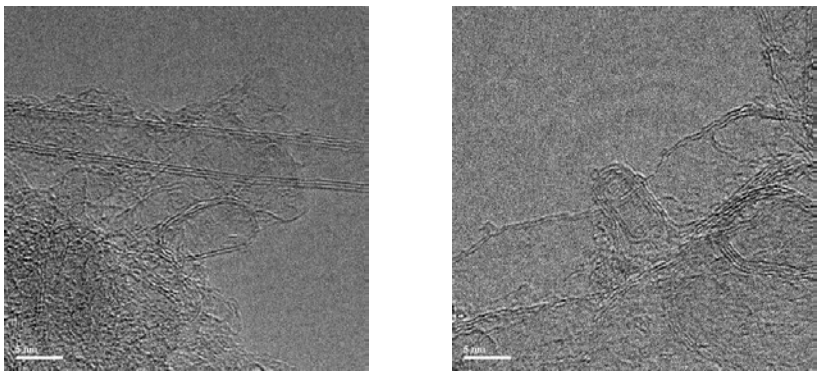

Figure 5. The defective carbon nanostructures produced by magnetic disturb arc discharge in water

3.Tentative Physical Model

After analyzing and summarizing above experimental results and relevant investigations by other researchers, we proposed that the formation of the nanomaterials should be determined by following parameters: directionality of carbon species (carbon ions, atoms and dimers), density of carbon species and quenching effect (temperature gradient).

In most cases, it was the cooling wall where the seeds of nanotubes or nuclei of carbon onions products formed and then growth. The cooling wall provides a relative high temperature gradient that is favourable for seeds or nuclei formation. The pressure of atmosphere gas, if used, may affect the temperature gradient and the moving speed of carbon species.

The carbon vapor density plays an important role in the growing process. Low carbon vapor density will lead only nuclei formation but no further growth. The experiment of the discovery of C_{60} is a good example. The carbon vapor density is not high enough at the large reaction chamber wall, that's why C_{60} formed rather than carbon onions. Certainly, the growth nanotubes also needs a sufficient density. Otherwise, the open end of nanotubes will come to close.

The aforementioned mechanism should be applicable to arc discharge in liquid (water, liquid nitrogen) for the nanomaterials fabrication. The tentative physical model is shown in figure 6. It was assumed that the reaction between carbon and the liquid material does not participate the nanomaterials formation. The major difference between arc discharge in liquid and in gases is that the liquid provides both the cooling for electrodes and an ideal quenching wall (bubble wall). High temperature gradient and high carbon species density near the bubble wall contributed to the small bubble size. As shown in Figure 6, the carbon ions and atoms come from anode and arc

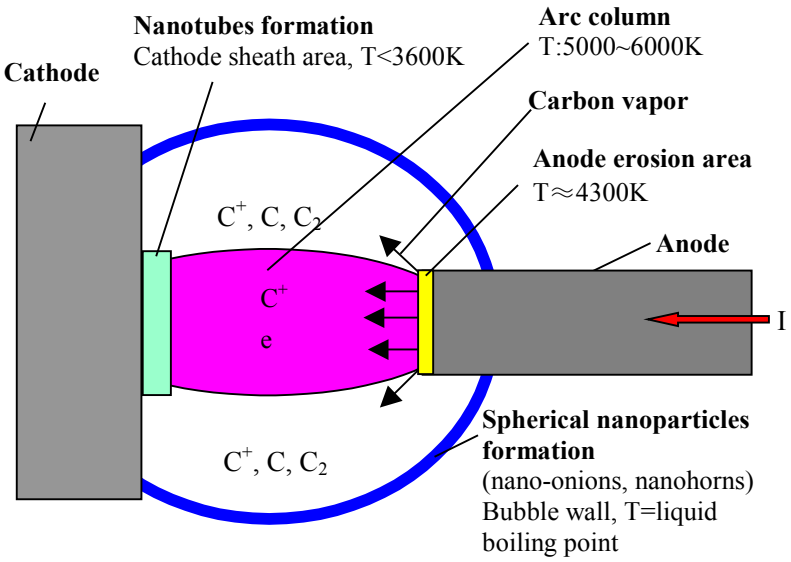

Figure 6. Schematic of physical model arc discharge in liquid

column gradually formed C_2 and further bonded into small fragments as the temperature decreasing when they move toward to cold bubble wall. The cooling sheath near the bubble wall provides a sufficient temperature gradient that is the critical parameter for fullerene and related structures to nucleate and growth. The temperature of liquid nitrogen was much lower than water. So the temperature gradient in the cooling sheath near the bubble wall of liquid nitrogen was higher than that in water. When the fragments move into cooling sheath of liquid nitrogen, they intend to bend due to strong quenching effect and formed single- wall graphene sheets, which finally agglomerate to carbon nanohorns. But in water, the fragments can grow to perfect spherical carbon onions due to the weaker quenching effect. The carbon species flow from anode to cathode formed nanotubes contributed to their directional movement.

4.Conclusion

We experimentally investigated fabrication of carbon nanomaterials by arc discharge in water and liquid nitrogen, carbon onions and carbon nanohorns were produced respectively besides multi-wall nanotubes, and 2 or 3 layers defective carbon nanostructures were produced when cross magnetic field added to arc discharge in water. A tentative model to explain the experiments phenomena was proposed. The major parameters for nanomaterials fabrication should be temperature gradient and the density of carbon species.

Abstract
The diffusion and reaction of oxygen molecules in the expanding thermal plasma (ETP) leads to reduction of the ion density and creation of oxygen atoms. The reduction of the ion density was investigated with a Langmuir probe. An analytical model shows that the ratio of the reaction and diffusion rate governs the mixing behavior. It can at least qualitatively reproduce the experimental results. A computational fluid dynamics (CFD) simulation shows that the assumptions made in the analytical model are justified.

1. Introduction

Expanding thermal plasmas are outstanding in the deposition of a wide variety of materials such as amorphous silicon, diamond-like carbon and carbon-doped silicondioxide [1-3]. Adiabatic expansion of a nearly atmospheric argon plasma into a low-pressure reaction chamber leads to the formation of a stationary, normal shock wave. The deposition precursor is often injected through a ring downstream of the shock. The deposition process can be perfectly controlled because of the strong, spatial separation between the argon plasma generation and the background plasma containing the deposition precursor. Charge transfer between argon ions and precursor molecules, which is followed by dissociative recombination, is an important source of radicals. Therefore, the mixing of argon ions and precursor molecules is an important issue in the deposition of uniform, high-quality thin films.

The influence of oxygen injection on the radial ion density profile was investigated in order to clarify the exact nature of the mixing. Experiments were performed with oxygen because oxygen has a single dissociation path whereas other deposition precursors often have highly complicated dissociation patterns, for example, hexamethyldisiloxane (HMDSO). Besides, oxygen is an important reactant in the deposition of silicon oxides. For example, oxygen is used together with HMDSO to deposit abrasion-resistant, carbon-doped silicondioxide layers on polycarbonate substrates. The dissociation path of oxygen is shown in scheme 1.

Charge Transfer
$Ar^+ + O_2 \quad \Rightarrow \quad Ar + O_2^+$

Dissociative Recombination
$O_2^+ + e^- \quad \Rightarrow \quad 2O$

Scheme 1. The charge transfer and dissociative recombination mechanism of argon and oxygen.

Both the results of experimental work and numerical modeling are presented the next three sections of this paper. First, the ion density in the ETP was measured with a Langmuir probe. The amount of charge transfer followed by dissociative recombination was derived from the difference of the ion density before and after oxygen injection. The measured ion density is thus an indirect measure of the mixing. Second, a numerical model was developed to investigate the diffusion-reaction mechanism. The experimental data were used to validate the results obtained for a 3-dimensional, cylindrical reactor geometry assuming a uniform flow velocity. Third, the full flow pattern was simulated with a commercially available CFD code to investigate all details of the mixing in the reactor and to verify the assumptions of the model.

2. Experiment

The plasma is generated in a cascade arc, which ionizes the argon efficiently at near atmospheric pressure. The plasma flows through a 2.5 mm wide and 30 mm long cylindrical channel after which it expands supersonically through a nozzle into the low-pressure reactor chamber. The reactor set-up was described extensively by other authors [4,5]. Oxygen is injected downstream in the reactor chamber. Good separation of the plasma generation and the plasma chemistry is achieved due to the remote plasma generation. The argon flow was in the range of 500 sccm to 2000 sccm, the oxygen flow in the range of 0 sccm to 200 sccm, the arc pressure in the range of 262 mbar to 714 mbar, and, the reactor pressure in the range of 20 Pa to 200 Pa. The arc current was fixed at 70 A.

The influence of downstream oxygen injection on the plasma properties was investigated with a double Langmuir probe. Radial ion density and electron temperature profiles were measured at a distance of 200 mm from the nozzle. The radial ion density profile is both reduced in height and width after oxygen injection, which is shown in figure 1a. The reduction of the height is exponential as a function of the oxygen density. The reaction is of first order if oxygen is abundantly available. The reduction of the width can only be caused by a higher concentration of oxygen molecules at the sides of the plasma jet. It indicates that the diffusion of oxygen molecules is considerably limited, which is directly related to the short residence time in the plasma jet because of the high flow speed (subsonic). The measurements also show that the injection ring position only has a small influence on the radial ion density profile. It can be explained if it is assumed that the background plasma is well mixed.

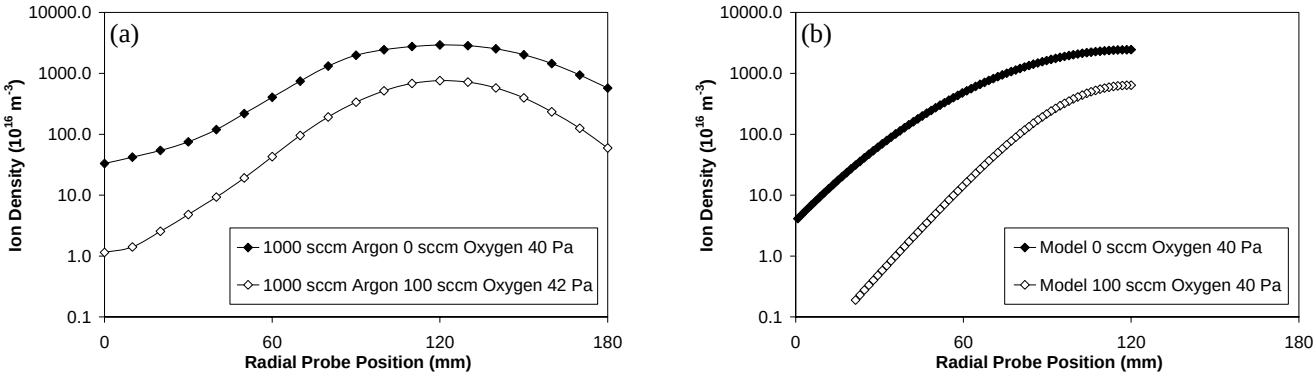

Figure 1. The height and the width of the radial ion density profile decrease if oxygen is injected (a). The calculated radial ion density profiles resemble the experimental results for radial probe positions between 60 mm and 120 mm (b).

The ion density profiles with and without oxygen are approximately Gaussian. The Gaussian form is preserved if the oxygen density profile has a parabolic form. Since the simplest approximation of an arbitrary oxygen density profile is a constant plus a quadratic term, the profile remains approximately Gaussian with oxygen injection. The width and the amplitude that were obtained by curve fitting were used to calculate the ion flow assuming a constant flow velocity of 600 m·s^{-1}. It was found that the ionization degree is approximately 0.1 in pure argon plasmas. Exact analysis of the flow-diffusion-reaction problem is very complicated because radial diffusion of both argon ions and oxygen molecules and their reactions need to be considered. Moreover the axial flow speed is non-uniform requiring a 3-dimensional model. The results of a numerical model describing the basics of process are presented in the next section.

3. Analytical modeling of diffusion and reaction

The flow-diffusion-reaction process was modeled analytically by a set of differential equations each representing one plasma species. Cylindrical reactor geometry is used. The model is a simplified representation of reality yet the main physical processes are included. It is assumed that diffusion from the background plasma into the plasma jet starts after the shock. The residence time before the shock is very short so that little oxygen diffuses into the plasma jet during this period. Further assumptions are: uniform flow velocity (plug flow), no axial diffusion, good mixing of oxygen with the background plasma, and, immediate dissociation after charge

transfer. With these assumptions the transport in the radial direction is governed by diffusion only and the transport in the axial direction is governed by flow only. The plasma jet diameter is constant because the pressure and the flow velocity are constant. The boundary conditions are: zero gradient for all species in the centre of the plasma jet, full recombination of argon ions and oxygen atoms at the reactor walls, and, no recombination of oxygen molecules. The initial argon ion density profile is a Gaussian centered on the middle of the plasma jet. The plasma jet is surrounded by a background plasma containing oxygen with a uniform density. It has been shown that strong recirculation exists, which makes it possible to distribute oxygen throughout the whole reactor. In spite of this, the model does not include recirculation but it assumes that the background plasma is initially well mixed. The experiments show that the reduction of the argon ions does not depend on the injection position, which can be understood if the background plasma is well mixed. The set of differential equations was solved with the Mathematica 5.0 software package. The physical quantities were: uniform flow velocity of 600 $m \cdot s^{-1}$, plasma jet diameter of 29 mm (reactor pressure of 40 Pa), reactor diameter of 159 mm, argon ion diffusion constant of 1.683 $m^2 \cdot s^{-1}$, oxygen diffusion constant of 0.858 $m^2 \cdot s^{-1}$, and, background oxygen density of $1 \cdot 10^{20}$ m^{-3} (partial pressure of 4 Pa). The species profiles are given for distances from 50 mm to 200 mm from the nozzle.

For comparison with the experimental results, the radial ion density profile at the Langmuir probe position before and after oxygen injection are shown in figure 1b. With a rate constant for charge transfer of $2.5 \cdot 10^{-16}$ $m^3 \cdot s^{-1}$, the decrease of the argon ion density is in line with the experiments. The rate constant is in reasonable agreement with the rate constant of $1.5 \cdot 10^{-16}$ $m^3 \cdot s^{-1}$ that is calculated using a reaction cross-section from literature [6]. The radial density profiles of argon ions, oxygen atoms, and, oxygen molecules are given in figure 2. Oxygen atoms are first produced at the edges of the plasma jet. The production in the middle of the plasma jet only starts when oxygen molecules have arrived here. Note that the oxygen atom density profile is fairly flat in the centre.

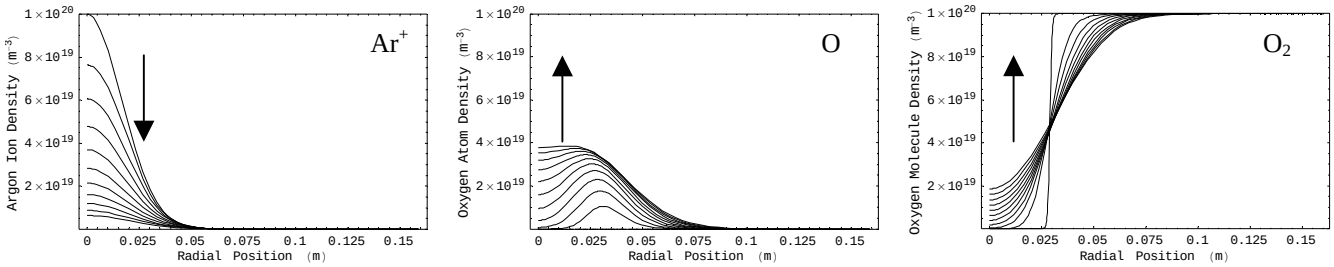

Figure 2. The behavior of the argon ion, oxygen atom and oxygen molecule densities in the downstream region of the reactor. Radial density profiles are given between 50 mm and 200 mm from the nozzle where the arrow shows the direction of the successive curves. The argon ion flux is strongly reduced due to reaction with oxygen molecules. Initially, oxygen atoms are only produced at the sides of the plasma jet. When oxygen molecules have reached the centre, reactions also take place over there. In the end, the oxygen atom density is fairly constant in the plasma jet.

The diffusion of argon ions from the centre of the plasma jet can be observed well when the density profiles are normalized. The narrowing of the profiles as a result of reaction can be observed in figure 3. Depletion of oxygen increases as a function of pressure, which is shown in figure 4. Without reactions the oxygen density in the centre is equal for all pressures. The higher ion density due to compression of the plasma jet leads to a higher reaction rate and more depletion. The relative reduction of the ion density in the centre of the plasma jet decreases.

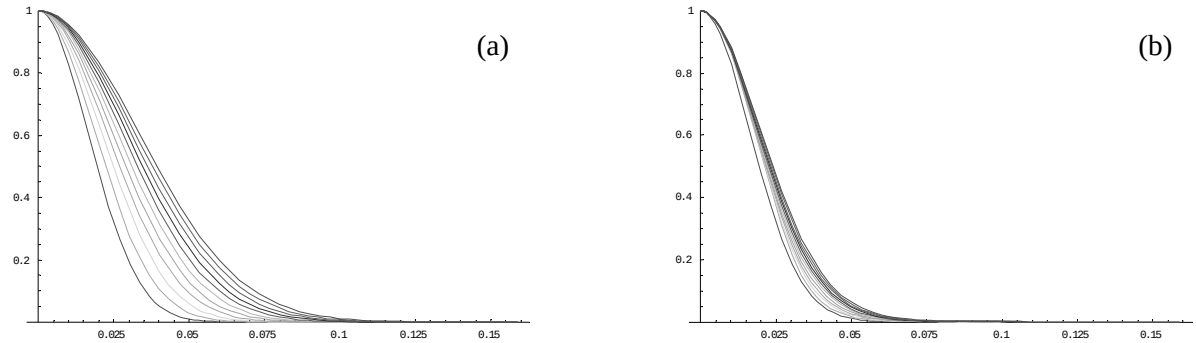

Figure 3. Normalized argon ion density profiles show widening by diffusion if no reactions take place (a). Widening of the argon ion density profiles is reduced as a result of the plasma chemistry, which is in line with the experiments (b).

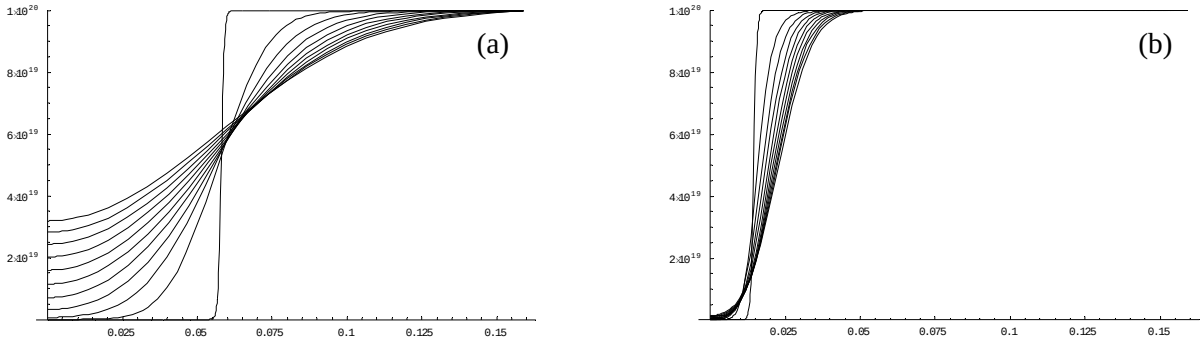

Figure 4. Depletion of oxygen in the centre of the plasma jet increase as a function of pressure. Oxygen density profiles for a pressure of 10 Pa (a). Oxygen density profiles for a pressure of 160 Pa (b).

Depletion of oxygen is a major effect if the reaction rate is larger than the diffusion rate. The balance between reaction and diffusion is given by the second Damkohler number

$$\text{Da II} = \frac{\kappa \cdot n_{Ar^+}}{\frac{D}{d_J^2}}$$

where κ is the rate constant, n_{Ar+} the argon ion density in the plasma jet, D the oxygen diffusion constant and d_J the plasma jet diameter. Note that the oxygen density does not appear in this expression. For a constant argon flow, the characteristic diffusion time, D/d_J^2, does not depend on the reactor pressure because both the plasma jet diameter and the diffusion length are inversely proportional to the square root of the pressure.

Depletion plays a role if the reaction rate is much larger than the diffusion rate. If the ion density is much lower than the oxygen density, all ions are swept by the oxygen diffusion front. On the contrary, if the ion to oxygen density ratio is much larger than one, all oxygen disappears at the edge of the ion density profile. In the situation that the reaction rate is much smaller than the diffusion rate, oxygen will distribute uniformly before significant reaction takes place. In this situation, no narrowing of the ion density profile is observed. In the model, the reaction rate and the diffusion rate are approximately equal. Only a fraction of the oxygen molecules reaches the centre of the plasma jet, which leads to narrowing of the ion density profile because of the higher oxygen density at the edges of the plasma jet. If sufficient oxygen is available, the ion density decreases significantly downstream.

The influence of the reaction rate on the oxygen density profile was investigated. Modeling results are shown in figure 5a, 5b, and, 5c for a reaction rate of 0 $m^3 \cdot s^{-1}$ (no reaction), $2.5 \cdot 10^{-16}$ $m^3 \cdot s^{-1}$ and $10 \cdot 10^{-16}$ $m^3 \cdot s^{-1}$, respectively. The background oxygen density is $1 \cdot 10^{20}$ m^{-3}. For figure 5d, the reaction rate is $10 \cdot 10^{-16}$ $m^3 \cdot s^{-1}$ and the background oxygen density is $1 \cdot 10^{19}$ m^{-3}. The depletion of the oxygen is larger for a higher rate constant, as expected. The reduction of the argon ion density (not shown) is also larger. If the background oxygen density is

reduced by a factor of 10, there is not enough oxygen available to significantly reduce the ion density. The second Damkohler number remains invariably high and oxygen depletion is large.

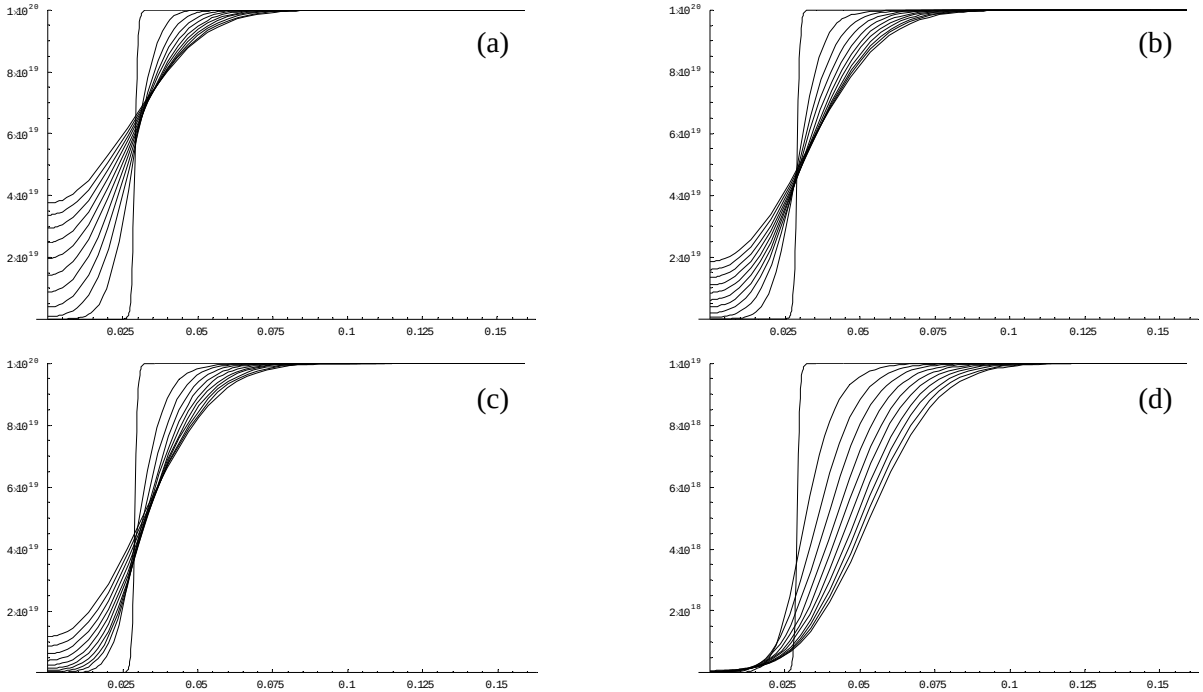

Figure 5. Influence of the reaction rate on the oxygen density profile. The oxygen density profiles if no reactions take place (a). The oxygen density profiles for a rate constant of $2.5 \cdot 10^{-16}$ $m^3 \cdot s^{-1}$ (b). The oxygen density profiles for a rate constant of $10 \cdot 10^{-16}$ $m^3 \cdot s^{-1}$ (c). The oxygen density profiles for a rate constant of $10 \cdot 10^{-16}$ $m^3 \cdot s^{-1}$ and a background oxygen density of $1 \cdot 10^{19}$ m^{-3} (d).

4. Computational fluid dynamics simulation

The supersonic expansion and the subsonic flow in the reactor were simulated using the commercially available CFD code FLUENT 6.0. Simulations of pure argon plasmas have been reported in literature [7]. Nearly the same reactor geometry and physical properties were used in this work. A new element is the oxygen ring injection 50 mm downstream of the nozzle. Ions were not taken into account since they do not influence the flow properties of the plasma much. An argon flow of 3000 sccm is forced into the nozzle at a temperature near 12000 K, and, an oxygen flow of 300 sccm is forced into the reactor at a temperature of 600 K. The reactor wall temperature is set to 300 K. The pressure is fixed at 40 Pa in the pumping region.

The temperature along the symmetry axis of the cylindrical reactor has been plotted in figure 6a. The temperature contours near the nozzle are shown in figure 6b. The shock is clearly visible. However, the temperature jump is only a factor of 2.3 whereas a factor of about 10 is expected on theoretical grounds. The shock thickness is significant compared to the distance from the nozzle to the Mach disk location, which is approximately 42 mm in this case. The shock is thus transparent. As a result, dissipative effects such as viscosity and heat conductivity reduce the temperature jump.

The oxygen mole fraction contours in the entire reactor are shown in figure 7a. The oxygen mole fraction contours near the nozzle are shown in figure 7b. In the background plasma, oxygen has a fairly constant density. Mixing is thus described by diffusion of oxygen from the background plasma into the plasma jet, which was assumed in the previous section. Oxygen can also be found before the maximum of temperature, which indicates that the shock is transparent for molecular transport. In the previous section it was assumed that diffusion starts after the shock. However, the results are still qualitatively correct because the origin of the model is only shifted towards the nozzle.

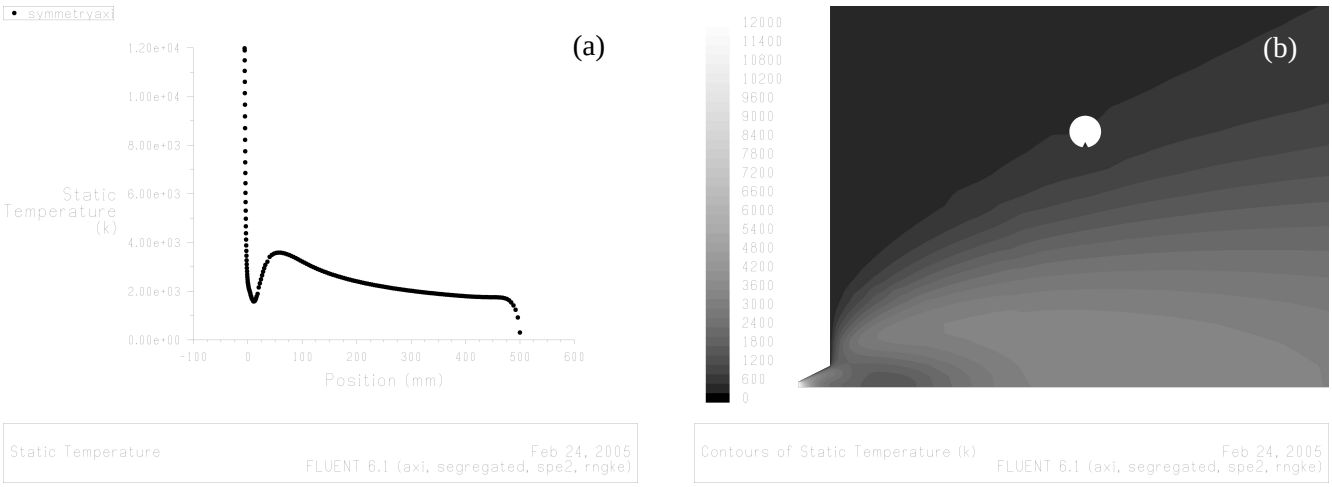

Figure 6. The temperature along the symmetry axis of the reactor shows a clear jump at the shock (a). Temperature contours near the nozzle (b).

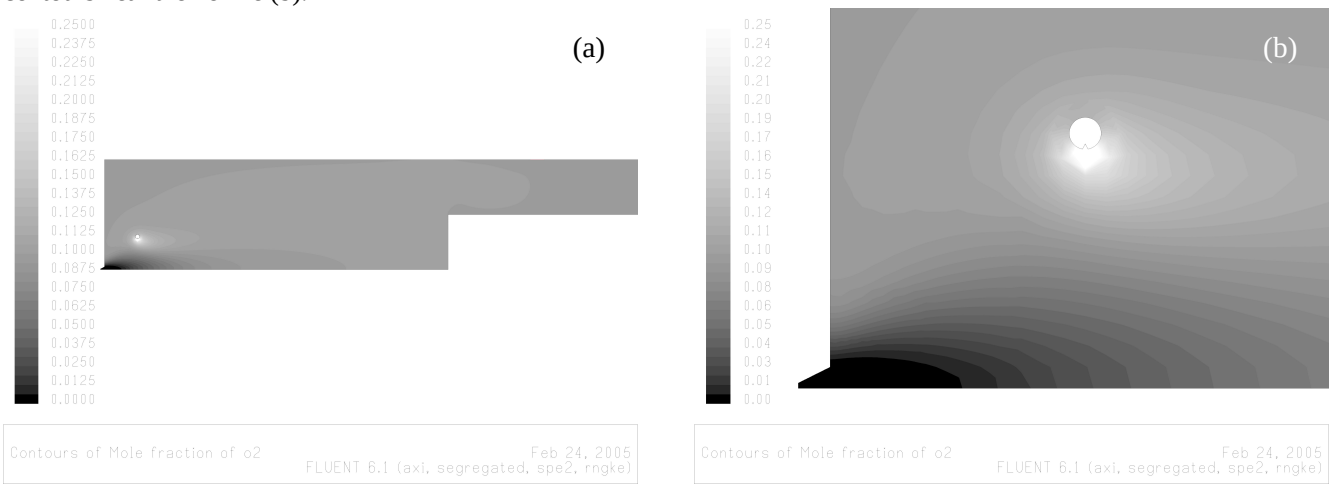

Figure 7. Oxygen mole fraction contours in the entire reactor (a). Oxygen mole fraction contours near the nozzle (b).

5. Conclusion

Both the height and the width of the ion density profiles are influenced by oxygen injection as a result of charge transfer and dissociative recombination. Diffusion of oxygen molecules from the background plasma into plasma jet is a limiting factor. The width is reduced because the oxygen density is higher at the edges of the plasma jet. An analytical model of the flow-diffusion-reaction process describes the main properties of the process well. The numerically calculated reduction of the ion density is in line with the experiments. Depletion of oxygen molecules is observed if the reaction rate is larger than the diffusion rate, which is quantified by the second Damkohler number. More detailed CFD simulations show that oxygen mixes well in the background plasma, which is assumed in the analytical model. However, they also show that oxygen diffuses into the plasma jet before the shock. As a result, the origin of the analytical model should be shifted towards the nozzle.

Abstract

Here we report the results of killing of different bacteria using ambient non-thermal plasma. We have developed a radio frequency driven non-thermal plasma source, which has been shown to be very effective in killing bacteria under controlled conditions. The studies were done for gram negative bacteria *E.coli*, and endospores *B. cereus* and *B.megaterium.* The effect of RF power, exposure time and oxygen concentration on the destruction of these bacteria are discussed.

1. Introduction

Relatively large volume low temperature plasmas are traditionally generated at reduced pressures. However, for practical sterilization/decontamination purposes, to have a vacuum system-based device would be inconvenient and expensive. Today, cold plasmas at atmospheric pressure can be generated by various methods. Amongst these, the Dielectric barrier discharge (DBD) [1] and the Atmospheric Pressure Plasma Jet (APPJ) [2] have been especially researched in the past few years. These devices can generate relatively large volumes of non-equilibrium, low temperature plasmas at or near atmospheric pressure. Air or other gas mixtures can be used. The plasmas produced by these devices have typically electron densities in 10^9 cm^{-3} - 10^{11} cm^{-3} range, plasma power densities in the 10 – 300 mW/cm3, and gas temperatures generally below 100 ^oF. They are sources of UV, visible, and IR radiation, and free radicals such as O and OH, which play important roles in the destruction of microorganisms.

Historically, Siemens used atmospheric pressure plasma (corona discharge) to generate ozone to disinfect water. Later, Menashi [3] used a corona discharge to sterilize the surface of materials. In the mid-nineties Laroussi [1] used a DBD – based diffuse discharge at atmospheric pressure to decontaminate biological media. Other experiments soon followed using various discharge configurations to destroy both gram-negative and gram-positive bacteria, as well as other microorganisms such as viruses.

UV affects the cells of bacteria by inducing the formation of thymine dimers in the DNA [1]. This inhibits the bacteria's ability to replicate properly. By comparing the killing kinetics of UV radiation from a low-pressure mercury vapor lamp and that of atmospheric pressure cold plasma, Laroussi [1] concluded that UV does not play the prominent inactivation role in atmospheric pressure plasmas. This claim was later supported by the work of Herrmann et al. [4] and others.

It has always been recognized that the reactive species, generated in a high-pressure non-equilibrium discharge through electron impact excitation and dissociation, play an important role in its germicidal characteristics. Several investigators showed that discharges containing Oxygen have a strong germicidal effect: The D-value (the time for a one log 10 reduction) decreases if a certain amount of Oxygen is added. This is due to the presence, in such discharges, of Oxygen-based active species such as atomic Oxygen and ozone. Other radicals such as OH have also been found to play an important role in the inactivation process.

Mendis et al. [5] suggested that charged particles might play a very significant role in the rupture of the outer membrane of bacterial cells. They showed that the electrostatic force caused by charge accumulation on the outer surface of the cells' membrane could overcome the tensile strength of the membrane and cause its rupture. They claim that this scenario is more likely to occur for gram-negative bacteria, the membrane of which possesses an irregular surface.

Several reports have been published on the interaction of plasmas with chemical and biological agents, in particular in context of sterilization and decontamination has received much attention in recent years. Particular emphasis has been on the utilization of atmospheric-pressure plasmas as they do not require operation in costly vacuum enclosures and thus facilitate the convenient and low-cost treatment of large surface areas. However, atmospheric-pressure discharge plasmas are highly susceptible to instabilities and the generation and reliable maintenance of uniform, large-volume discharge plasmas at or near atmospheric pressure remain formidable Challenges.

Spore-forming bacteria, in particular bacteria of the genera *Bacillus*, are believed to be among the most resistant microorganisms. The species *Bacillus subtilis* has received particular attention, as these bacteria are easy to grow in a reproducible fashion under chemically well-defined conditions. As a result, *Bacillus subtilis* has been the species of choice in many sterilization experiments in the past (see e.g. Refs. [6], [7], and references therein to earlier work. Reliable and reproducible experimental data on sterilization rates have been obtained by different investigators using a variety of methods and can readily be compared.

First experiments aimed at the quantitative determination of the destruction of spore-forming bacteria, which are believed to be among the most resistant microorganisms, using a novel atmospheric-pressure plasma shower reactor whose design utilizes patented atmospheric-pressure dielectric capillary electrode discharge plasma [8]. In those experiments, N.S.Panikov established a straightforward protocol to prepare and characterize various bacteria including *Bacillus subtilis* on either glass or aluminum surface supports and analyze the samples after treatment by atmospheric-pressure plasma jets emanating from the plasma reactor using either in He or in air (N2 /O2mixture) as a carrier gas at varying power levels and exposure times. They found significant reductions in colony-forming units ranging from 104 (He plasma) to 108(air plasma) for plasma exposure times of less than 10 minutes [4].

2. Results and Discussions

Shown in Fig. 1 is the picture of the plasma source. In the configuration shown, the discharge is "struck" in the noble gas (Argon) and the reactive gas is added to the afterglow. The centered electrode is bored to allow the reactive gases to flow into the afterglow. This is critical for the

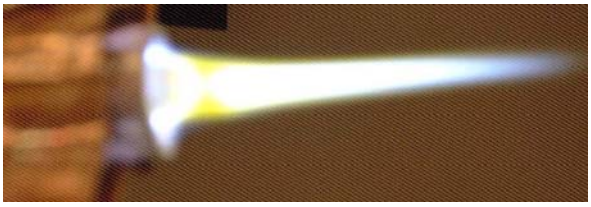

Figure 1: The picture of an atmospheric afterglow in a radio frequency Argon discharge.

stability of the discharge: Gases like H_2 and O_2 are attaching and change the physical characteristics of the discharge. Due to increase in breakdown voltage, even for concentration of reactive gases in few percentages, it is difficult to strike a discharge using radio frequency (RF). RF is the most suitable power source because it can be tuned to the load easily compared to low

frequencies: Low frequency discharges have very high capacitive current, which is difficult to correct. Similar discharges at radio frequency are being investigated [3]. The discharges by Park et al. produce a narrow plasma jet and are stabilized by very high flow of helium at 600 Torr. Our approach does not depend on high gas flow, but uses a dielectric to stabilize the discharge. The dielectric is alumina with an outer diameter of 6.4 mm and an inner diameter of 2.4 mm. The inner electrode is 1.6 mm in diameter, and the active discharge length is 30 mm.

The mechanism of destruction of microorganism by nonthermal plasma is not very well understood. However, we have shown that the UV in the atmospheric pressure plasma does not play an important role. This was done by allowing the UV from the plasma to pass through a quartz window without the direct contact of the bacteria to plasma. Therefore it may be concluded that plasma chemical reactions are important in the destruction of microorganisms.

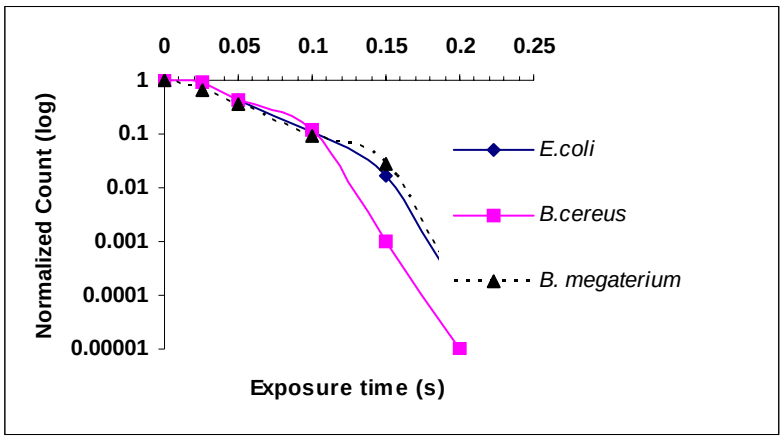

Figure 2: Fractional surviving colonies after treatment with RF plasma.

The OH radicals are strong oxidizing agents. In an Argon/Oxygen plasma the following

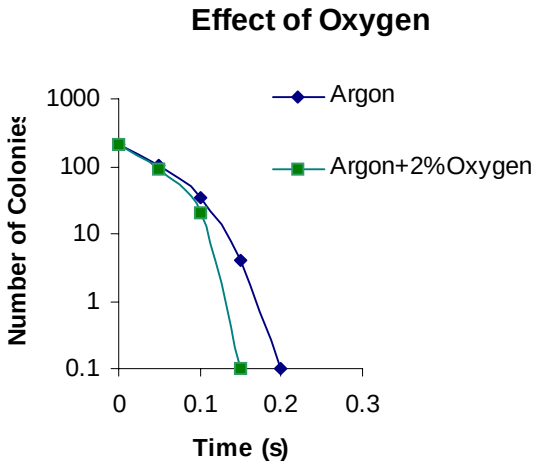

Figure 3: The killing of bacteria for an Argon and Argon/Oxygen plasma.

additional electron impact reaction is present

$$O_2 + e \rightarrow O + O^* + e$$

$$H_2O + O^* \rightarrow 2OH$$

Therefore addition of oxygen to Argon plasma produces additional oxidizing radicals and is more effective as an oxidizer. However, when the oxygen concentration is above 2-3% of the total gas, it starts to affect the discharge negatively. Since oxygen is an electronegative gas, it scavenges electrons in the plasma to form negative ions. The depletion of the electrons in the plasma leads to instabilities.

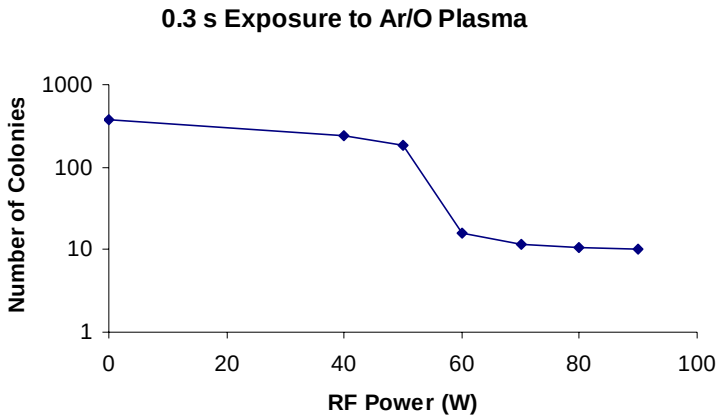

Figure 4: Number of surviving colonies as a function of applied power for an exposure time of 0.3 s of RF plasma.

We used several Bacillus subtilis strains such as Bacillus subtilis in its colonial morphologies, prototypical examples of spore-forming bacteria. We also used non-spore-forming bacteria (*E.coli*) for selected experiments for comparison. The bacteria were sub-cultured on agar plates. The spore suspensions were obtained from homogeneous batch cultures grown on chemically defined media.

Experiments aimed at the quantitative determination of the destruction of all kinds of bacteria especially spore-forming bacteria, which are believed to be among the most resistant microorganisms, were carried out using an atmospheric-pressure plasma. Various well-characterized cultures of Ecoli, Bacillus Cereous, Bacillus Magaterium were prepared, placed in petri dish, subjected to atmospheric-pressure plasma jets emanating from dielectric barrier discharge, RF plasma generator using either in Ar or Oxygen (Ar/O2 mixture) as a carried gas at

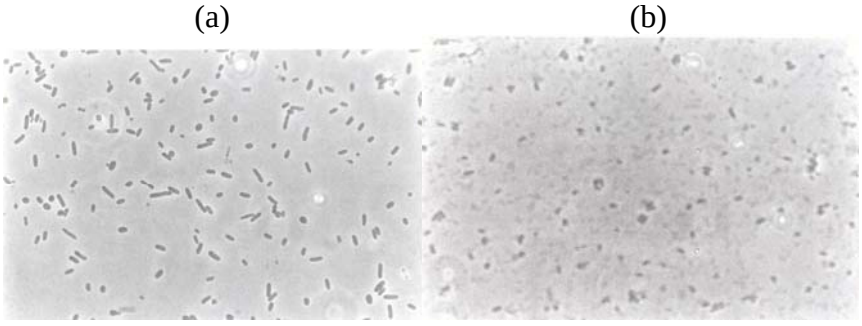

Figure 5: (a) Unexposed *Bacillus megaterium* 1000x photomicrograph, (b) *Bacillus megaterium* 1000x photomicrograph, exposed to RF plasma for 0.25 s.

varying power levels and exposure times, and analyzed after plasma treatment. A reduction in colony-forming units by exposure of the bacteria to ambient afterglow plasma is shown in Fugure 2. All three type of bacteria show rapid reduction of colonies with increasing exposure time. Within 0.25 s exposure time, all three bacteria show a reduction by an order of 4. The maximum cell kill rate was found in the presence of oxygen. The results of surviving colonies for argon and argon/oxygen mixture are shown in Fig. 3. Due to the presence fo Oxygen in the Ar/O_2 mixture, radicals such as O and OH are formed which are very effective in destroying the bacteria. Figure 4 shows the kill rate as a function of power for exposure time of 0.3 s. There seems to be optimum power at which maximum killing is achieved. Increasing power produces diminishing returns because at high power a large fraction of the energy goes into heating.

Figure 5 shows microscopic observations of unexposed *Bacillus megaterium* samples with 1000x magnification. Figure 4.11 shows microscopic observations of exposed *Bacillus megaterium* samples with 1000x magnification. In Figure 4.11 you can see debris and lice of dead *Bacillus megaterium* cells caused by exposure to plasma. Montie and coworkers have shown that non-thermal plasma is capable of sterilizing both porous and nonporous surfaces at standard pressure and temperatures [1]. They have shown that plasma kills different types of microorganisms including bacterial vegetative cells, bacterial endospores, viruses, and fungi (yeast). Their data suggests that membrane lipids are the most vulnerable macromolecule of the cell to atomic oxygen attack.

3. Conclusions

Non-thermal Dielectric barrier discharge and radio frequency plasmas have been shown to be effective in destroying different types of bacteria. Since the RF plasma has more power density, it is more effective in destroying the microorganisms. *Escherichia coli,* which is a most common bacterium, is easily destroyable when compared to *Bacillus cereus* and *Bacillus megaterium*. *Bacillus cereus* and *Bacillus megaterium* are spore-forming bacteria and so it is hard to destroy them. *Escherichia coli,* when treated with Dielectric barrier discharge took lot of time to get the same killing rate as that of when treated with RF discharge. So, using RF discharge is much more effective when compared with Dielectric barrier discharge for destruction of bacteria.

Abstract

A radio frequency driven atmospheric-pressure afterglow plasma source is discussed. The light intensity measurement shows that the discharge is continuous in time unlike low frequency dielectric-barrier discharges, which are intermittent in nature. The discharge, under ambient conditions, can be generated in Argon, Helium and Nitrogen. Trace amounts of N_2 or O_2 in Ar or He produce dissociated N and O respectively.

1. Introduction

At atmospheric pressures, there are two popular methods for producing non-thermal plasmas; (1) a corona discharge and (2) a barrier-type ac discharge. Although corona discharges have found numerous applications, they are not particularly suitable for large surface or volume gas phase plasma processing [1]. The dielectric-barrier discharge, also known as a silent discharge or a partial discharge, is widely used in industry for ozone synthesis. These discharges are best characterized by streamers, which are a result of space charge dominated transport at high electric fields [2] A disadvantage of existing plasma sources is that the specific energy (energy per unit volume of the processing gas) is low. This is a major shortcoming for adaptability to manufacturing processes. We have taken a different approach for the generation of plasma under ambient conditions.

2. Results and Discussions

Shown in Fig. 1 is the picture of the plasma source. In the configuration shown, the discharge is "struck" in the noble gas (Argon) and the reactive gas is added to the afterglow. The centered electrode is bored to allow the reactive gases to flow into the afterglow. This is critical for the stability of the discharge: Gases like H_2 and O_2 are attaching and change the physical characteristics of the discharge. Due to increase in breakdown voltage, even for concentration of reactive gases in few percentages, it is difficult to strike a discharge using radio frequency (RF). RF is the most suitable power source because it can be tuned to the load easily compared to low frequencies: Low frequency discharges have very high capacitive current, which is difficult to correct. Similar discharges at radio frequency are being investigated [3]. The discharges by Park et al. produce a narrow plasma jet and are stabilized by very high flow of helium at 600 Torr. Our approach does not depend on high gas flow, but uses a dielectric to stabilize the discharge. The dielectric is alumina with an outer diameter of 6.4 mm and an inner diameter of 2.4 mm. The inner electrode is 1.6 mm in

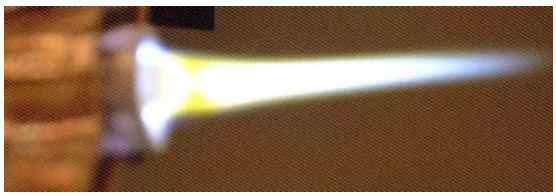

Figure 1: The picture of an atmospheric afterglow in a radio frequency Argon discharge.

diameter, and the active discharge length is 30 mm. For the RF discharge discussed in this paper, the air gap capacitance, c_g= 4.1 pF and the dielectric capacitance, c_d=9.2 pf, and the excitation frequency is 13.56 MHz. The electric field (E_m) is the highest on the surface of the inner electrode and is given by

$$E_m = \frac{c_d}{c_d + c_g} \frac{V}{a \ln(b/a)} \quad (1)$$

Where V is the applied voltage and a and b are the inner and outer radius of the air gap respectively. In the RF discharge the argon breakdown occurs around 575 V, which corresponds to a peak field of 12 kV/cm, which is less than the static breakdown voltage of argon of 15 kV/cm at atmospheric pressure [4]. This is expected for frequencies, f, greater than the critical frequency, $f_c = v_+ / (\pi d)$ where v_+ is the argon ion mobility, and d the typical dimension of the air gap [4]. In atmospheric pressure argon discharge, the positive ion mobility at a field of 12 kV/cm is approximately 1.5 cm^2/Vs [5]. For our discharge with an air gap of about 0.4 mm, we estimate the critical frequency to be 145 kHz. The discharge is in the mobility-controlled region as the frequency (13.56 MHz) is lower than the second critical frequency, $f_{c0} = v_e / (\pi d)$ for diffusion-controlled discharge [5]. For an electric field of 12 kV/cm, the electron drift velocity, $v_e = 5\times10^6$cm/s at atmospheric pressure and the f_{c0} is about 40 MHz [6]. The discharge electrodes do not play any significant role at these pressures and the DC bias on the powered electrode is measured to be near zero.

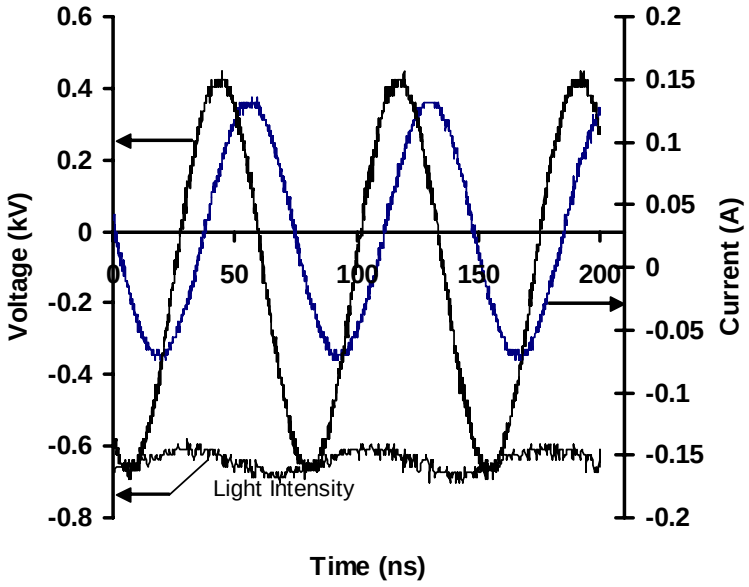

Figure 2: The waveforms for current, voltage, and the integrated light output for the RF discharge.

Figure 2 shows the RF current through the discharge and the voltage across the discharge. The RF current was measured with IPC CM-10-M (0.1 V/A into 50Ω) current monitor. The current waveform is sinusoidal indicating a temporally uniform discharge. Also shown in Figure 2 is the total light intensity. Again, the light is uniform in time therefore the discharge at 13.56 MHZ is temporally uniform. Low frequency dielectric barrier discharge is intermittent and show spikes in the current waveform [3].

The discharge power, P, in a dielectric-barrier type discharge is given by [3]

$$P = 4 f V_c' [c_d V_p - (c_g + c_d) V_c] = 4 f V_c' c_d [V_p - \frac{(c_g + c_d)}{c_d} V_c] \quad (2)$$

where f is the power frequency, c_g and c_d are the gap and dielectric capacitance respectively, v_p, v_c', and v_c are the peak to peak applied voltage, the critical gap voltage required to sustain a discharge, and the critical voltage at which the gap breaks down, respectively. The voltages v_c and v_c' are nearly equal, however we have observed that v_c' tends to be lower than v_c [5]. This equation shows that the power input to a dielectric type discharge has a linear dependence on voltage. At low frequencies, dielectric-barrier discharges show these characteristics for all gases [4, 8]. However for a discharge continuous in time, the power absorbed per unit volume, Vol, in a field $E=E_0 \cos(\omega t)$ is given by [9]

$$\frac{P}{Vol}=\frac{1}{2}\frac{e^2 n_e}{m_e \nu}\frac{\nu^2}{\nu^2+\omega^2}E_0^2 \qquad (3)$$

This shows a square dependence on the applied field. The power versus voltage plot of the RF discharge shown in Fig. 3 is consistent with Eq. 3. The dependence of discharge power is faster than linear as expected for a continuous discharge. Therefore the RF discharge at atmospheric pressure is continuous unlike low frequency dielectric-barrier discharges.

The light intensity measurement shows that the discharge is continuous in time unlike low frequency discharges, which are intermittent in nature. The gas temperatures are near ambient and the afterglow temperatures do not exceed 85°C. Spectroscopic measurements show that He and Ar metastables in the discharge produce excited Nitrogen and Oxygen atoms.

In plasma chemical devices, the aim is to produce desired radicals to carry out a particular reaction. The main thrust for atmospheric pressure plasma for our application is the production of H and O radicals and Ar ions. For efficient cleaning the production of radicals rather than gas heating is important. The ambient afterglow discharge is a cold discharge with most of its energy being utilized for the production of excited species. In He/Air plasma the following electron impact processes will be present

$$He + e \rightarrow He^+ + 2e \text{ and } He^* + e$$
$$He^* + N_2/O_2 \rightarrow \text{excited species}$$

Figure 4 shows a typical spectrum of the afterglow Helium plasma in ambient air. The ambient afterglow discharge is a cold discharge with most of its energy being utilized for the production of excited species. The afterglow interacts with the ambient gas and a typical optical emission spectrum of the helium afterglow is shown in Figure 4. The highest peak in the spectrum is the transition $O^*(3p \rightarrow 3s)$ at 777.2. Clearly the He metastables excite the oxygen molecules to produce excited

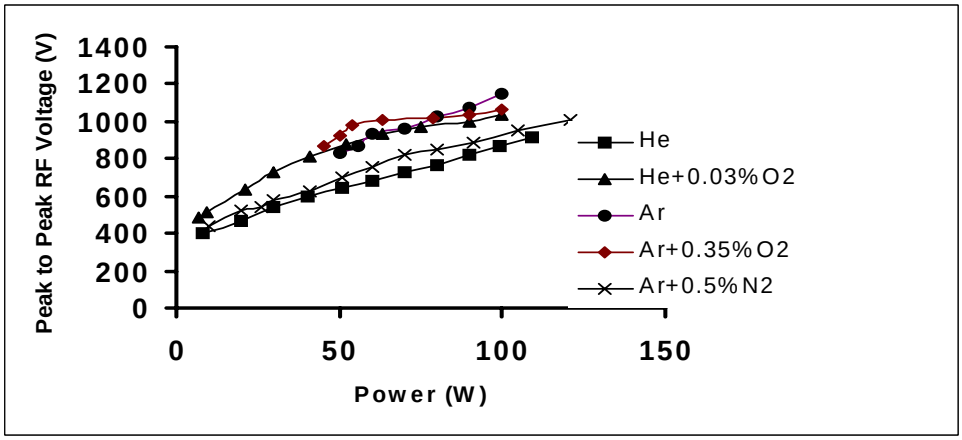

Figure 3: The RF peak voltage versus power for different gases.

oxygen atoms.

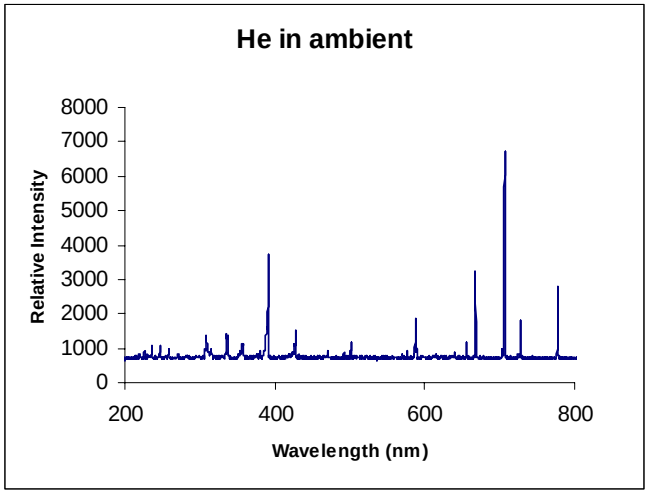

Figure 4: Optical emission spectra of He afterglow in ambient air.

In metal surface cleaning experiments, the afterglow plasma with a 1% hydrogen additive was very effective in cleaning metal surfaces. Figure 5 shows the XPS analysis of a stainless steel surface treated with and without plasma. Both the He and Ar afterglow plasmas are very effective in removing organic contaminants.

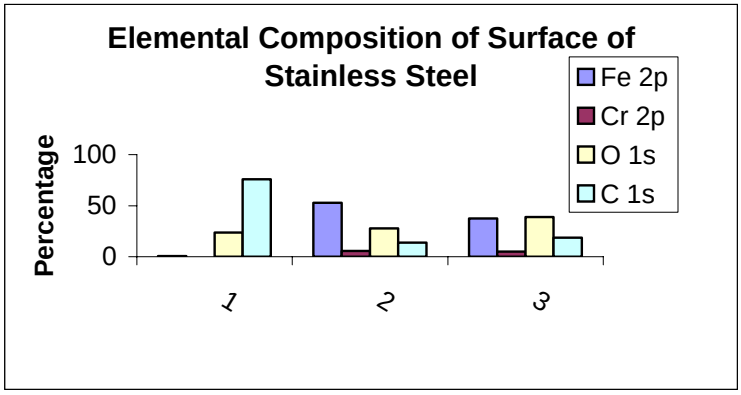

Figure 5: XPS analysis of stainless steel surface. The blank sample of steel has a coating of adhesive on it. (1) The surface composition of the blank. (2) The surface after 30 seconds of Ar/H_2 plasma treatment. (3) The surface composition after 30 seconds of He/H_2 plasma.

3. Conclusions

In conclusion, an ambient afterglow plasma source driven by RF power source has been demonstrated, which is continuous in time and behaves like a glow discharge. The discharge is stable for non-attaching gases and small concentration of additives. The afterglow has excited species that can be used for plasma chemical reactions.

This research work was partially supported by a grant from the National Science Foundation.

Study of anode phenomena in dc arc plasma torch by electric probes

O. Chumak, M. Hrabovský, T. Kavka, V. Kopecký

Thermal Plasma Department, Institute of Plasma Physics, Prague, Czech Republic

Abstract
Currents on electric probes connected to an anode via biasing resistances were measured in an anode region of arc in dc plasma torch. Existence of conductive layer near an arc column and flowing of the diffuse currents onto the anode surface upstream of constricted anode attachment position is showed. This current is assumed to be controlled by distributed resistance of the intermediate layer between highly conductive arc core and an anode surface. Importance of anode surface roughness and shape for the diffuse current distribution is discussed.
Keywords: anode attachment, plasma torch, arc fringe

1. Introduction

Anode processes have strong influence on plasma properties and flow character of a plasma jet generated by dc arc plasma torch. Arc attachment to an anode surface, which is parallel to arc column in typical plasma torch is commonly represented by bright constricted current channel. Dc arc torches usually works in so called restrike mode that is characterized by periodical movement of the anode attachment in stream-wise direction followed by ignition of new anode attachment in an upstream position and accompanied with sudden decrease of arc voltage and shortening of the arc [1]. This phenomenon causes fluctuations of arc power as position of the arc root determines arc voltage [2, 3]. Downstream movement of arc root is caused by gas dynamic drag acting on arc attachment in gas flow in the arc fringes and by action of self-magnetic field on current loop in the anode region. The mechanism of sudden restrike in the upstream position is not fully understood and often is referred as breakdown. Another hypothesis assumes existence of diffuse current flowing through conductive intermediate layer between the arc column and the anode surface and thermal building of the new attachment [4].
Our previous measurements with electric probes reveal significant currents flowing to the probes in the fringes of arc column in positions close to the anode [5]. However, these measurements were made in a free boundary of arc, where physical conditions could be substantially different from conditions in a gap between conductive arc column and the anode surface. Therefore in present experiments the probe measurements were made in a situation, which better simulates conditions in an anode region of dc arc plasma torches. Electric probes were housed into steel cube, which was connected to anode via ballast resistor to simulate anode surface around the probes.

2. Experimental set-up

Anode region of dc arc plasma torch WSP-500H with hybrid argon-water stabilization of arc [6] was investigated. The torch has an external anode and thus observation and investigation of the anode region is possible. The anode is created by water cooled rotating copper disc. The Active surface of the electrode is parallel to plasma jet axis as in common plasma torches, as it is shown in Fig. 1a. The anode was positioned 12 mm from the exit nozzle in order to create long stable free arc for measurements of current and potential distributions along it. Plasma torch working parameters were not changed during experimentation: arc current was 300 A, argon (secondary plasma forming gas) flow rate was 12.5 slm, nozzle with diameter 5.6 mm was used. These parameters correspond to plasma torch power 75 kW, plasma jet axial temperature at the nozzle exit 17000 K and diameter of the high radiative plasma jet core about 4 mm.
For simulation of the anode the stainless steel cube connected to the anode via ballast resistor was used. Resistance 0.5 Ω was chosen for limitation of current to the cube in order to prevent formation of constricted attachment of arc. To avoid overheating the cube was driven transversally to the jet through boundary layer with the speed of about 1 m/s. The cube movement was considered to have no influence on plasma jet as plasma has

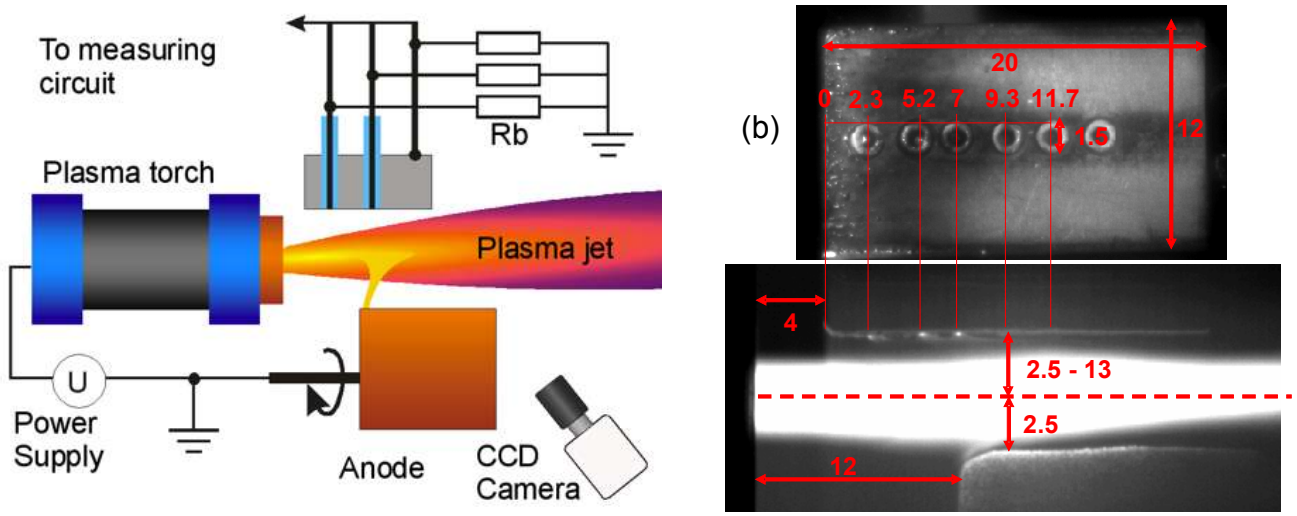

Fig. 1. Schematic picture of experimental setup (a), photo of the cube with the probes e from the bottom(b) and photo of anode region(c). All dimensions are in mm.

velocity three orders higher than cube speed. The anode region and the cube passing the jet fringes were photographed by fast shutter CCD camera with exposure time 10 μs.

Five molybdenum wires (probes) insulated by ceramic tubes were housed into the cube (Fig. 2b, 2c) for measurement of the current distribution. The probes had plain end surface and were 0.6 mm in diameter. Insulator tubes were made of alumina, and had inner diameter 1 mm and outer diameter – 1.5 mm. As the wires had smaller diameter than insulator tubes, it was difficult to determine their active surface gathering the current. But since all probes had the same dimensions, it can be assumed that they had the same area of active surface. The probes and ceramic tubes ends were aligned with bar surface. The alignment accuracy was estimated to be ±0.2 mm. Probes were connected to the anode via biasing resistances with values varying in the range of 0.53-8.3 Ω. The probes and cube potentials were recorded by oscilloscope with time resolution of 1 μs.

3. Results and Discussion

An example of an oscilloscope record of signals from the five probes and from the cube is shown in Fig. 2a. An accompanying photo (Fig. 2b) of the anode region was taken at the time corresponding to 15 ms in the oscilloscope record. The increase of the probe current due to movement of the probe towards the jet is followed by the current decrease when the probe moves from the jet. It is evident that a layer between the cube surface

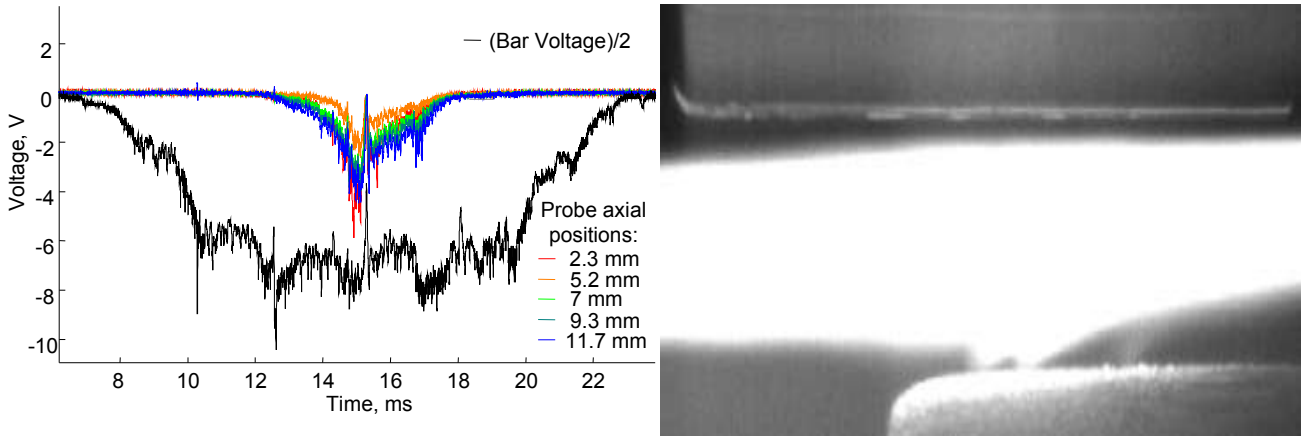

Fig. 2. Signals of the probes in different axial positions (a) and accompanying photo (b) of anode region. Probe biasing resistance is 4.7 Ω, bar – 0.56 Ω. Distance of the bar from the arc axis is 3 mm.

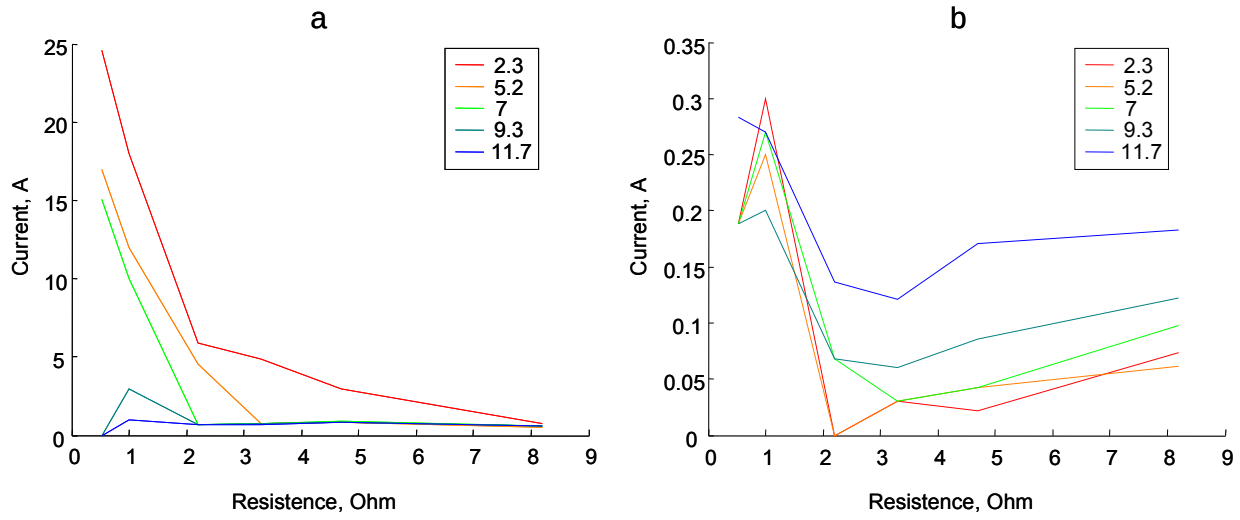

Fig. 3. Dependence of probe current on biasing resistance for different axial positions along the (in mm) jet at radial distances 2.5 mm (a) and 4 mm(b) from the plasma jet axis.

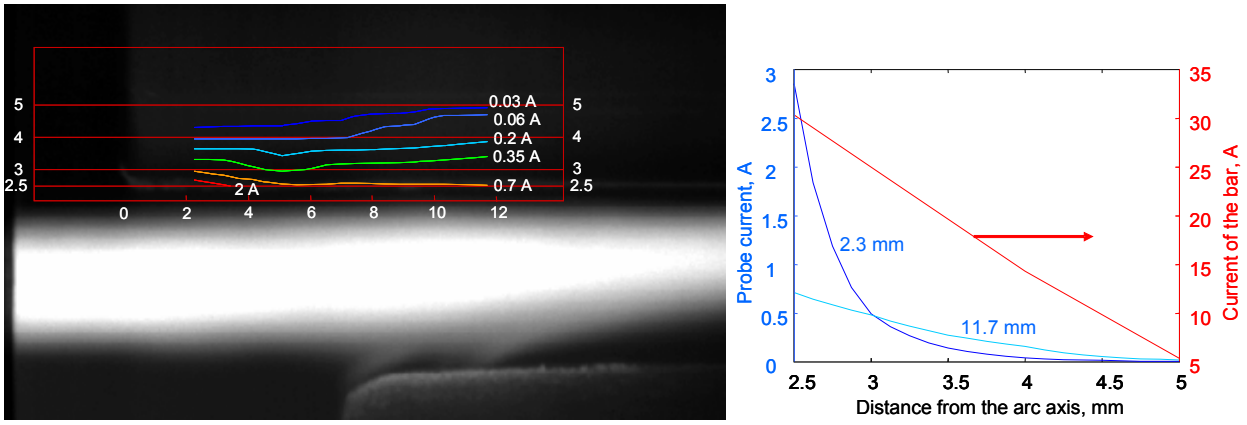
and the arc core is conductive. The signal of the cube current has similar rise and decrease, but it has steady maximum because of cube width. The current to the cube was about 28 A during the passage of the cube above the arc. Although this current is relatively high, no spot on the cube surface was found on the images of the cube. It seems that the current is distributed over the cube surface without constriction of current carrying channel.

In Fig. 3 the probe current at two distances from the arc axis and for different axial positions is shown in dependence on biasing resistance. At the distance 3 mm from the axis (Fig. 3 a) low biasing resistance allowed flowing of currents high enough to establish a thermal current channel. Evaporation from the probe surface is observed in these cases on the images of the probes. For biasing resistance 3.3 Ω and higher at both radial distances the probe currents were much lower and no constricted current channels were observed on photos. Moreover for biasing resistances 8.2, 4.7, 3.3 Ω and sometimes for 2.2 Ω the probe current almost did not depend on biasing resistance, which implies an independence on the voltage difference probe-plasma.

In Fig. 4a an axial distribution of probe currents for different radial distances from the arc column axis is shown in the form of contours of the same current. This type of visualization is chosen for better demonstration of development of the intermediate layer along the jet. The current contours were evaluated from repeated measurements of probe currents at different radial distances of the cube. Diffuse currents were considerably



(a) (b)

Fig. 5. Distribution of probe current (axes are in mm), and dependence of bar current and probe current for two axial positions on radial distance.

lower for higher distances of the cube from the arc axis. The shape of the counters changes with increasing distance from the jet axis, which represents the changes of axial distribution of current. For distances closer than 3 mm the current decreases stream-wise of the jet, while for distances higher than 4 mm the current increases. At the distance 3.5 mm the current was almost constant. Probe currents for two axial positions and cube current are shown in Fig. 4b. For the upstream position 2.3 mm the dependence of the current on radial distance from the arc is much steeper. It can be expected that for distance of anode surface in range 2.5-3 mm from the axis most current flows in the part closest to a nozzle. Bar current decreases linearly with increase of distance from the axis, and almost disappears at 5 mm.
Changes of diffuse current axial distribution can be caused by two effects. The first effect is broadening of the conductive core downstream the plasma jet, caused probably by heating of intermediate layer, convection and developing of instabilities. Second effect concerns magnetic interaction of anode attachment with plasma jet causing deflection of plasma jet opposite to the attachment and toward the cube, as can be seen on the photos (Fig. 2b). Both effects seem to be much weaker for the cube position closer to the jet.

4. Summary

Electric probes measurements were provided in anode region of plasma generated by dc arc plasma torch. Anode surface was parallel to arc column axis, like in common plasma torches. Probes were housed into the steel cube, which simulated anode.
Currents flowing on probes in the fringes of the arc column prove existence of conductive layer between the arc column and the anode surface. The currents had diffuse character. It was confirmed by absence of bright constricted channel at a current of 28 A flowing onto the cube surface. Diffuse current axial distribution was found to depend strongly on distance from the arc axis As strong dependence of probe current on distance from the arc axis was found it can be concluded that shape and relief of anode surface can strongly influence diffuse current distribution on anode surface.

Abstract

We used low-pressure microwave plasma to treat plastic substrate in pure CF_4. The plastic surface has changed into very high wettability. The super-hydrophilic surface is made by using a mask and controls the gap between the mask and substrate.

1. Introduction

Low-pressure plasma is widely used for the surface modification of various materials, such as increasing the adhesion between the polymers and the metal and changing the wettability of materials [1-3]. In general, oxygen-containing plasma can be used to enhance the wettability of polymers, whilst CF_4 plasma treatment can improve its hydrophobicity. In our study, it is a little against to the general concept. We used low-pressure microwave plasma to treat plastic in pure CF_4. The plastic surface has changed into very high wettability. The super-hydrophilic surface is made by using a mask and controls the gap between the mask and substrate. The contact angle measurement, atomic force microscopy (AFM) and x-ray photoelectron spectroscopy (XPS) are using for characterizing the surface properties.

2. Experiment

In these experimental, plasma treatments were performed on DuPont Kapton® HN polyimide films with a thickness of 25 μm. The Kapton films, cut in a sample size of 5 cm× 5 cm and mounted on a sample frame, were plasma treated using a commercial installation of Plasma Systems 400 from PVA Tepla .The microwaves of 2.45 GHz are applied through a window in the wall of the vacuum chamber producing an extended plasma.

The chemical natures of the treated films were measured by X-ray photoelectron spectroscopy (XPS). The XPS measurements were carried out in a Thermo-VG- Scientific Escalab 250 system using a monochromatized Al Kα (1486.6 eV) x-ray .Photoelectrons were collected at a take-off angle of 90^o with respect to the sample plane. The reference binding energy was set at 284.6 eV for the C-C component of C 1s peak.

The surface roughness and morphology of the Kapton films before and after plasma- treated was measured with an Atomic Force Microscope (AFM). AFM measurements were performed with a scanning probe microscope SPA 300HV (Seiko Instrument Incorporation, Japan) in air at room temperature, operated in the contact mode and using a silicon nitride tip.

The contact angles of water on Kapton surface were measured at room temperature by the sessile drop technique with VCA 2500XE surface analysis equipment (AST Products Incorporation, USA). For each sample, the contact angle value reported here was the mean of five locations where uniformly distributed on each sample was measured.

To obtain patterned metal copper by first patterning plastic substrate by using a mask in glow-discharge plasma treatment, then performing electroless copper plating to obtain metal copper within the regions of mask shielded, that is, hydrophilic area.

3. Results and discussion

Table 1 shows the water contact angle and relative peak areas of curve-fitted spectra for C (1s) .TyKaptoncal C (1s) spectrum for the CF_4 treated Kapton films and untreated Kapton film are shown in Fig.1. The C (1s) spectrum for untreated Kapton film [Fig. 1(a)] is fitted with four peaks. The carbon atoms in Phenyl ring at 284.6 eV, the carbon atoms singly bond to oxygen or nitrogen at 285.7 eV, the carbonyl carbons appear at 288.6 eV, and the π-π* shake up peak at 290.6 eV. The C (1s) spectra of plasma treatment on shielded and nonshielded surface are shown in Figure 1(b) and 1(c). CF_4 plasma treatments of Kapton films result in an enormous amount of fluorine incorporation at the surface. There is a dramatic change in the C (1s) XPS envelope, which can be attributed to formation of fluorinate carbon functionalities: $\underline{C}FH\text{-}CF_2$ at ～286.9 eV, $\underline{C}F_2\text{-}CH_2$ at ～290.5 eV, and $\underline{C}F_2\text{-}CF_2$ at 292.2 eV [4-6]. From table 1, there is abundant fluorine atoms incorporated to the non-shielded Kapton surface. The water contact angle raises to 108 deg is its appearance. F/C ratio increases to 1.51 and O/C ratio is only 0.17 at non-shielded Kapton surface. On the contrary, the shielded Kapton surface after plasma treatment is exhibiting super hydrophilic property, that is, lower than 5 deg. The F/C ratio is only 0.21 and O/C ratio rises from 0.18 to 0.36.

Glow discharge plasmas generally consist of energetic particles (e.g., positive ions, electrons, free radicals, metastable species and photons). The plastic surface with the energetic particles breaks the covalent bonds on the surface of the bombarded polymer and leads to the formation of the surface radicals on the treated polymer. These surface radicals interact with the active plasma species to form various functional groups on the surface of polymer. Furthermore, the predominant reactive components of CF_4 plasma are reported to be F atoms and relatively low concentrations of CF_n (n = 1, 2, 3) radicals [7-8]. With a low CF_n/F ratio, CF_4 does not polymerize in plasma, it can produces fluorination through a direct grafting of F atoms onto polymer surface [9-12]. Therefore, the fluorine atoms in the CF_4 plasma undergo hydrogen abstraction and substitution reaction at the Kapton surface yield $\underline{C}FH\text{-}CF_2$, $\underline{C}F_2\text{-}CH_2$, and $\underline{C}F_2\text{-}CF_2$ functionalities.

Table 1: The water contact angle data and relative areas for cure-fitted XPS data for CF_4 plasma treated Kapton

Treatment		Untreated Kapton	Shielded substrate	Nonshielded substrate
Water Contact Angle (degree)		76.08 ± 1.211	< 5	108.275 ± 0.657
	F/C	0.00	0.21	1.54
	O/C	0.18	0.36	0.17
% C (1s)	C-C/C-H	40.18	26.47	11.67
	C-O/C-N	45.99	36.76	0.00
	O=C/$\underline{C}$FH-CF_2	13.83	25.73	32.50
	$\underline{C}F_2$ -CH_2	-	5.15	41.67
	$\underline{C}F_2$ -CF_2	-	5.88	14.17

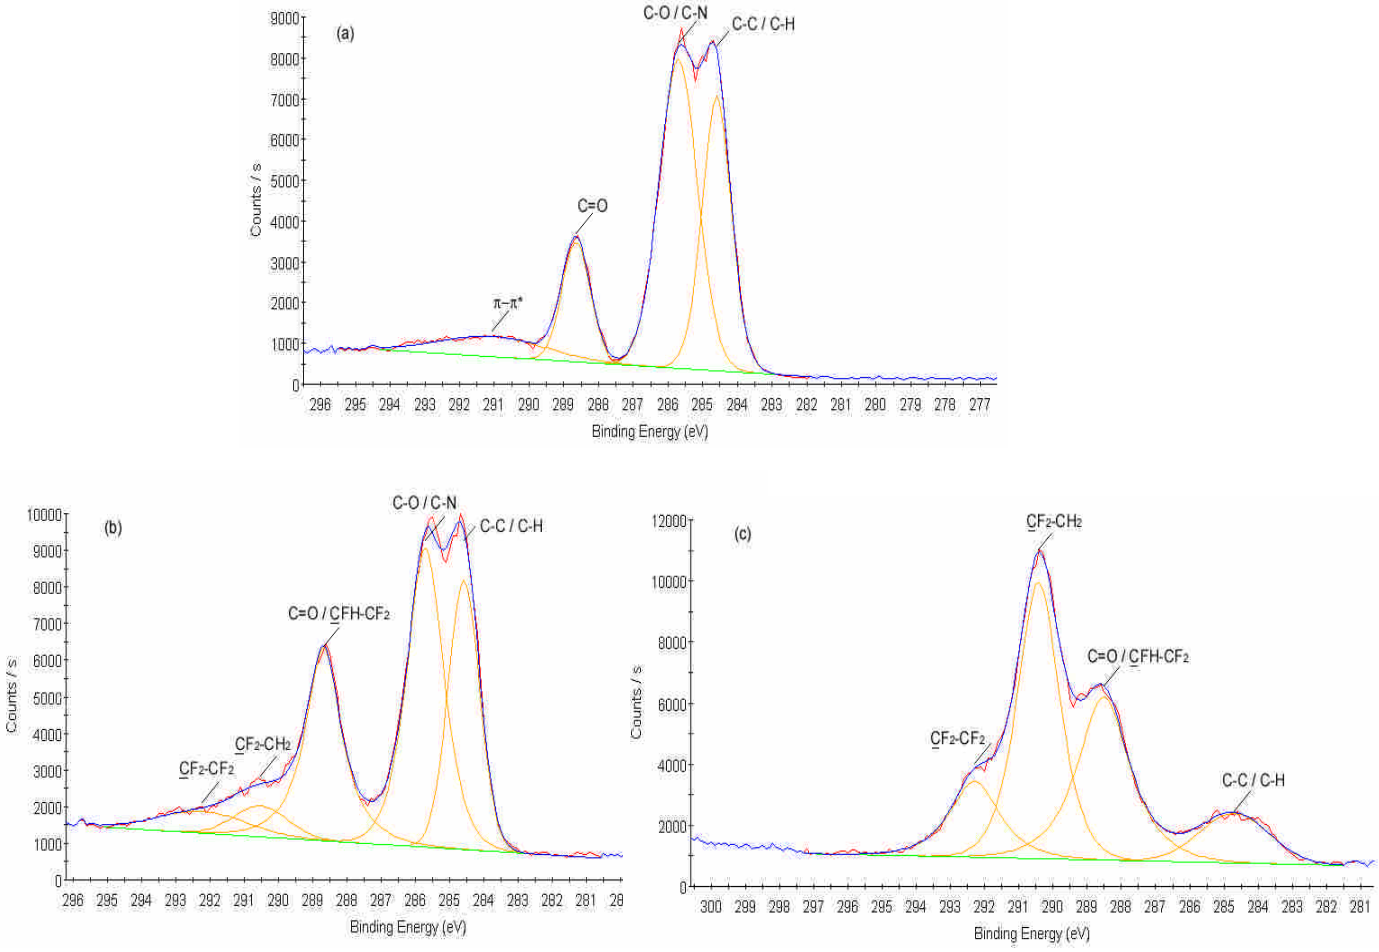

Fig. 1. XPS C(1s) spectra for untreated Kapton film (a), an CF_4 plasma treated shielded substrate (b), and an CF_4 plasma treated nonshielded substrate.

To evaluate the influence of plasma treatment upon surface physical nature, AFM analysis was performed with both the untreated Kapton and plasma treated Kapton. The results are shown in table 2. The difference of RMS value for the non-shielded surface (0.50 nm) is much larger then those for the shielded surface (0.23 nm). This is the case that the non-shielded surface with the more energetic particles bombarded than shielded surface and therefore the reactions on both surfaces were dissimilar.

Table 2: The surface roughness of CF4 plasma treated Kapton films

Treatment	RMS (nm)	ΔRMS (nm)
Untreated Kapton	0.59	-
Shielded area	0.82	0.23
Nonshielded area	1.09	0.50

RMS : Root-mean-square height
ΔRMS : Difference of RMS

Figure 2 is the optical microscopy image that is finished patterning hydrophilic and hydrophobic surface by plasma surface modification then fabricating a metallic pattern on plastic substrate. The Metal Cu is only growth at hydrophilic area and its shortest line width is 180μm.

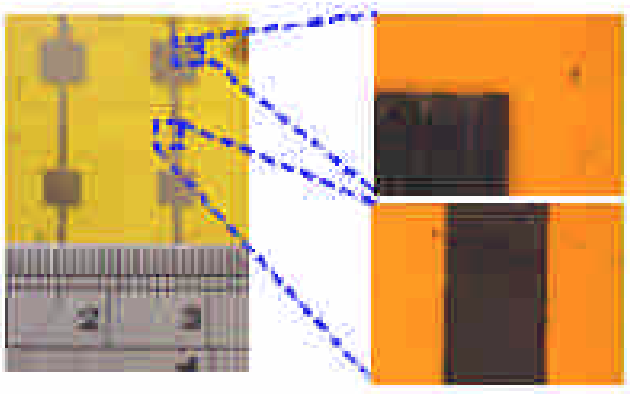

Fig. 2: Optical microscopy image of a copper pattern onto a Kapton surface.

4. Conclusions

In the conclusion, we succeed in getting super-hydrophilic surface on plastic substrate, by using microwave plasma with pure CF_4 and a mask with certain distance to the substrate. The contact angle measurement and XPS analysis result indicate the non-shielded surface, water contact angle is 108 degree and the O/C and F/C ratios are 0.17 and 1.54, respectively. On the other hand, the shielded surface is less than 5 degree, the O/C and F/C

ratios are 0.36 and 0.21, respectively. Furthermore, we have also success in fabricating a metallic pattern on plastic substrate patterning metal on plastic substrate without photo lithography process. The Metal Cu is only growth at hydrophilic area and its shortest line width is 180μm.

Abstract

The synergy of the plasma-photocatalyst combination for Volatile Organic Compounds (VOC) removal is investigated using a pulsed DC discharge at low pressure (210 Pa). The photocatalyst is TiO_2 and the VOC is acetylene 1000 ppm in dry air. Time resolved Tuneable Diode Laser Absorption Spectroscopy (TDLAS) in the mid infrared region is performed in-situ the discharge tube to measure the decrease of C_2H_2 during 1 s plasma pulse duration. The respective influence of external ultraviolet radiation and of the plasma exposure, with and without photocatalyst is checked. It is shown that the combination of plasma and ultraviolet radiation in presence of TiO_2 pellets leads to a strong increase of the C_2H_2 oxidation efficiency.

1. Introduction

Indoor air cleaning has become a new technological challenge for odours or diluted pollutant removal. Photocatalysis is based on the oxidation of molecules on the surface of a porous semiconductor material illuminated with ultraviolet radiation; the main advantage of this technique is that it leads to complete oxidation of Volatile Organic Compounds (VOC) to CO_2 and salts [1]. It was recently shown that the combination of photocatalytic material with a non-thermal plasma activates the oxidation process [2-7]. The synergy between the plasma and the photocatalytic material leads to a higher CO_2/CO ratio (selectivity) [2,7], as well as a better oxidation efficiency [3,7]. Up to now there is no clear explanation concerning the reason of such a synergy of the photocatalyst by the non-thermal plasma. When TiO_2 is located inside the discharge region, it is bombarded by ultraviolet radiation generated by excited nitrogen molecules, by charged particles, by metastable states of molecules and atoms, and by ground states O and N atoms. However, atmospheric pressure plasmas such as Dielectric Barrier Discharges (DBD) are strongly non-uniform and direct in-situ measurements are not possible. In the present study, to avoid this major difficulty, time resolved and in-situ absorption spectroscopy measurements are performed in the positive column of a low pressure pulsed DC discharge, which is approximately spatially homogenous. This gives a practical way to study the plasma-photocatalyst interaction by Tuneable Diode Laser Absorption Spectroscopy (TDLAS) in the infrared region. Moreover such DC discharges have been extensively studied in continuous current by two groups, Gordiets et al. [8] and Smirnov et al. [9]. Therefore, plasma parameters such as reduced electric field, plasma density and temperature are known for various set of experimental conditions. We report the time evolution of C_2H_2 under plasma exposure, with or without TiO_2 pellets, with or without additional ultraviolet irradiation.

The pulsed discharge is ignited in a 47 cm long (59 cm optical length) and 2,1 cm inner diameter pyrex tube (Figure 1).

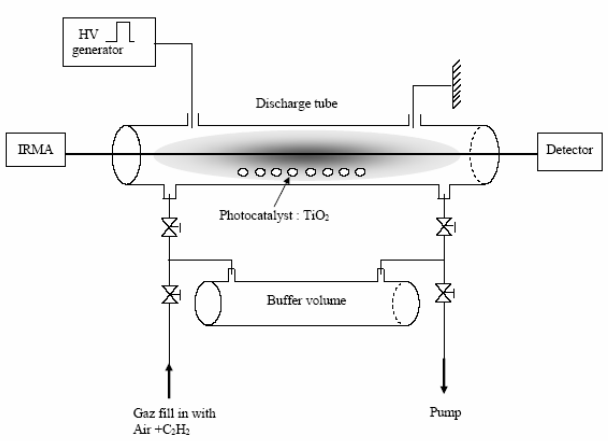

Figure 1. Experimental set-up showing the pulsed DC discharge containing TiO_2 pellets and the in situ laser absorption spectroscopy

2. Experiment

The pulsed DC generator delivers a current of 3 mA, with a pulse duration of 1 s. Commercially available TiO_2 pellets (20g of pure anatase, Alfa Aesar #43828, size specific surface 37 m^2/g) may be introduced inside the tube. Experiments are performed under static conditions: dry synthetic air N_2/O_2 = 80/20 % (< 3 ppm of H2O and 0,5ppm of hydrocarbons) is first pre-mixed to reach 900 ppm C_2H_2 in a buffer volume, the discharge tube being pumped out to a base vacuum of less than 5 Pa. The pre-mixed gas is injected in the discharge tube, which is then closed, the pressure being equal to 210 Pa. When TiO_2 pellets are present inside the discharge tube, part of the injected C_2H_2 molecules are adsorbed until a steady state is reached (Figure 2); following this, pulsed TDLAS measurements are performed starting from the steady state conditions shown in Fig. 2.

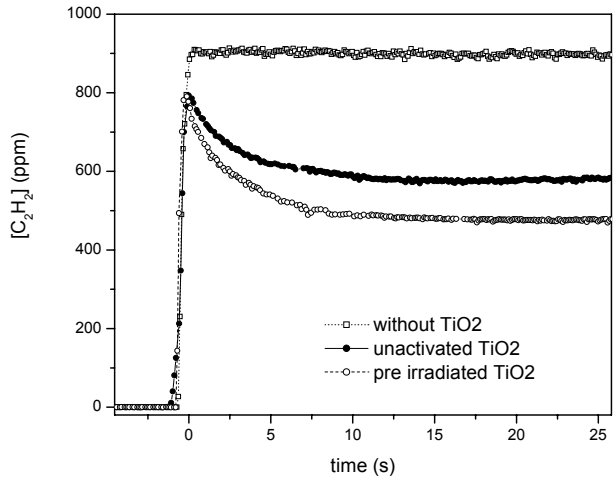

Figure 2. Filling of the discharge tube showing adsorption of C_2H_2 on TiO_2 pellets: time evolution of the C_2H_2 concentration, without pellets, with TiO_2 pellets, with TiO_2 pellets after UV irradiation. Pressure 210 Pa.

In order to check the influence of external ultraviolet radiation, two mercury lamps (Philips PL-L 24W/10/4P) were mounted parallel to the discharge tube axis.

In-situ laser absorption spectroscopy is performed on C_2H_2 molecule by single path through the discharge tube (Figure 1). The infrared diode laser is a helium cooled IRMA, described in Röpcke et al.10, which may be externally triggered and provides a pulse resolution of 0.46 ms. C_2H_2 density is deduced from the Beer's law:

$$I(\nu) = I_0(\nu)\exp[-k(\nu)L] \quad (1)$$

where I(ν) is the transmitted radiation intensity, $I_0(\nu)$ is the incident intensity on the sample, k(ν) is the absorption coefficient per unit length and L is the total absorption path length. The integrated absorption coefficient over frequency, Kν, for a homogeneous sample is

$$K_\nu = \int_\nu k(\nu)d\nu = \frac{1}{L}\int_\nu \ln\left(\frac{I_0}{I}\right)d\nu = N\,S(T) \quad (2)$$

where N is the total density of the absorbing species; S(T) is the line strength of the rovibronic transition used for species measurement. The temperature increase during the plasma pulse was estimated to be less than 50°C from thermal diffusion equation; hence, the temperature dependency of S(T) was neglected. At room temperature (296 K) the line strength value was taken from Rothman et al. 11 to be 3.65 x 10^{-19} cm molecule-1. In the present work a strong line of C_2H_2 which is located at 771,40482 cm^{-1} has been used. The IRMA system measured the integrated absorption coefficients, then by using the line strength value, absolute concentrations were obtained.

3. Results

The steady state density of C_2H_2 is about 900 ppm, without TiO_2 pellets inserted inside the discharge tube. On the contrary, when the discharge tube is filled with the pre-mixed gas in the presence of TiO_2 pellets, its steady state density is only 580 ppm. This means that about 36 % of the injected C_2H_2 is adsorbed on the TiO_2 pellets with a characteristic adsorption time of about 3.5 s (Figure 2). Let us notice that N_2/O_2 molecules are not adsorbed since no measurable pressure drop is observed during C_2H_2 adsorption. Figure 2 also shows the time evolution of C_2H_2 density when the discharge tube contains TiO_2 pellets, which have been irradiated by UV lamp just before filling. At the steady state about 47 % have disappeared from the gas phase, which is notably higher than without UV pre-irradiation. We have no evidence whether this is due to an increase of the adsorption efficiency or if it is partly due to an oxidation of C_2H_2 on the pre-irradiated photocatalyst. It is worthwhile to notice that such a pre-irradiation effect last for more than 20s (time between pre-irradiation and filling of the discharge tube).

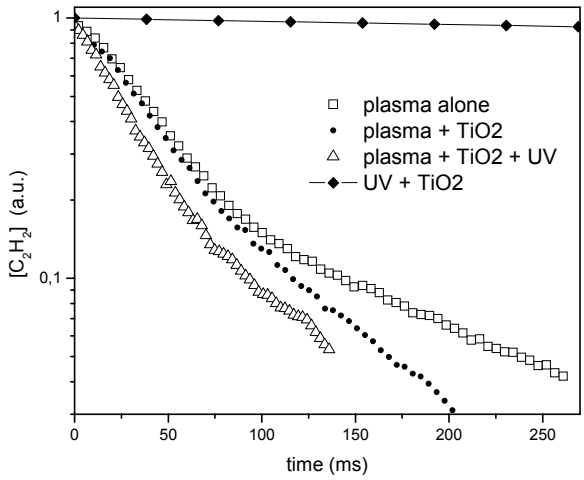

Figure 3 shows the time evolution of C_2H_2 (for first 250 ms) during a 1 s pulse duration for different experimental conditions.

Most of the curves show a bi-exponential decay of C_2H_2 and the corresponding characteristic frequency are presented in Table 1.

case	Conditions	1st decay frequency (s^{-1})	2nd decay frequency (s^{-1})
a	UV + TiO_2	0.33	-
b	Plasma only	20.8	7
c	Plasma + TiO_2	22.2	14
d	Plasma + TiO_2 + UV	30.3	14

Table 1: Decay frequencies for different experimental conditions. 1st and 2nd decay frequency refer to the biexponential function of C_2H_2 time evolution.

For case b (plasma only), the decay frequency is reduced by a factor 3 (from 20.8 to 7 s^{-1}) about 100 ms after the beginning of the pulse. The electron density and reduced electric field being about constant during the pulse duration, such an effect must be attributed to gas phase kinetics between neutrals. When some photocatalytic surface is inserted inside the plasma region, the decay decreases only by 37 % (from 22.2 to 14 s^{-1}). This may be due either to surface oxidation of C_2H_2 and/or to a modification density of oxidative radicals and molecules in the gas phase.

The presence of photocatalytic pellets lead to a very small increase of the first decay frequency from 20.8 to 22.2 s^{-1} (case b, c). This shows that, for low pressure conditions, plasma only is not able to activate efficiently TiO_2. More over, it was recently shown, under similar experimental conditions that the reduced electric field E/N increases from 80 to 92 Td [12]. From Fig. 3 we conclude that C_2H_2 destruction in the gas phase is not controlled by electron impact dissociation since an increase of electron energy does has no definite influence on the C_2H_2 destruction frequency.

The most interesting result is the strong synergetic effect obtained when the plasma is combined with TiO_2 pellets with external UV irradiation (case d). The 1st decay frequency is increased from 22.2 s^{-1} in the case of plasma / TiO_2 combination (case c) to 30.3 s^{-1} when external UV irradiation is added (case d); this represents a 36 % increase of the C_2H_2 decay frequency. Hence the photocatalytic effect of TiO_2 irradiated with UV is strongly enhanced when non-thermal plasma is added: the decay frequency increases from 0.33 s^{-1} (case a), to 30.3-22.2 = 8.1 s^{-1} (case d). Hence, TiO_2 is much more effectively activated by UV when exposed to the plasma and the photocatalytic activity is increased by a factor of 25. The reason of such a synergy may be due a priori to : i) enhancement of electron-hole pair formation; ii) promotion of oxidative radicals in the gas phase, which are activated by photocatalysis onto the TiO_2 surface, iii) desorption of adsorbed C_2H_2 or intermediate oxidative products.

First, there is no clear evidence as to why exposure of TiO_2 to the plasma should lead to an increase of electron-hole formation (hypothesis (i)); it is well known that the plasma generates UV in the 330–390 nm region (2nd positive system of nitrogen molecules), which are, in principle, suitable for photocatalysis; however, comparing cases b and c shows that UV produced by the plasma itself do not lead to appreciable photoactivation of TiO_2 (22.2 s^{-1} vs 20.8 s^{-1}), because the UV flux produced by the plasma is much weaker than the one produced by the UV lamps.

Second, plasma produces active species such as O atoms, O_2 (1Δ) molecules as well charged particles; this species may be adsorbed on the TiO_2 surface. It was recently shown by Roland et al [13] that a porous surface, such as silica or alumina located inside the plasma region increases oxidation processes of pollutants, because of the presence of physi- or chemisorbed species on the surface of the pores. O atoms created by the plasma may be adsorbed on the TiO_2 surface and react with adsorbed C_2H_2. This could also contribute to the small increase of the decay frequency from case b to case c. However, when external UV irradiation is applied to the TiO_2 surface, electron-hole pairs may activate these adsorbed species and increase the oxidation rate of C_2H_2.

Third, it is more likely that, in the present study, plasma bombardment increases the number of adsorption sites as shown by Cartry et al. [14] under similar experimental conditions; it was also shown by Futamura et al. [2] , under atmospheric pressure conditions, that the cleaning effect of plasma bombardment prevents deactivation of TiO_2 catalyst.

Conclusions

Time resolved laser absorption measurements have been performed in the gas phase of a pulse d plasma exposed to a photocatalytic material (TiO_2 anatase). It was shown that:

i) the combination of a non thermal plasma with photocatalysis leads to a strong increase of photocatalytic activity by a factor 25.

ii) Under our experimental conditions, UVs generated by the plasma itself are insufficient to ensure such a synergetic effect.

Therefore the observed synergetic effect is due to an increase of the photocatalysis efficiency when the photocatalytic material is exposed to species produced by the plasma such as radicals, excited molecules, ions… Additional work is needed to understand the mechanisms of plasma-photocatalysis synergy and to characterize the oxidation products: activation of adsorbed species by electron-hole pair or an increase of the number of adsorption sites.

Abstract: The dispersion of TiO_2 nanoparticles after acrylic acid plasma coating was measured by ultraviolet absorbency measurements. The results showed that the absorbency of TiO_2-glycol suspensions reached an optimal value at certain discharge power. The EDLVO theory of colloid stability was applied to simulate the potential energy of TiO_2 nanoparticles in glycol according to the surface energy measured. It was found that the potential maxima in the EDLVO curves matched well with the optimal dispersion values.

1.Introduction

Functional organic/inorganic composites are attracting more and more attention and interest these years. In these kinds of materials, the properties of composites directly depend on the aggregation state of nanofillers. Only when the inorganic phase is dispersed at a nanoscale level in the matrix phase [1-5], some composites with special functionality can be formed. However, nanoparticles are difficult to well disperse in the background media due to severe agglomeration and high ratio of surface area to volume. Hence, dispersion is the "bottleneck" problem to hinder the applications of nanoparticles.

TiO_2 nanoparticle is one of the most studied transition metal oxide for various applications ranging from pigment, ultraviolet light absorber, visible light photo catalyst, gas sensors, etc. A lot of novel composites and fibers with good functions are prepared based on its special properties and the dispersion state in the medium. Many studies have been reported about the surface modification of TiO_2 nanoparticles [5] to obtain well-dispersed composites by chemical methods. But the rare is done on surface coating of TiO_2 nanoparticles by pulsed plasma polymerization. It is not only a simple, dry state and environmental-friendly process operating at room temperature but also suitable to all kinds of inorganic, organic, solvable and insolvable nanoparticles.

In our previous study [6], a plasma polymer coating of acrylic acid (AA) has been successfully applied to the surface modification of TiO_2 nanoparticles. This allows us to effectively control the desired chemical components, physical morphology and thickness of the coating on particle surface by adjusting discharge parameters. So in the present study the surface energy of TiO_2 nanoparticles is measured and calculated through a custom-built measurement system and Lifshitz-van der Waals/acid-base (LW-AB) approach. The dispersion investigation of AA-coated TiO_2 nanoparticles in glycol solution is carried out by ultraviolet absorbency measurement experimentally and potential simulation between particles through the extended DLVO (EDLVO) theory (A further application of this project is to obtain TiO_2-polyester composite, then glycol is selected as the dispersion medium). The aim of this work is to correlate the ultraviolet absorbency results of TiO_2-glycol suspensions with the discharge parameters, the surface properties as well as the surface energy of nanopowders to investigate the dispersion behaviors and even explain the dispersion modifications of surface-coated TiO_2 nanoparticles in glycol solution.

2.Experimental

2.1 Surface coating

TiO_2 nanoparticles (rutile) were coated in a custom-built fluidized bed reactor [6] through exposing to AA plasma. At first TiO_2 nanoparticles with a primary mean size of 35nm were put into the reactor. Then a base pressure in the reactor was pumped down to less than 3 Pa. The mixture of monomer and carrier gas (argon) in a certain ratio was introduced into the reactor to fluidize the nanoparticles through a porous plate and mass flow controllers. Finally the RF plasma generator (13.56 MHz) was turned on at gas pressure of 150 Pa, gas flow rate of 15 sccm, pulsed rate of 15% and coating time of 4 hours. To obtain desired surface coating on nanoparticles, the discharge power was changed in turn.

An amorphous thin film about 3-5 nanometers was tightly bound to the nanoparticle surface according to the HRTEM and EDS tests in our previous study [6].

2.2 Surface energy calculation

The contact angle measurement system was specially designed based on the Washburn's equation [7]. The measurement process was illustrated as follows. At first a piece of cotton cloth was stuck at one end of a cleaned glass tube. Then the powders were put into the tube and vibrated until no further change of the powder column height was observed. The packed tube was hung under an electronic balance vertically and the tube bottom was made to contact with the liquid surface by carefully moving up the liquid container on a platform. Thus the weight of liquid penetrating into the packed powders was automatically transmitted to the computer and recorded as a function of time.

In the contact angle measurement of TiO_2 nanoparticles, Methanol is considered as a liquid that may perfectly wet the sample. Water, glycol and dimethyl sulfoxide are selected as tested liquids. The surface energy of powder is calculated by LW-AB approach [8].

2.3 Ultraviolet absorbency measurement

Some nanopowders were put into glycol solution and a dilute suspension was made. After dispersed the suspension for 15 minutes by ultrasonic, it was poured into the rectangular cell of quartz and the absorbency measurement was carried out through UV-3000 ultraviolet spectrophotometer (Shimadzu Cor., Japan).

3.Results and discussion

3.1 Surface energy of TiO_2 nanoparticles

The experimental results of contact angles and surface energy of TiO_2 nanopowders are reported as Tab.1. It displays that the surface energy (γ_S^{Total}) as well as the nonpolar (γ_S^{LW}) and the polar component parts (γ_S^{AB}) of any AA-plasma-coated nanoparticles is much lower than that of the uncoated TiO_2. But the surface energy and its parts do not decrease linearly with the discharge power.

Tab.1. Surface energy and it parts of TiO_2 nanoparticles coated under different power

Monomer	Power (W)	Contact angle (cosθ)			Surface energy (mJ/m^2)				
		Water	Glycol	Dimethyl sulfoxide	γ_S^{Total}	γ_S^{LW}	γ_S^{+}	γ_S^{-}	γ_S^{AB}
Uncoated		0.113	0.903	0.129	35.31	16.64	2.22	39.26	18.67
AA	5	0.209	0.517	0.671	7.70	6.81	2.79	0.07	0.88
AA	20	0.133	0.292	0.484	8.58	7.63	3.24	0.07	0.95
AA	25	0.058	0.151	0.315	7.12	6.09	3.31	0.08	1.03
AA	40	0.044	0.193	0.256	4.34	3.11	3.17	0.12	1.23

* γ_S^{+} and γ_S^{-} are the electron accepting part and the electron giving part in the polar part of the surface energy, respectively.

3.2 Dispersion of TiO_2 nanoparticles

The measured absorbency may yield the most significant information about the particle-particle

conglomeration because the diameters of TiO_2 nanoparticles play an important role in the ultraviolet shielding effect of TiO_2. The less the conglomeration of nanoparticles in solution, the higher the absorbency value. Fig.1(A) displays the ultraviolet absorbency curves of TiO_2-glycol (in Tab.1) suspensions at the ultraviolet-visible bands. It is clearly seen that all the absorbency curves move upwards from the baseline of untreated TiO_2 particle and there exists a maximum at about 310nm. Then the ultraviolet absorbency maximum (UAM for short) is recorded and plotted as a function of plasma discharge power to correlate the dispersion behaviors of nanoparticles and the discharge parameters. Note how the UAM in Fig.1(B) progressively increases with the power until reaching a maximum close to 25W. A further increase in the discharge power yields a significant decrease of the slope. From these absorbency tests, it is indicated that the dispersion of any AA-plasma-polymer coated TiO_2 nanoparticles is greatly improved in 200-400nm ultraviolet bands. The optimum dispersion of TiO_2-glycol suspensions takes place at the discharge power of 25W. Such a dispersion improvement of nanoparticles is mainly caused by the change of the surface properties of nanoparticle through plasma polymer coating. The particular reason for this will be discussed later.

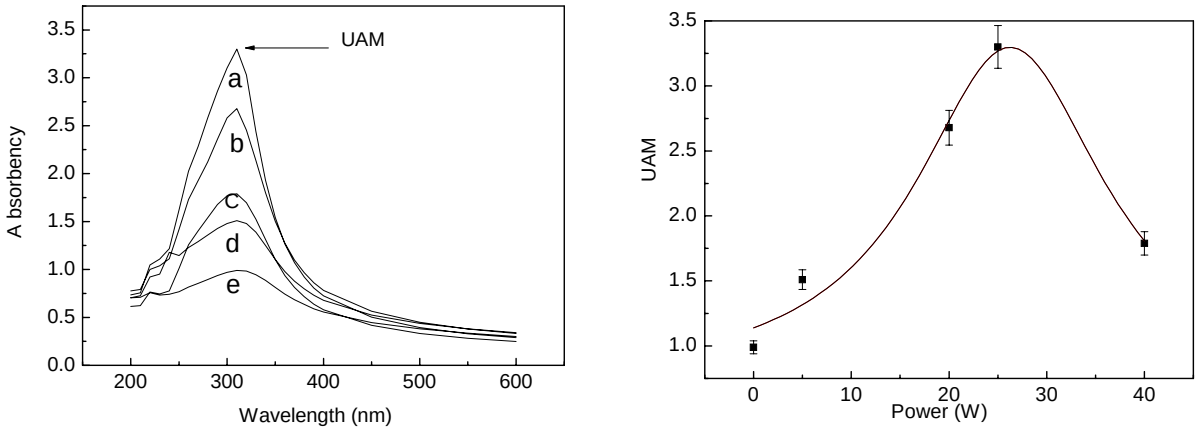

Fig.1. (A) Ultraviolet absorbency curves and (B) UAM curve of TiO_2-glycos suspensions coated under different power (a) 25W (b) 20W (c) 40W (d) 5W (e) uncoated TiO_2

3.3 Potential energy of interaction between nanoparticles

Until now the surface energy of TiO_2 nanoparticles and their dispersion behaviors in glycol solution have been carefully investigated. Here, we will try to simulate the potential energy of interaction between nanoparticles according to the EDLVO theory and measured surface energy to explain the dispersion behaviors of nanoparticles in glycol suspension. The AA-plasma-polymer coated TiO_2 is assumed to be a spherical particle covered with a concentric, continuous layer as show in Fig.2, where R is the particle radius, h is the surface-to-surface distance between the particles and d is the thickness of the coating layer.

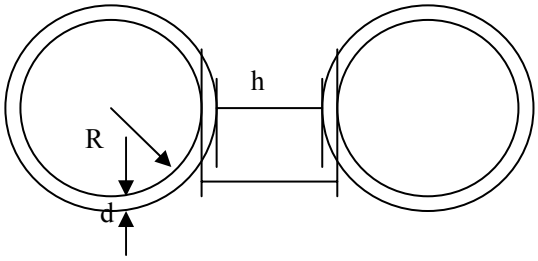

Fig.2. Schematic diagram of coated particulate

The total potential energy of interaction is the sum of three contributions, namely, electrostatic double-layer repulsion (V^{EL}), Van der Waals attraction (V^{LW}) and Lewis AB (electron-acceptor /electron-donor) interaction (V^{AB}). The following equation is used for V^{EL}:

$$V^{EL} = \frac{\varepsilon_o \varepsilon_r R \ \varphi_0^2}{2} \exp(-\kappa h) \tag{1}$$

where $\varepsilon_0\varepsilon_r$ is the dielectric constant of the solution, κ is the inverse Debye length and φ_0 is the zeta potential.

The Van der Waals attraction has been calculated according to the following expression [9]:

$$V^{LW} = -\frac{1}{12}\left[\left(A_p^{\frac{1}{2}} - A_i^{\frac{1}{2}}\right)^2 H_p + \left(A_i^{\frac{1}{2}} - A_m^{\frac{1}{2}}\right)^2 H_i + 2\left(A_i^{\frac{1}{2}} - A_m^{\frac{1}{2}}\right)\left(A_p^{\frac{1}{2}} - A_i^{\frac{1}{2}}\right)H_{ip}\right] \quad (2)$$

where subscript 'p' refers to the central part of the particles, subscript 'i' refers to the coating layer , subscript 'm' refers to the intervening continuous medium between particles, and A is the Hamaker constant of material (liquid or solid). Because the Hamaker constant (A) is unknown for the materials, it is estimated from the nonpolar part of the surface energy, which may be given by [10]:

$$A = 24\pi l_0^2\ \gamma^{LW} \quad (3)$$

where l_0 is the so-called equilibrium separation distance between the interfaces and a good estimation of it is l_0=0.157nm.

The H functions are defined in the equations displayed below. For various situations:

$$H(X,Y) = \frac{Y}{X^2 + XY + X} + \frac{Y}{X^2 + XY + X + Y} + 2Ln\left(\frac{X^2 + XY + X}{X^2 + XY + X + Y}\right) \quad (4)$$

$$H_p : X = \frac{(h+2d)}{2R}, Y = 1 \qquad H_i : X = \frac{h}{2(R+d)}, Y = 1 \qquad H_{ip} : X = \frac{(h+d)}{2R}, Y = \frac{(R+d)}{R}$$

The Lewis AB interaction between two spherical surfaces, immersed in a solution, is presented by [11]:

$$V^{AB} = \pi R \cdot \lambda \cdot \Delta G_{l_0}^{AB} \cdot \exp\left[(l_0 - h)/\lambda\right] \quad (5)$$

where λ is the characteristic length, for hydrophilic system λ=1.0 nm, and $\Delta G_{l_0}^{AB}$ is expressed as a function of the electron accepting part and the electron giving part of the polar surface energy of solid and liquid.

$$\Delta G_{l_0}^{AB} = -4\left(\sqrt{r_l^+\gamma_l^-} + \sqrt{\gamma_s^+\gamma_s^-} - \sqrt{\gamma_s^+\gamma_l^-} - \sqrt{\gamma_l^+\gamma_s^-}\right) \quad (6)$$

The total potential energy of interaction (V) between particles is formulated by:

$$V £½ V^{EL} £« V^{LW} + V^{AB} \quad (7)$$

In many cases, a small amount of water exists in the polar organic solution. Although it is difficult to develop surface charges on particles in nonaqueous liquids, the contribution of water ionization to V^{EL} should not be neglected. So in this simulation model the inverse Debye length and the zeta potential of nanoparticles coated under any discharge parameters in glycol are supposed similar of κ=0 and φ_0=20mV, respectively. The diameter of uncoated TiO_2 nanoparticles is taken as a constant of 35nm. Then the diameter of the coated TiO_2 nanoparticle is 41nm according to the average coating thickness of 3nm measured by HRTEM [6].

Using the surface energy data shown in Tab.1 and Eq.(1-7), the potential energy curves of EDLVO are plotted in Fig.3, which express the relationship between the total potential energy and the distance h between nanoparticles. It is notable that the relative tendencies of simulated curves V(h) are almost the same when TiO_2 nanoparticles is coated under different discharge parameters. A potential maximum, which expresses the maximal long-range repulsion between two particles, observes at distance within 0-5nm for any nanoparticles. This potential maximum among particles governs the conglomeration/dispersion behaviors of ultra-fine

nanoparticle in suspension. The larger the potential maximum in the EDLVO curves, the greater the stability of the nanoparticles suspension since that two particles must surpass such a potential maximum at a critical distance prior to encounter and aggregate together.

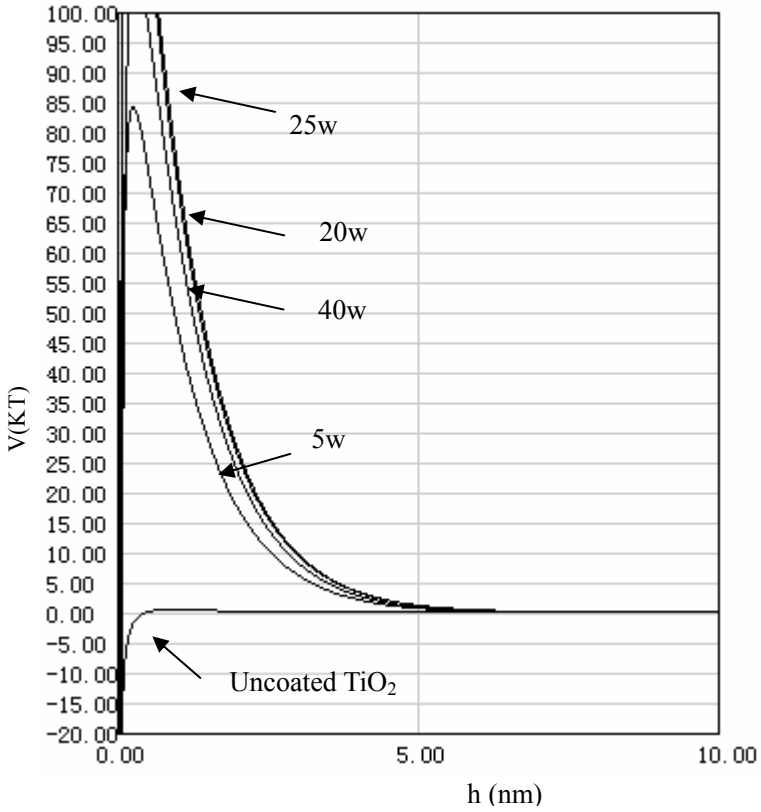

Fig.3. Potential energy curves of TiO_2- glycol suspensions coated under different power
(The potential maximum at 25W (139.74KT) is a little higher than that at 20W (138.74KT).)

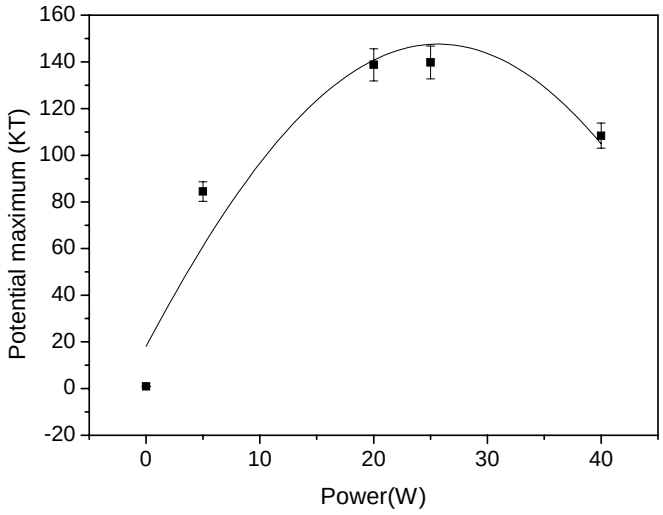

Fig.4. Potential maximum curve of TiO_2-glycol suspensions coated under different power

To character and compare the dispersion of colloidal suspensions, the potential maximum in Fig.3 are plotted in Fig.4 as a function of discharge power. Note how the experimental data in Fig.1 are explained in view of the potential maximum curve as discharge parameters increase. It is distinctly shown that there is a large difference in the simulated potential maximum between the uncoated and the coated TiO_2 nanoparticles.

The uncoated TiO_2 yields a very small potential maximum of repulsive interaction, while this repulsive interaction becomes larger for any AA-plasma-coated nanoparticles. The increasing tendency of simulated maxima in the EDLVO theory corresponds to the UAM values in the ultraviolet absorbency experiment very well. The higher the UAM, the larger the potential maximum.

Although the simulated curves in the Fig.4 does not match well with the surface energy data in Tab.1, the potential maxima in the EDLVO theory verify the experimental results of ultraviolet dispersion in Fig.1 (B) quite well by using the surface energy of nanopraticles as a main entrance. It is therefore demonstrated that such an increase in the potential maximum between nanoparticles, which is caused by the surface energy tailoring of nanoparticles through plasma polymer coating, is the reason of the great dispersion improvement of nanoparticles suspensions. It is also indicates that the surface energy of TiO_2 nanoparticles governs the overall dispersion process of nanoparticles in organic solution.

4.Conclusions

In this study, the dispersion behaviors of AA-plasma-polymer coated TiO_2 nanoparticles in glycol solution is evaluated through the ultraviolet absorbency measurements. From the measured absorbency data, it is clearly seen that the dispersion of TiO_2-glycol suspensions is effectively improved after plasma polymer coating. The optimum dispersion of TiO_2-glycol suspensions takes place at the discharge power of 25W. It is therefore concluded that pulsed RF plasma polymerization is a useful surface coating way to make well-dispersed nanoparticles in the background medium through controlling discharge parameters.

The EDLVO theory is used to simulate the dispersion of nanoparticles in glycol solution through the calculation of V^{EL}, V^{LW} and V^{AB} potential energy, which are the function of the measured surface energy of TiO_2 nanoparticles and glycol solution. It is displayed that the potential maxima in the simulated EDLVO curves correspond with the experimental phenomena very well. It is also indicated that the dispersion results of nanoparticles in organic solution are explained by the classical EDLVO theory after estimation the surface energy of TiO_2 nanoparticles. This simulation method is applicable to estimate the dispersion behaviors of other nanoparticles systems.

Abstract
Plasma activation promotes more effective and environmental friendly low-rank coal incineration. The work presents new plasma-fuel systems improving the efficiency of coal combustion, numerical modelling results of plasma ignition, gasification and thermochemical preparation of a pulverized coal for incineration at power boilers. Comprehensive image of plasma activated coal combustion processes in a combustion chamber of pulverised coal fired boiler was obtained.

Introduction
Coal is one of the main energy resources of the 21 century. To improve efficiency of coal gasification and incineration new plasma-energy technologies are developing. The main element of these technologies realization is plasma-fuel systems (PFS). Plasma chemical activation using PFS promotes more effective and environmental friendly low-rank coals incineration and gasification increasing reactivity of solid fuels. PFS have been tested for boilers starting up by plasma ignition of pulverized coal and flame stabilization in different countries at 26 power boilers steam-productivity 75 to 670 t/h equipped with different type of pulverized coal burners (direct flow, muffle and swirl burners) [1]. At PFS testing power coals of all ranks (brown, stone, anthracite and their mixtures) were incinerated. Volatile content of them was from 4 to 50%, ash varied from 15 to 48% and heat of combustion was from 1600 to 6000 kcal/kg.

For wide dissemination of the plasma technology there is necessity to show their advantages before conventional technologies of coal combustion. Experimental investigation on full-scale boilers is expensive and laborious and some times practically impossible. In this connection numerical experiment with full-scale boiler is the most realized method. Numerical investigation of plasma ignition, gasification and thermochemical preparation of a pulverized coal for incineration at a power boiler was fulfilled. Three reliable codes were used for the research [2]. Thermodynamic code TERRA allows calculating products species and thermal physics coefficients of plasma activated pulverized coal depended on temperature, pressure and plasma source power. 1D kinetic code PLASMA-COAL with an emphasis on complex chemistry calculates concentrations of species (CO, CO_2, H_2, CH_4, C_6H_6, N_2, H_2O), temperatures and velocities of treated coal-air mixture along the chamber with plasmatron. It gives initial data for 3D-modeling of power boiler furnace by FLOREAN code. The computer simulation experiments were conducted for low-rank bituminous coal with ash content 44% incinerated at the boiler of steam productivity 475 ton per hour. Twelve swirl burners are mounted on the furnace of the boiler; in accordance with our presumption all of them are equipped with plasmatrons.

1. Realization of the Plasma-Fuel Systems at Coal-Fired Thermal Power Plants
Plasmatron (Fig.1) is a main element of the PFS. Plasma forming gas is air blown through the electrodes. Plasmatron power is varied from 100 to 350 kW and geometrical sizes are as follows: the height is 0.4-0.5 m, diameter is 0.2-0.25 m and the weight is 25-30 kg. Mass averaged temperature of the plasma-air flame on plasmatron outlet is varied from 5000 to 6000 K. The technology encloses in air-fuel mixture plasma heating up to the temperature of coal volatile release and char carbon partial gasification. Thus no matter whether the initial coal is high or low rank from air-coal mixture highly reactive two-component fuel is obtained. When mixed with secondary air at a furnace it can be ignited and burn stably without using of additional fuels (fuel oil or natural gas) traditionally applied for starting up the boilers and low-rank power coals flame stabilization.

Fig.2 illustrates a diagram of arrangement of BKZ-420 boiler burners with PFS at Ulan-Bator TPP-4. 12 burners are placed in three layers in the corners of the boiler. Two PFS were mounted on the low layer opposite each other. In 2-3 seconds from start of PFS the temperature of both pulverised coal flames achieved 1100 to 1150 ^{O}C. In an hour the flames temperature which were 7 to 8 meters in length was 1260-1290 ^{O}C. In

accordance with operating instruction duration of the boiler starting up was 4 hours. All eight boilers of the power plant were equipped with PFS for fuel oil free boiler starting up.

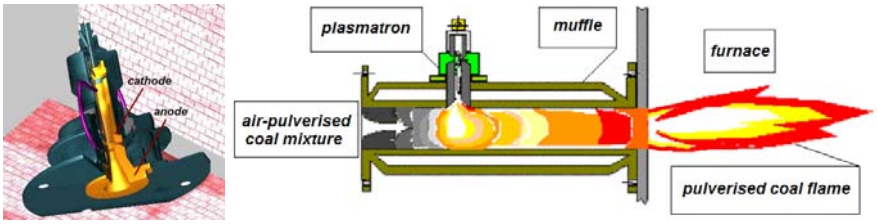

Figure 1. Plasmatron and Scheme of its Mounting onto Direct Flow Pulverized Coal Burner.

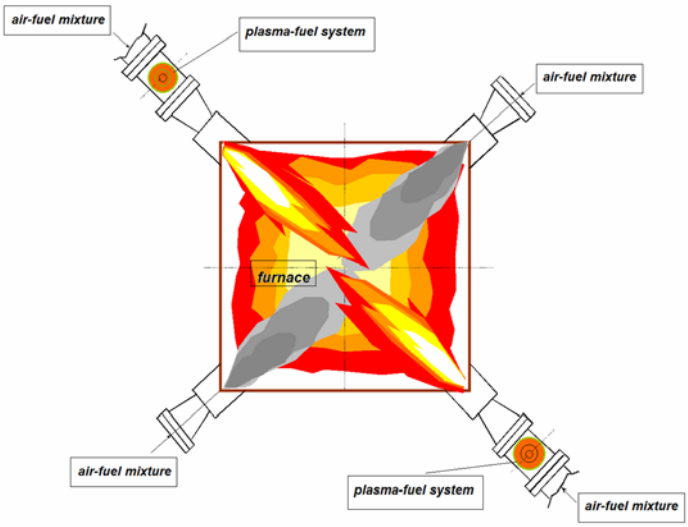

Figure 2. Diagram of Mounting Equipped with Plasma-Fuel Systems for Pulverised Coal Ignition Burners onto the Boiler of 420 t/h Steam Productivity at Ulan-Bator Thermal Power Plant - 4 (Mongolia).

Fig.3 (*a*) presents results of experiments on NO_X reduction and decrease of unburned carbon at plasma ignition of coals on the outlet of a furnace [1]. When a plasmatron operates (in a regime of plasma stabilization of a flame), NO_X concentration is reduced twice, amount of unburned carbon is reduced 4 times. NO_X is reduced owing to two-stage pulverised coal combustion. The first one is PFS where ignition and partial gasification of coal in primary air is realised.

P – plasmatron electric power; Q – heat of coal combustion; G – coal consumption through a plasma-fuel system.

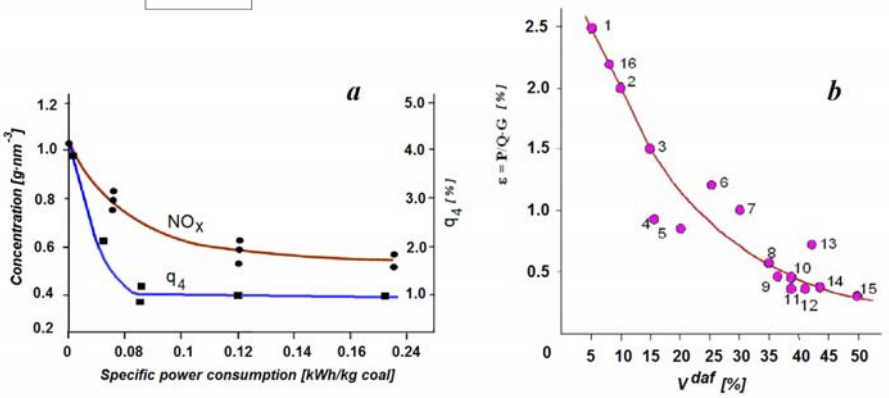

Figure 3. Specific Power Consumption Influence onto NO_X and Unburned Carbon (q_4) Reduction at Plasma Activation of a Pulverised Coal Flame (*a*) and Relative Power Consumption of a Plasmatron versus Coal Volatiles Content for Different Thermal Power Plants (*b*).

The second stage is a furnace of a boiler where combustion of the products after the first stage in the secondary air is taken place. Fuel nitrogen is released with coal volatile inside PFS. It forms molecular nitrogen due to deficit of oxygen in air-fuel mixture treated in PFS. In the second stage mainly thermal NO_X are formed. As known [3] fuel nitrogen is a main source of nitrogen oxide emission from furnace. But thermal NO_X can reach 10-15% of all NO_X emission in a furnace at temperature more than 1700 ^{O}C. As regards unburned carbon (q_4), its decrease can be explained by the fuel reaction ability increase. It happens due to formation of two-component high-reactive fuel from pulverised coal and heat explosion of coal particles at their interaction with arc plasma. Coal particles of 50-100 μm initial size in PFS undergo heat shock. As a result they are crushed into fragments. Each fragment is of a size of 5-10 μm. This leads to intensive devolatilization (CO, CO_2, H_2, N_2, CH_4, C_6H_6 and

others) and 3-4 times accelerates the process fuel combustible matter oxidation. An experimental dependence of specific electric power consumptions on a plasmatron versus coal volatiles content (Fig.3 (*b*)) was gotten during PFS tests at different thermal power plants. We can see the specific power consumption for PFS decrease with coal volatile content increase, i.e. when coal reactivity rises. Mark, power consumption for plasmatron is within 2.5 % from heat capacity of the pulverised coal burner, even for the anthracite coal with minimal reactivity. For example own needs of electric power for a boiler are 8-10 %.

2. Numerical Experiment for PFS and a Power Boiler Furnace

TERRA code [4] was used for thermodynamic modelling. It was created for high temperature processes computation. The program is based on the principle of entropy maximum for isolated thermodynamic systems in equilibrium. It has its own database of thermo chemical properties for more than 3500 chemical agents over a temperature interval from 300 to 6000K.

Computation of thermochemical preparation of the Ekibastuz bituminous coal of Kazakhstan with ash content 44%, heat of combustion 16750 kJ/kg, moisture content 7% and volatile matter 24% was fulfilled. The calculations were performed over a range of temperatures from 600 to 4000K and pressure 0.1 MPa. Thermochemical preparation of coal-air mixture for incineration is realised in the space of PFS, at dust concentration in air-coal mixture about 0.4 kg of coal per kg of air. It corresponds to 0.44 of air theoretically necessary for complete combustion of the coal. Calculations showed that big part of gaseous phase is synthesis gas. At 1200K CO concentration is 28.5 % and H_2 concentration is 11 %. Concentrations of oxidants CO_2 and H_2O are less than 6 % all over the temperature range. Nitrogen-containing compounds are basically molecular nitrogen. Concentration of it is 71 % at the temperature 600 K and decreases linearly to 44.6 % by the temperature 4000 K. NO_X concentration is less than 0.006 % (60 ppm) at the temperature below 2800K and increases to 0.8% (8000 ppm) by the temperature 4000 K. There are no sulphur oxides and fuel sulphur is represented as oxygen-free species such as H_2S, SH, SiS and S. At the temperatures more than 2000K species of coal mineral mass appeared in the gaseous phase. They are silicon monoxide (SiO), aluminium monoxide (AlO), aluminium (Al) etc.

For modelling thermochemical preparation of coal for combustion by “Plasma-coal” code described below the main thermo-physical constants for the gas phase were determined and polynomial approximated.

The calculations of the coal thermo chemical plasma preparation processes at the PFS are performed with the help of the code PLASMA-COAL [5]. The code accounts two-phase (coal particles and gas-oxidiser), chemically reacting flow, with an internal heat source (electric arc, plasma flame or chemical reactions) [5-7]. Detailed kinetics of chemical reactions is used. Its general scheme, along with the reactions of devolatilization and char carbon gasification, takes into account the reactions of their products further transformations. The temperature dependence of rate constants is governed by the Arrhenius equation. The list of the chemical reactions used in the model consists of 116 reactions. The starting chemical stage of coal conversion in the PFS is volatile matter evolution (CO, CO_2, CH_4, H_2, H_2O, C_6H_6, C_5H_5N, C_4H_5N, CH_3SH, C_4H_4S). Then there are two more stages. They are char carbon gasification including fuel nitrogen oxidation (seven reactions with H_2O, CO_2, CO, O_2, NO, H_2S) and conversation of evolved volatile products in the gas phase. For NO formation a model of fuel NO, thermal NO and prompt NO is considered. The model comprises 36 chemical reactions [3]. Among them there are reactions of C_5H_5N and C_4H_5N emission from coal, char-N oxidation, the following transformation of them through HCN and NH_3 to NO. Experimental validation of the one dimensional model was performed for different coal–oxygen rates, power of plasma source and processes (steam gasification, combustion and air gasification) and showed satisfied results [2, 5].

Calculations were performed for the cylindrical direct-flow burner equipped with plasmatron of 100 kW power. The diameter of the burner is 0.73 m, wall temperature is accepted as 700 K. Mean diameter of coal particles is 60 μm. Temperature of the air-coal mixture on the inlet of the burner is 423 K. Coal consumption through the burner was 7.3 t/h. This PFS efficiency was taken as 90%.

The results of the numerical simulations are presented in Table 1 for the PFS outlet. These data were taken as initial parameters for 3D simulation of the furnace equipped with PFS.

For 3D-modeling of power boiler of steam productivity 475 ton per hour FLOREAN code [8] was used. This code is based on the solution of the conservative equations of the flue gas mixture by finite volume method. It includes a submodel of momentum and energy balances, SIMPLE-method for pressure corrections, k-ε turbulence model, six-flow model for radiation heat transfer calculations and balance equation for the components of substance. This computer code allows to extract the velocity components {u,v,w}, the temperature T, the pressure P, the concentration of combustion products and other characteristics of the process. Two-fluid model is considered. For description of chemistry simplified models were used. They account only chemical reactions of the main components and integral reactions of fuel components oxidizing up to stable end-products of the reactions. At that intermediate reactions are not considered. For NOx formation global mechanism is used [9]. The code FLOREAN has been validated in details for a lot of experiments in laboratory and industrial furnaces [2, 8].

The computer simulation experiments were conducted for the boiler with steam productivity 475 ton per hour. The boiler is installed on Ermakovsk Thermal Power Plant in Kazakhstan. The furnace size is as follows: 30 m height, 10 m in width and 7 m depth. Twelve swirl burners are mounted on the furnace of the boiler. They are placed in two layers by six ones in every layer on the opposed walls. In accordance with our presumption six of the burners are equipped with plasmatrons. They are placed in the lower layer. The furnace grid of 25x47x58 size, this comprises 68150 control volumes, was used for numerical simulation. The numerical results for combustion of the pulverised coal in the furnace are presented in the following figures. All the results are presented for plasma activated coal combustion in comparison with conventional regime of coal incineration.

Fig. 4 shows temperatures and NO concentrations along the furnace with account of plasmatrons and without it. One can see in general the temperatures along the furnace for plasma-activated coal combustion are less than ones for conventional incineration of coal. But there is a zone where the temperature of coal combustion with plasma activation is more than one without it. This zone is lower part of the furnace. It extends till the level of the upper tier of the burners. It can be explained by influence of plasma-fuel systems. They cause earlier heating and ignition of air mixture and subsequent front of combustion displacement to the PFS orifice. NO concentration along the furnace relatively less for plasma activated combustion for mean, maximal and minimal values. Fig. 5 illustrates the oxygen and carbon dioxide concentration distribution along the furnace height. Mean level of oxygen (curves 3 and 4) along the full height of the furnace is lower for the plasma activated coal combustion, but as consequence mean values of carbon dioxide is higher. These data confirm more complete coal incineration and unburned carbon decrease when plasma-fuel systems assist combustion process.

Fig. 6 visually demonstrates the difference between traditional and plasma activated coal incineration in the furnace by the example of NO formation. PFS influence is developed in forming of NO_X in wall area on the outlet of plasma-fuel systems. On the contrary at conventional coal combustion NO_X is formed in the centre area of the furnace on the level of the burners. Said above is confirmed by NO curves behaviour in Fig. 4. For instance curve 1 has two and curve 2 has one pronounced peaks on the level of the burners. Plasma-fuel systems influence on NO formation can be seen along the full height of the furnace. Interesting, plasma-fuel systems decrease NO concentration even in the lower part of the furnace (below the level of PFS allocation). That is explained by phenomena of suppression of fuel NO_X formation inside the PFS. Fuel nitrogen is released with coal volatile inside PFS. It forms molecular nitrogen due to deficit of oxygen in air-fuel mixture treated by plasma that is confirmed by low NO concentration (3.67 ppm) on the outlet of plasma-fuel system (see Table 1), but as known [3] fuel nitrogen is a main source of NOx at coal combustion.

Table 2 gives a comparison of the two calculated variants (conventional and plasma activated coal combustion). Comparison of the numerical and experimental data for traditional coal incineration [10] showed satisfactory

agreement. The difference in experimental and calculated parameters is within 17%. Influence of plasma-fuel systems onto coal combustion in the furnace is developed in decrease of mean level of temperature (9%), NO_X (11.5%) and O_2 (14%) concentration and increase of CO_2 (7%) concentration. These values show an improvement of the main characteristics of the process at plasma supported coal combustion.

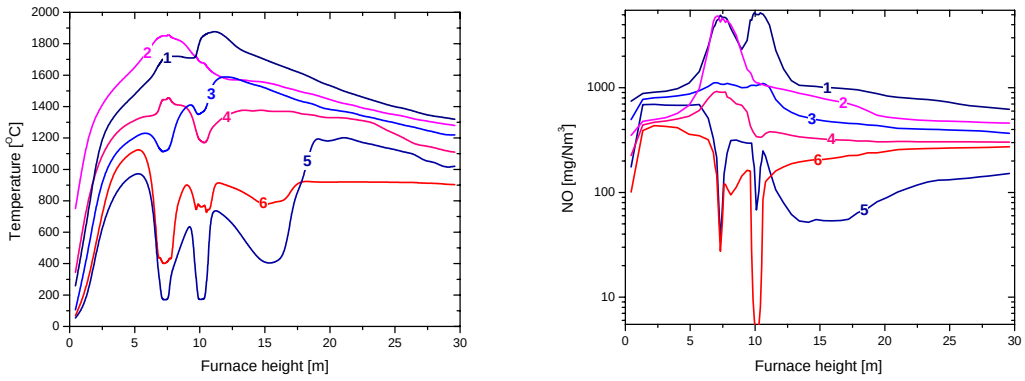

Figure 4. Temperature (on the Left) and NO Concentration (on the Right) Variation along the Furnace.

Conventional coal combustion | Plasma-activated coal combustion in six PFS

Figure 6. Nitrogen Oxide Distribution in Cross Section of the Furnace on the Level of PFS and along the Furnace Height.

Table 2. Comparison of flue gas characteristics on the outlet of the furnace.

	Conventional incineration (experiment)	*Plasma activated incineration*
T, ^{O}C	1220 (1180)	1110
NO, ppm	180	137
CO_2, kg/kg	0.185 (0.17)	0.188
O_2, kg/kg	$3.18\ 10^{-2}$ ($3.5\ 10^{-2}$)	$1.74\ 10^{-2}$

Conclusion

Thermodynamic and two fluid dynamics kinetic models were used for the research. Computer simulation of pulverised coal combustion with use of plasma-fuel systems was fulfilled from the burner's inlet to the furnace outlet. Analysis of the numerical experiment and experience of PFS industrial use showed ecological efficiency of the plasma technology. The most familiar advantages of PFS include decrease in NO_X emission through the suppression of their formation in PFS and increase in efficiency of solid fuel incineration by reducing unburned carbon. Thus when 1 kWh of electric power or 1Gcal of heat power is generated with the help of PFS a lesser quantity of fuel is burnt and a lesser quantity of CO_2 is produced. In other words, specific emissions of greenhouse gases on generating the unit of electric or heat power decrease by 2%.

Droplet Impact during the Plasma Spray Coating Process- Effect of Surface Roughness on Splat Shapes

M. Raessi, J. Mostaghimi and M. Bussmann

Department of Mechanical and Industrial Engineering, University of Toronto, Canada

Abstract
We used a three-dimensional model of droplet impact and solidification to simulate the effect of surface roughness on the impact dynamics and the splat shape of an alumina droplet impinging onto a substrate. The substrate surface was patterned by a regular array of cubes spaced at an interval twice their size. Three different cube sizes were considered, and the results were compared to the case of droplet impact onto a smooth substrate. To understand the effect of solidification on the droplet impact dynamics and splat morphology, the simulations were run with and without considering solidification. Comparing the results, we have concluded that solidification plays a major role in determining splat shape on a rough surface. We also present results of the distribution of voids between the splat and the substrate.

Keywords: Surface roughness, droplet impact, numerical model, solidification

1. Introduction

Thermal sprayed coatings are applied to protect substrates against wear, corrosion, and thermal shock. In thermal spray processes a hot gaseous jet is used to melt and accelerate the powder of a metallic or ceramic coating material. The hot jet draws energy from either a plasma or a combustion source. During these processes, a spray of molten (or partially-molten) droplets, or particles is directed at a substrate. As the droplets impact the substrate, they spread and solidify, each forming a so-called *splat*. A coating forms as a result of the accumulation of many such splats.

Among many experimental and numerical studies that have been done on droplet impact and solidification, only a few have considered the effect of surface roughness. For instance, Ahmed and Rangel [1] numerically studied the impingement and solidification of an aluminum droplet on uneven substrates, using a two-dimensional axi-symmetric model. Their results show that droplet impact onto an uneven substrate is almost always accompanied by splashing. However, the degree of splashing decreases with the increase in surface roughness height. Fukanuma [2] presented a formula which describes the flattening process of a droplet onto a rough surface, and concluded that the flattening ratio and the flattening time decreases with increasing roughness. Liu et al. [3] numerically studied the impact of a droplet onto substrates with wavy surfaces; however, their two-dimensional axi-symmetric model did not include solidification. They found that for wavelengths of the surface larger than the droplet diameter, droplet spreading ended with breakup.

This paper then, presents the results of three-dimensional numerical simulations of droplet impact and solidification onto substrates with rough surfaces. The effect of surface roughness on splat morphology and the bonding between the splat and the substrate are studied.

2. Numerical Method

The three-dimensional numerical model of droplet impact and solidification which is used in this study was developed by Bussmann et al. [4] and Pasandideh-Fard et al. [5]. Detailed discussion of the model is in [4, 5] and is not repeated here.

Equations of conservation of mass and momentum governing the liquid phase in the presence of a solid phase are

$$\vec{\nabla} \cdot (\Theta \vec{V}) = 0$$

$$\frac{\partial(\Theta \vec{V})}{\partial t} + (\Theta \vec{V} \cdot \vec{\nabla})\vec{V} = \frac{-\Theta}{\rho}\vec{\nabla} p + \Theta \upsilon \nabla^2 \vec{V} + \frac{\Theta}{\rho}\overrightarrow{F_b}$$

where $\vec{V}$ represents the velocity vector, p the pressure, ρ the density, υ the kinematic viscosity, and $\overrightarrow{F_b}$ any body forces acting on the fluid. In these equations, Θ denotes the liquid-solid fraction, and it is equal to one within the liquid phase and zero within the solid phase. The free surface of the liquid is defined by using the "Volume of Fluid" (VOF) method, in which a scalar function f is defined equal to one within the droplet material (liquid or solid) and equal to zero without. Since f is passively advected with the flow, it satisfies the advection equation which in the presence of the solid phase is

$$\frac{\partial f}{\partial t} + (\Theta \vec{V} \cdot \vec{\nabla}) f = 0$$

The energy equation which is solved for heat transfer and phase change is [5]

$$\rho \frac{\partial h}{\partial t} + \rho(\vec{V} \cdot \vec{\nabla})h = \vec{\nabla} \cdot (k \vec{\nabla} T)$$

where h represents the enthalpy, k the conductivity, and T the temperature. To solve the energy equation, the enthalpy transforming model [6] is used to convert the energy equation to one with a single dependent variable: the enthalpy. The main advantage of this method is that it represents the energy equation for both phases simultaneously.

These governing equations are solved using a finite volume technique on a three-dimensional Cartesian structured grid. According to the problem geometry, symmetry boundaries are utilized to reduce the problem size and therefore to save computational time. Along symmetry boundaries, fluid flow obeys free slip and no-penetration conditions, and an adiabatic thermal boundary condition is applied. Numerical computations were performed on an AMD Athlon 1.4 GHz PC; the average CPU time was 36 hours.

3. Results and Discussion

Fig. 1 shows simulated images of 40 μm diameter alumina droplets, initially at 2055ºC, impinging with an impact velocity of 65 m/s onto smooth and rough alumina substrates. Each column shows a droplet during successive stages of impact. For the rough substrates, the surface is patterned by cubes which are regularly spaced at an interval twice their size. Three different cube sizes, of 1, 2, and 3 μm, were considered. In Fig. 1(a) to (d), the fluid flow, heat transfer and phase change are modeled. The splat shape on the smooth substrate (Fig. 1(a)) differs little from the shape on the 1 μm rough substrate (Fig. 1(b)). But as the roughness size increases further to 2 and 3 μm, the splat shape changes substantially. In particular, on the 3 μm rough substrate, the droplet is blocked at t = 0.8 μs from spreading along the 45º diagonal and effectively the liquid flow is channeled in two directions. To understand the effect of solidification, Fig. 1(e) presents results of fluid flow without solidification for the case of 3 μm roughness.

In Fig. 2, a quarter of the final shape of the alumina splats is depicted for different substrate surface conditions. It clearly depicts the effect of roughness size on the splat morphology. As it is shown in Fig. 3(a), as the size of the surface roughness increases from zero (smooth) to 1 and 2 μm, the splat radius also increases. However, on the 3 μm rough substrate, the extent of spreading along the horizontal and vertical axes is approximately equal to that on the smooth substrate.

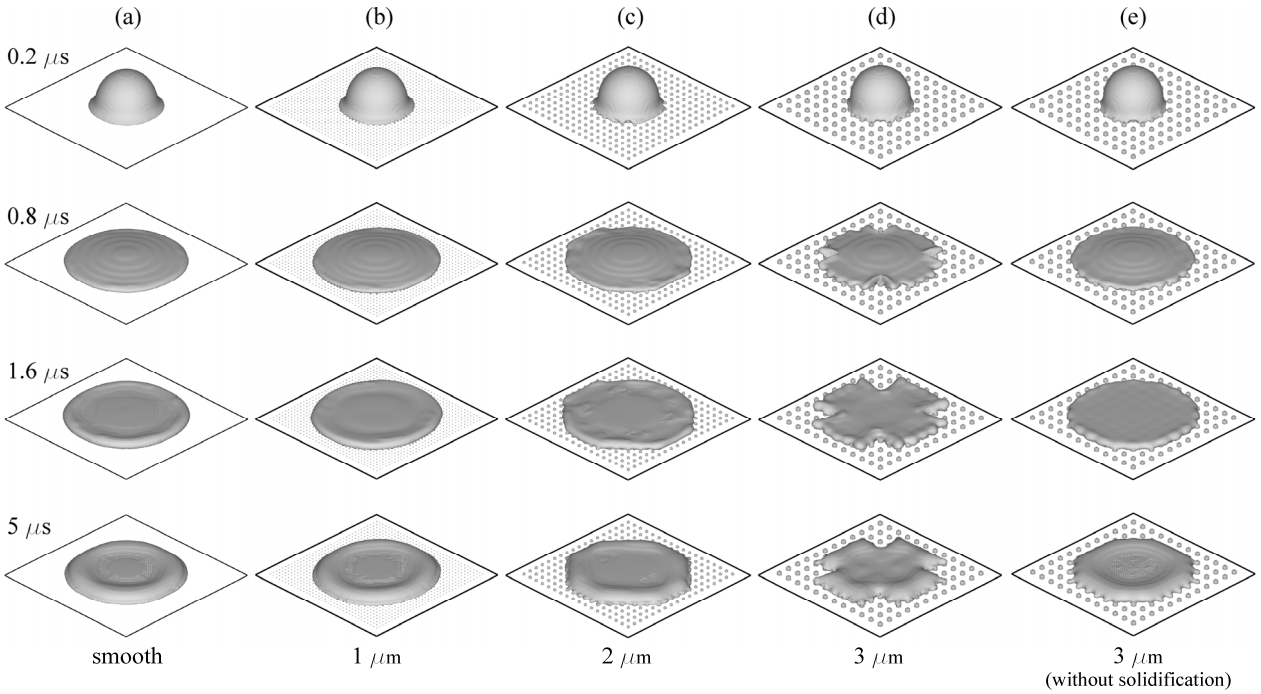

Fig. 1. Computer generated images of 40 μm diameter alumina droplets at 2055 °C impacting with a velocity of 65 m/s onto alumina substrates initially at 25 °C, characterized by different values of surface roughness.

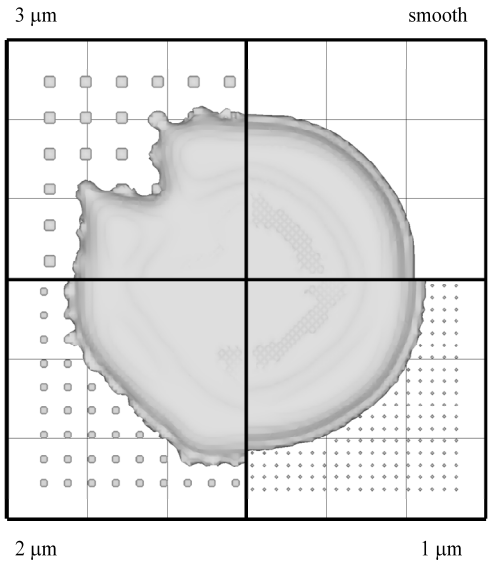

Fig. 2. Comparison of alumina splats on different surface conditions in the presence of solidification.

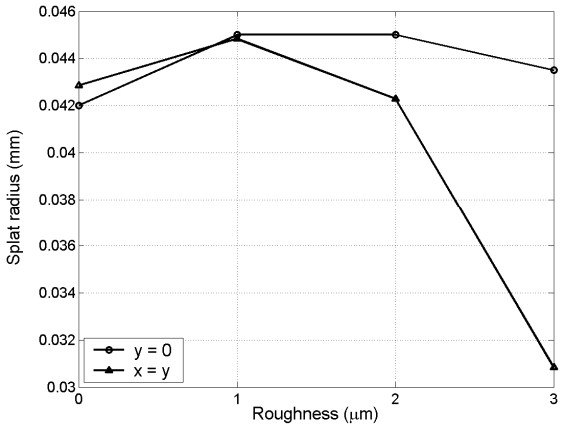

Fig. 3. Splat radius versus surface roughness.

The maximum spreading radii along y=0 and x=y axes are plotted for different surface conditions in Fig. 4. As the surface roughness changes from zero to 1 μm, maximum spreading radii along two axes increase, similar to splat radius. As the roughness size is increased to 2 μm, the radius along y=0 axis remain almost unchanged; however, the maximum spreading radius along x=y axis decreases. Further increase in roughness size to 3 μm decreases both radii along both axes.

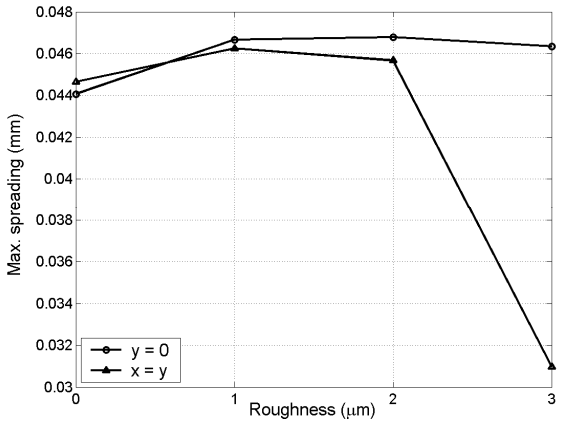

Fig. 4. Maximum spreading raidus versus surface roughness.

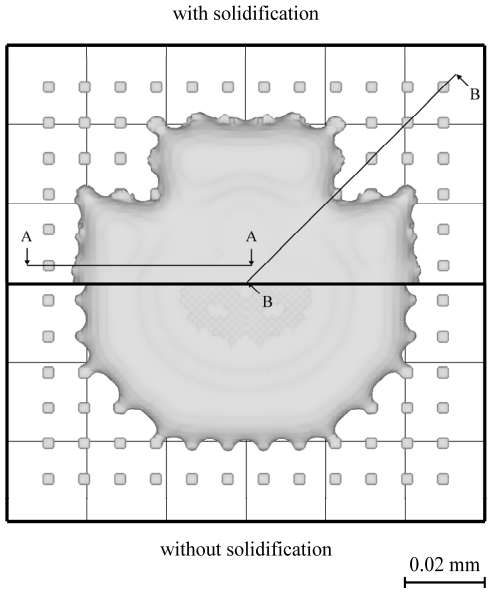

Fig. 5. Comparison of splat shape on a substrate with 3 μm roughness with and without solidification.

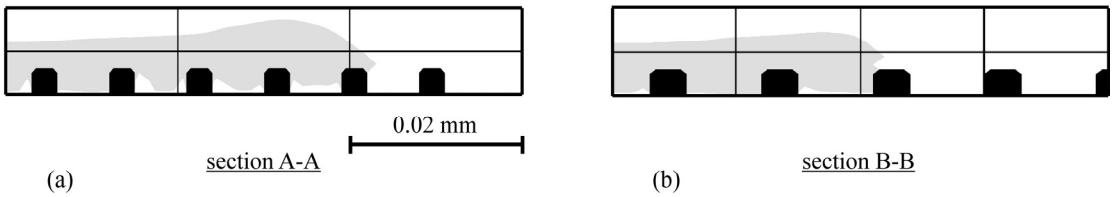

Fig. 3 Cross section of an alumina splat on a substrate with 3 μm roughness in the directions shown in Fig 2(b). The cubes on the substrate and the splat are shown in black and gray, respectively.

The upper half of Fig. 5 shows an alumina splat on the substrate of 3 μm roughness at t = 5 μs, for the case when solidification is modeled. For comparison, the lower half of Fig. 5 shows the droplet shape on the same substrate and at the same time, but without solidification. Comparing the two cases, the effect of solidification on the splat shape is very well seen. It must be mentioned that without solidification, the droplet recoils further until it reaches to its equilibrium configuration which is not shown here.

Finally, Fig. 6 shows the cross sections of the alumina splat on the 3 μm rough substrate, along directions A-A (horizontal) and B-B (45º diagonal) shown in Fig 5. The cubes on the substrate and the splat are shown in black and gray, respectively. The splat appears to bond more completely with the substrate along the diagonals, as the voids beneath the splat are smaller along section B-B than along section A-A. Hence, heat transfer and consequently solidification rate are larger along the diagonals than along section A-A. Therefore, the droplet spreads less along B-B section due to faster solidificiation in this direction.

4. Conclusion

The effect of substrate roughness on an alumina splat shape was studied. We concluded that droplet solidification is the main mechanism responsible for changing the splat shape. An increase in roughness size up to a certain value increases the splat diameter. For the case of a splat on a substrate of 3 μm roughness, voids between the splat and the substrate are seen to be smaller along the 45 º diagonal than along the horizontal

direction. This causes faster solidification along the diagonal and stops the droplet from further spreading earlier than in other regions.

Hydrogen Creation in a Water-Plasma Non-Self Sustained Discharge.

A.S. Galov, V.A. Gostev, A.A. Fomkin.

Department of physics engineering, Petrozavodsk state university, Petrozavodsk, Russia.

Abstract.
There are results of the research on non-self-sustain discharge initiated by plasma jet from a liquid water electrode in this paper. The experimental devise consists of a two-stage plasma generator with non-self-sustain discharge. The water is supplied in the plasmatron as the working substance. The atomic and molecular hydrogen is generated in the non-self-sustain discharge.

Introduction.
The problems of natural resources exhaustion such as petroleum, natural gas, high-grade coal are the essential problems of our civilization. Prepared fuel obtaining such as obtaining hydrogen from water is issue of the day.
Plasma jet generation from water surface is sufficiently new effect, whereas the use of discharge initiation from the gas phase is prevailing. The research on the discharge generation when one of the electrodes is placed into water is very interesting for some application.
The high rating of the nonequilibrium plasma systems and high gas flow rate through the discharge determine high specific capacity of plasmachemical reactors. From this point of view the plasmachemical methods of hydrogen creation are especially interesting according to the atomic-hydrogen power engineering. From the point of effectiveness, these methods similar to the other electrical methods of hydrogen creation, but the plasmachemical methods exceed other methods in the specific capacity.
The hydrogen obtaining in non-self-sustain discharge, generated by plasma get from water surface, is the essentially new method of hydrogen producing. The hydrogen synthesis is based on the use of water dissociation in non-self-sustain discharge onto the atoms of hydrogen and oxygen with the subsequent partial ionization up to the ions of hydrogen and oxygen. The obtained hydrogen can be use as effective fuel and for other application.

The experimental device.
The experimental device consists of a two-stage plasma generator with a non-self-maintained discharge (figure 1). The photo of the non-self sustained discharge is shown on the figure 2.

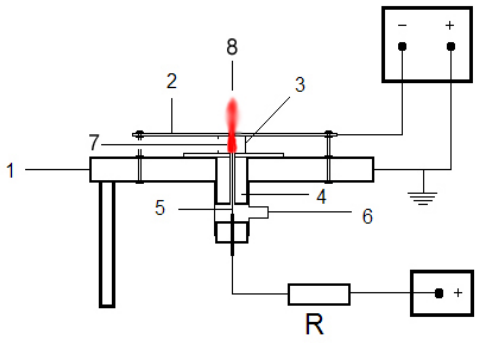

Figure 1. Scheme of a plasma generator.

Figure 2. Photo of the non-self sustained discharge.

Working substance – water – flows through the tube (6) and the ceramic tube (4). The anode – a nichrome needle (5) – is placed into water. When high voltage is put between the anode (5) and the flat ground cathode (1), the disruption of discharge gap occurs. The basic discharge gap is made with two flat electrodes (1) and (2). These electrodes are separated by the ceramic tube (3). The plasma jet (7), which is generated in the first

stage, is injected through the hole in the first electrode. The diameter of plasma jet is 2mm and the length is 30mm. Plasma (8) which permeated through the second electrode is a subject of the research.

Breakdown voltage in the first stage was 1500V. Voltage of stable jet burning was 300V in the first stage, current was 500mA. Voltage value was 600V in the second stage. Current value was 0.2A. Water flow was 0.03 milliliter per second. The temperature of plasma jet was 2000K. The first stage is a plasma source for discharge generation in the second discharge gap.

The water decomposes at the heating in the non-self-sustain discharge:
$H_2O \rightarrow OH + H \rightarrow O + H + H$
There is the ionization of atomic oxygen and atomic hydrogen in the plasma jet. There is the possibility of formation of molecular hydrogen and molecular oxygen.

Working conditions.
The working conditions of plasma jet burning depend on many factors. The output of obtained hydrogen depends on field density between flat electrodes. When the distance between electrodes was changed from 1cm to 0.5cm, the radiation power in ultraviolet area (which was conditioned by $(^2\Sigma_g \rightarrow ^1\Sigma_u)$ energy jump) increased by order. The plasma jet burning conditions are summarized in Table 1.

Table 1. Working conditions of plasma jet burning.

Working conditions.	Voltage	Current	Water flow ml/sec	Temperature of plasma jet.	Characteristics of plasma jet.
There is no voltage in the second stage	300V in the first stage	0,5A in the first stage	0.03	1000-1200C	 The plasma jet has orange color. There is the intensive molecular band in 590-600 nm spectral domain.
There is no voltage in the second stage	300V in the first stage	0,5A in the first stage	0.06	1500-1700C	 The plasma jet radiation is more intensive. The jet has green color. There is the intensive molecular band in 500-560 nm spectral domain.
There is high voltage between the flat electrodes. The distance between the electrodes is 1cm	300V in the first stage and 400V in the second stage.	0,5A in the first stage and 0,6A in the second satge.	0.03	2000C	 The plasma jet changes the color and the shape. There are intensive lines of atomic hydrogen (H_α and H_β) in the plasma jet spectrum.
There is high voltage between the flat electrodes. The distance between the electrodes is 0.5cm	300V in the first stage and 400V in the second stage.	0,5A in the first stage and 0,6A in the second satge.	0.03	1500C	 There are intensive lines of atomic hydrogen (H_α and H_β) and bands of triplet molecular hydrogen $(^2\Sigma_g \rightarrow ^1\Sigma_u)$ in the ultraviolet area in the plasma jet spectrum.

Measurements.
Energy and spectrometric characteristics of auxiliary plasma jet were measured. These characteristics showed that working substance (water steam) and active plasma particles are very effective for the formation of the non-self-sustained discharge.
The discharge radiation spectrum was registered using diffraction MUM-1 monochromator in a spectral interval 200-700 nm. The spectrum of auxiliary plasma jet was characterized by molecular bands in 500-560

nm spectral domains (N_2, O_2, NO, NO_2). The hydrogen lines were registered only on the plasmatrone output. The situation changed when we put a potential on the second electrode. The analysis of non-self-sustain discharge radiation spectrum showed that there were intensive Balmer lines of atomic hydrogen (H_α, H_β) in the non-self sustained discharge. Spectrum was also characterized by bands of triplet molecular hydrogen ($^2\Sigma_g \rightarrow {}^1\Sigma_u$) in the ultraviolet area, lines of atomic and molecular oxygen, and bands of OH group.

Energy characteristics of plasma jet.

The power of the plasma jet was measured using IKT-1M calorimeter. Mean heat power, which was generated by the plasma jet was 90W when the electric power was 150W. Efficiency factor was 60%. There is the integral distribution of the auxiliary plasma jet intensity in the figure 3 and the integral distribution of non-self-sustain discharge intensity in the figure 4.

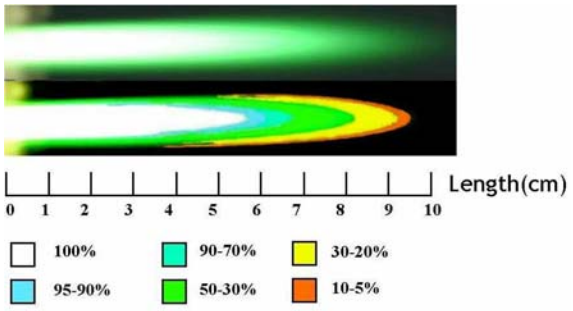

Figure 3. Distribution of the auxiliary plasma jet intensity.

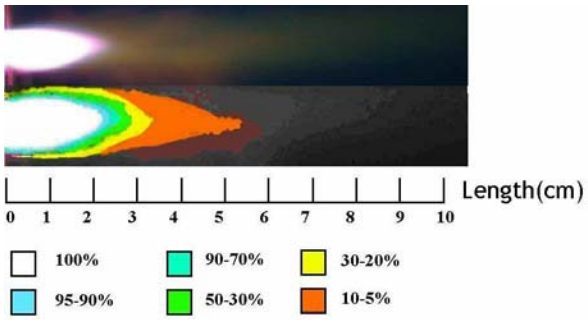

Figure 4. Distribution of the plasma jet intensity

As we can see, when we did not put a potential on the second electrode, the long plasma jet was generated. The intensity of the plasma jet zones changed fluently. When we put a potential on the second electrode, the length of plasma jet became shorter. The area of maximal intensity occupied the most part of plasma jet.

Conclusion.

The conducted research of the non-self-sustained discharge revealed some characteristics of plasmachemical processes in the jet. They account for technological applications of this plasmatron. In particular, this devise can be used as the injector of active plasma for a plasmachemical reactor, because of hydrogen creation in plasma jet. This devise also can be used for plasma spray obtaining.

Atmospheric pressure radio-frequency capacitive plasma jet operated with argon

J. Laimer, S. Haslinger, W. Meissl, J. Hell, H. Störi

Institut für Allgemeine Physik, Vienna University of Technology, Vienna, Austria

Abstract

We developed an atmospheric pressure RF capacitive plasma jet having planar electrodes und investigated its performance when operated with argon. A stable uniform glow-like discharge (α-mode of an RF discharge) can be sustained within a wide power range. However, a non-uniform discharge (coexisting α- and γ-mode) was observed immediately after ignition. A transition to the pure α-mode occurred at a very low RF power. Contrary, a transition from the pure α-mode to the coexisting α- and γ-mode took place at a high RF power.

Keywords: RF discharge, α-discharge, γ-discharge, atmospheric pressure, argon

1. Introduction

Today, non-equilibrium atmospheric pressure plasmas attract more and more attention. They can be realized by a variety of techniques, one of them is the atmospheric pressure plasma jet (APPJ), which was introduced a few years ago [1-4]. The APPJ operates in a capacitive mode using RF power and produces a stable glow-like discharge without dielectric material between the electrodes. Usually, it is operated with a high gas flow of pure helium or helium with addition of reactive gases in the range of a few percent. The gas flow out of the discharge has a relatively low gas kinetic temperature. Due to recombination the effluent consists only of neutral species, including metastable species and radicals (in case of reactive gas addition). Some applications in materials processing and decontamination have been already investigated [6-10]. Recently, Wang et al. claimed that they are able to operate an APPJ with argon as well [11]. However, they used a configuration with concentric electrodes.

Very recently we developed an APPJ with planar electrodes featuring a rectangular cross section of the effluent [12]. Tests with contaminated helium showed that the APPJ can be operated in a rather uniform glow-like mode within certain limits. This mode was identified as the α-mode of an RF discharge. However, at the upper limit of this mode a transition to the γ-mode occurred. This high current density mode covered the electrodes only partially. This type of transition is well known for capacitive RF discharges at moderate pressures [13], however, for APPJs the transition at the high power limit of the α-mode was often attributed to arcing.

2. Experimental details

The homemade APPJ with the lifted grounded counter electrode is shown in Fig. 1. A scheme of the discharge and the experimental setup is exhibited in Fig. 2. An RF generator with a frequency of 13.56 MHz and a manually adjustable matching network was used to supply the RF power for the APPJ. Forward as well as reflected power was measured. The discharge was produced between two planar copper electrodes; one is RF powered the other one is grounded. The reflected power was minimized by adjustment of the capacitances of the matching

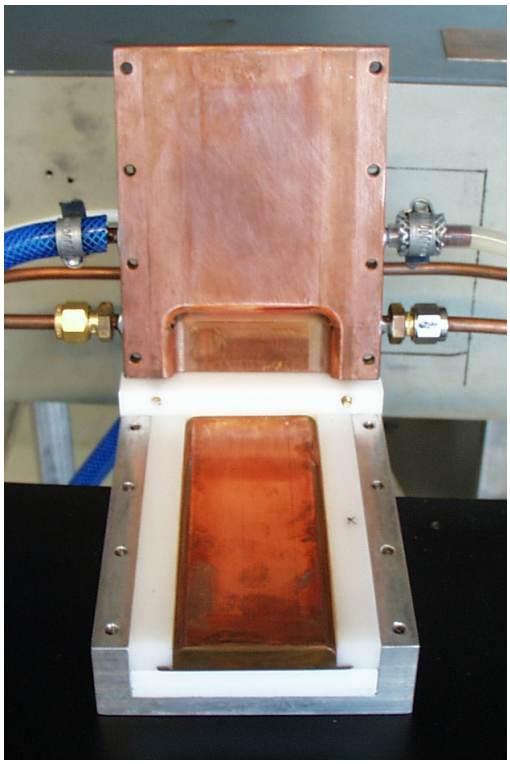

Fig. 1: Picture of the APPJ. RF electrode is in centre, grounded counter electrode is lifted.

network. The electrodes were cooled with water. The effective surface area was approximately 38 cm^2. The exit of the used APPJ has a width of approximately 50 mm and a gap spacing, which can be adjusted with PTFE spacers between 0.5 and 2.5 mm in steps of 0.5 mm. However, a gap spacing of 2.5 mm was used throughout the experiments. The APPJ was operated with argon (purity 99.999%) at a gas flow rate of 2 standard litres per minute (slm). The plasma was exhausted directly into ambient air. Ambient pressure in Vienna is in average roughly 960 hPa.

The electric properties of the APPJ were studied by measuring voltage and current simultaneously by using a high voltage probe (Tektronix P5100), a current probe (Tektronix P6021) and a digital oscilloscope (Tektronix TDS 3052B). Additionally, pictures showing the front view of the discharge were taken with a digital camera (Minolta Dimage Xt), while the APPJ was illuminated with a 500 W halogen lamp. Pictures with higher magnification were taken with the same digital camera in combination with an optical microscope (Zeiss OpMi-1) of 0.3 m focal length.

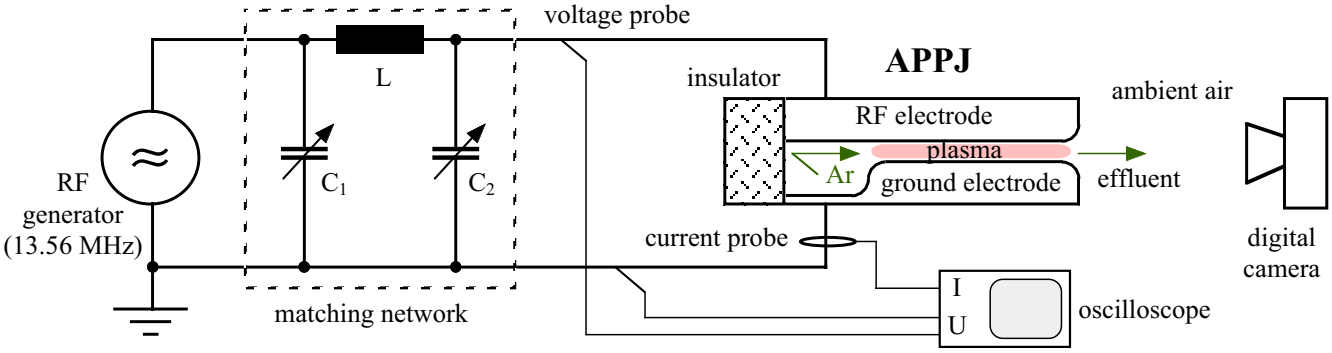

Fig. 2. Schematic illustration of the experimental setup.

3. Results and discussion

It turned out that the argon discharge is more difficult to ignite than the helium discharge. The current-voltage curves shown in Fig. 3 demonstrate the behaviour. An ignition was only accomplished by an increase of the forward power up to 200 W, whereby before ignition all power is reflected. Therefore, the “no discharge” operation mode shows a pure capacitive behaviour. The current leads the voltage by 90°. Both waveforms are purely sinusoidal. From the slope of the curve a capacitance of 57.8 pF was determined, consisting of a parallel plate capacitance of 13.5 pF and a parasitic capacitance of 44.3 pF.

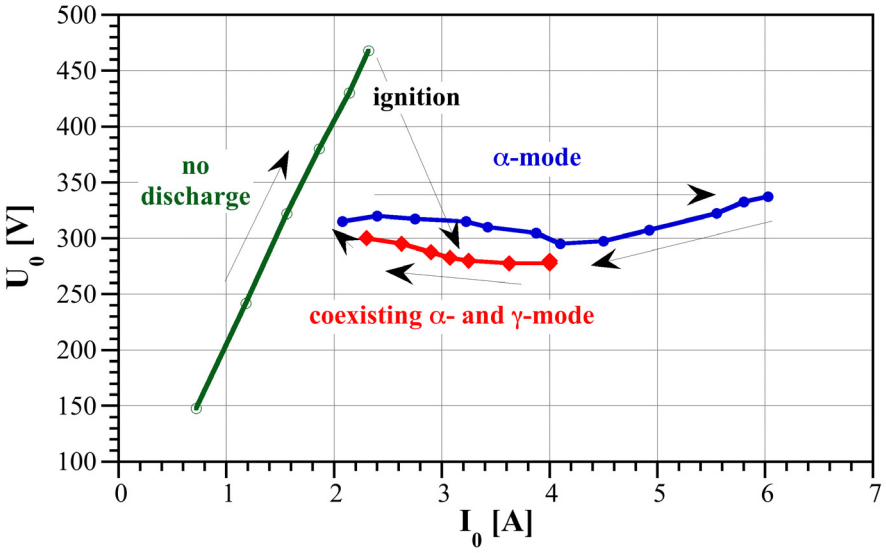

Fig. 3. Current and voltage characteristics of the APPJ. Peak-amplitudes are given. Different types of operating modes as well as transitions between them are indicated. Gap spacing is 2.5 mm.

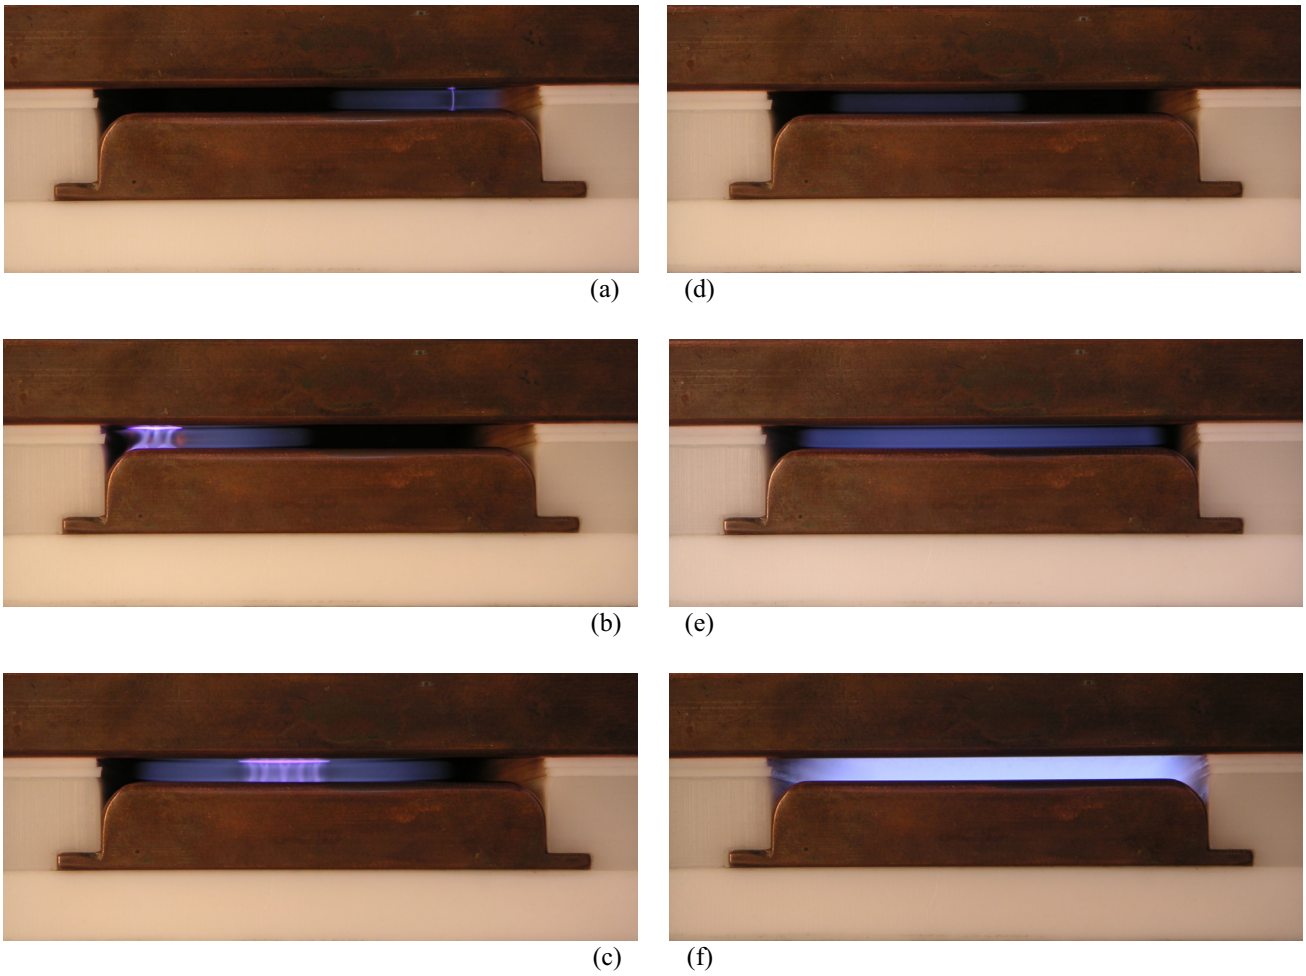

Fig. 4: Front view of the RF discharge for various operating conditions. Gap spacing is 2.5 mm. RF electrode is in centre and grounded electrode is on top. On the left side are the coexisting α- and γ-modes. On the right side are the pure α-modes.
(a) P = 20 W, lower power limit of the coexisting α- and γ-mode
(b) P = 200W, immediately after ignition
(c) P = 260 W, highest RF power investigated
(d) P ≤ 20 W, lower power limit of the pure α-.mode, partial coverage of the electrodes
(e) P = 20W, low power limit of the pure α-mode, full coverage of the electrodes
(f) P = 220 W, upper power limit of the pure α-mode

Fig. 4 shows all discharge patterns observed. Immediately after ignition the electrodes are only partially covered with a glow (Fig. 4b), which moves around between the left and the right electrode edge. Within this discharge two different regions can be distinguished. In the centre of the discharge there is a bright negative glow very close to both electrodes connected with a few filament-like contracted positive columns. It is surrounded by a region of reduced brightness (halo) featuring a much wider dark space. A comparison with [13] leads to the conclusion that a γ-discharge is present, which is surrounded by an α-discharge. Both discharge modes seem to coexist. An increase in RF power up to 260 W showed that the coexisting α- and γ-mode is present throughout this power rage. However, the coverage of the electrodes with the γ-mode as well as the number of filament-like positive columns increased (Fig. 4c). By reducing the RF power the discharge becomes weaker, whereby the number of filament-like positive columns is decreased. Fig. 4a shows the lower power limit of this type of discharge with a barely visible γ-mode. By reducing the RF power even further until the last filament-like

positive column is gone the discharge changes drastically. A transition to a pure α-discharge occurs (Fig. 4d). However, this takes place at very low RF powers (≤20 W). If one reduces the RF power to quickly the discharge extinguishes. At this very low power level the pure α-mode only partially covers the electrodes. However, an only slight increase in RF power (20 W) leads to a spreading of the α-discharge across the electrodes causing an already full coverage (Fig. 4e). It has to be mentioned that the power measurements at this very low power levels are not very accurate. By increasing the RF power the discharge becomes brighter and brighter (Fig. 4f). When the RF power exceeds approximately 220W a transition to the coexisting α- and γ-mode takes place.
We repeated the experiments several times, but we never accomplished a direct ignition of the α-discharge. On the other hand we also never observed arcing at the upper power limit of the α-discharge.
Pictures of the discharges taken with higher magnification show clearly visible dark spaces close to the electrodes in regions where the α-mode is present (Fig. 5). The sheath thickness estimated from the pictures is in the order of a few tens of a millimetre. Only in pure α-discharges at high power levels the dark space is less visible due to the high brightness of the discharge (Fig. 5d). In the region of the γ-discharge a very intense negative glow is visible close to the electrodes indicating a much higher current density. An increase in RF power leads to an increase of the surface covered by this high current negative glow. The sheath thickness of the γ-discharge is much smaller; it cannot be estimated from the pictures taken. The negative glows on both electrodes are connected with a bright positive column (e.g. Fig. 5a). At low RF powers the positive column is contracted and exhibits one plasma filament. With increasing RF power, first, branching of the plasma filament occurs, than the number of the plasma filaments increases, whereby branching might still occur (Fig. 5b). Each plasma filament seems to need a minimum on current and is able to carry only a limited amount of current. As such type of structural non-uniformity might transform a γ-discharge into an arc [13], we did not explore the stability of the coexisting α- and γ-mode at RF powers beyond 260 W.

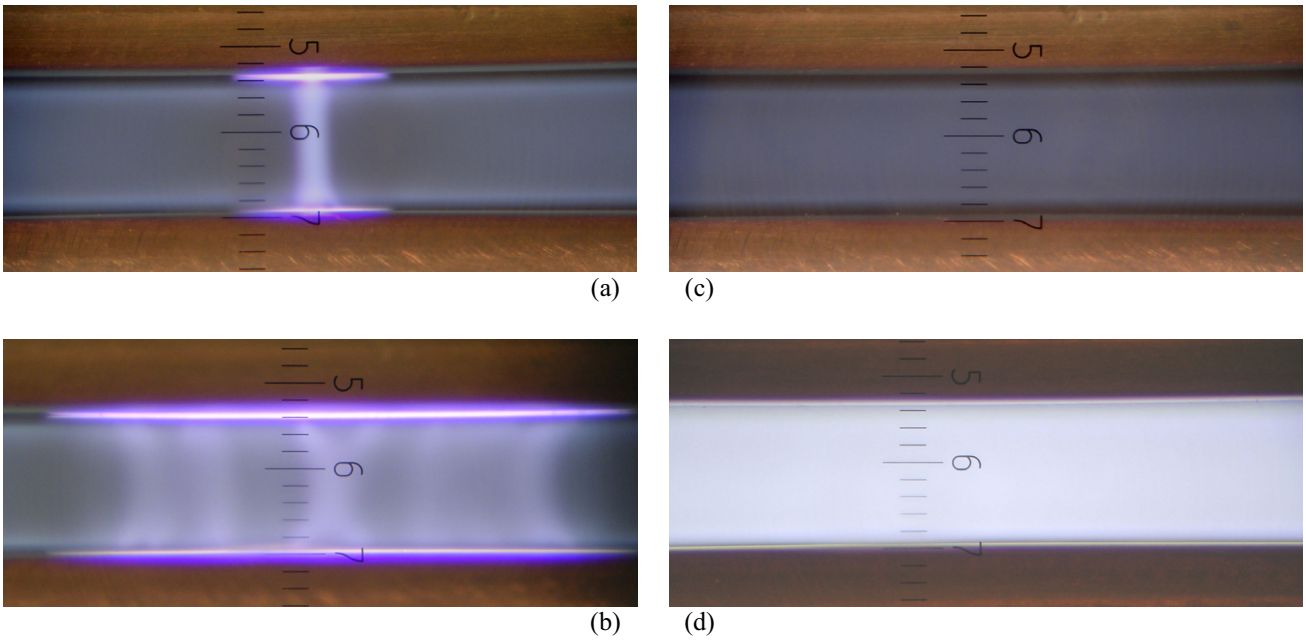

Fig. 5: Pictures of the RF discharge for various operating conditions taken with higher magnification. Gap spacing is 2.5 mm. RF electrode is on bottom and grounded electrode is on top. On the left side are the coexisting α- and γ-modes. On the right side are the pure α-modes: (a) P = 40 W, (b) P = 240W, (c) P = 20 W and (d) P = 220 W.

The current and voltage waveforms of both modes show a distinct behaviour with increasing RF power. At the low power limit of the α-mode both the current and voltage exhibit sinusoidal waveforms, whereby the current leads the voltage by more than 85°. With increasing RF power the phase difference between current and voltage

decreases. The current shows only a very small contribution of the third harmonic, even at a high RF power. At the low power limit of the coexisting α- and γ-mode the current leads the voltage by more than 80°. However, the current already shows a small contribution of the third harmonic. With increasing RF power the phase difference between current and voltage decreases much more than in the case of the pure α-mode. At the highest RF power investigated (260 W) the third harmonic makes up to 20% of the fundamental of the current. Even the voltage waveform exhibits a small distortion due to a contribution of a third harmonic.

4. Conclusions

A stable uniform glow-like discharge can be sustained in an APPJ operated with argon in a power range of 20 to 220 W. The uniform glow-like discharge was identified as the α-mode of an RF discharge. As the upper power limit of stability of the α-mode is due to a transition to a coexisting α- and γ-mode and not due to arcing, damaging of the electrodes is not a problem.

Besides the pure α-mode a non-uniform RF discharge, which was identified as a coexisting α- and γ-mode, was observed as well. It occurred at RF powers ranging from 20 W to at least 260 W. At even higher RF powers a transition to an arc might occur, which was, however, not investigated.

It was not possible to ignite the pure α-discharge directly. The breakdown always led to a coexisting α-and γ-mode. However, at very low RF powers a transition to the α-mode took place.

The APPJ operated with argon in the α-mode is surely an interesting tool for future plasma applications. Maybe, the high current density γ-mode can be used in a differently designed APPJ.

TGA study of the thermal decomposition of aqueous cerium nitrate solutions as liquid precursors for thermal plasma synthesis of cerium oxide particles.

M. J. Desroches, I. Castillo[1], R. J. Munz[1]

[1]*Plasma Technology Research Center (CRTP), McGill University, Montreal, Canada*

Abstract
The effect of fuel addition in the thermal decomposition of water soluble cerium nitrate salts was studied. The fuels investigated were glycine and alanine based on their low molecular weight and high energy of combustion. The results showed that both alanine and glycine effectively lowered the calcination temperature of the solution and that alanine is the preferred fuel based on its higher energy of combustion.

Keywords
Cerium oxide, SOFC, TGA, thermal decomposition, solution plasma synthesis.

1. Introduction

The synthesis of CeO_2 (cerium oxide) powders doped with controlled and precise compositions of gadolinium, yttrium and samarium has been recently investigated using a rf inductive coupled plasma reactor [1]. Cerium oxide doped powders are regarded as one of the most promising materials to substitute YSZ (yttria stabilized zirconia) as the preferred electrolyte in SOFCs (solid oxide fuel cells) operation. Cerium oxide doped powders were synthesized from solutions of cerium and dopants nitrate salts dissolved in water, which were injected as a fine mist into the plasma torch using an air-blast type atomizer. As the fine droplets come in contact with the plasma (mixture of argon-oxygen), a portion of the plasma's energy is employed in the evaporation of the solution's excess water; rather than in the direct calcination of the nitrate salts to form the oxide powders. Recent work done by Chung [2] and Wang [3] has shown that the addition of glycine or alanine to the nitrate precursor solution could serve as fuel. By providing additional energy, the combustion of the fuel could promote the thermal decomposition of the nitrates into the desired oxides at lower temperatures. Decreasing the calcination temperature is important to promote an *earlier* synthesis due to the very short residence times that the droplets are in contact with the plasma core. To corroborate this hypothesis, an analysis of the thermal decomposition of mixtures of cerium nitrate, fuels and water was conducted using thermogravimetric techniques, i.e. TGA. Selected combustion-synthesized powders were then characterized by X-ray diffraction and their morphology examined by SEM micrographs.

2. Thermal decomposition of cerium nitrate hexahydrate and associated fuel reactions

The thermal decomposition of hydrated rare earth nitrates in air into their corresponding oxides has been reported by Wendlandt [4,5]. It was found that CeO_2 was produced as follows:

$$Ce(NO_3)_3.6H_2O \rightarrow Ce(NO_3)_3 \rightarrow CeO_2$$

The hydrate begins to gradually lose its water of hydration at 80°C and the final metal oxide is formed beginning at ~350°C.

The fuels investigated were glycine (H_2NCH_2COOH) and alanine ($CH_3CH(H_2N)COOH$). These aminoacids are small molecules that posses large energies of combustion and that are unlikely to interfere with the thermolysis of the nitrate salts. The combustion energy of glycine (MW=75.07) is 13,000 J/g and that of alanine (MW=89.09) is 18,000 J/g [6]. Their respective combustion reactions assuming complete fuel decomposition are:

$$Ce(NO_3)_3 \cdot 6H_2O + \frac{15}{9} NH_2CH_2COOH + \frac{1}{4} O_2 \rightarrow CeO_2 + \frac{7}{3} N_2 + \frac{10}{3} CO_2 + \frac{61}{6} H_2O$$ ……..for glycine

$$Ce(NO_3)_3 \cdot 6H_2O + CH_3CH(NH_2)COOH + \frac{1}{4} O_2 \rightarrow CeO_2 + 2N_2 + 3CO_2 + \frac{19}{2} H_2O$$ …for alanine

3. Precursor mixtures investigated and experimental techniques

It was determined experimentally that a saturated solution at 25° C of hexahydrated cerium nitrate in water had the following proportions: 1.8g of salt per g of water [1] (base case). Three different amounts of fuel, either glycine or alanine, were added to the base case taking the nitrate salt as the basis of calculation, i.e. a stoichiometric amount, fuel-deficient (less than stoichiometric) and fuel-rich (more than stoichiometric).

Table 1 Summary of precursor mixtures

	Glycine				**Alanine**		
Mixture	A1	A2	A3	A4	C1	C2	C3
Description	No fuel	Stoichiometric	Fuel lean	Fuel rich	Stoichiometric	Fuel lean	Fuel rich
Molar ratio (Salt/Fuel)	-	1:1.67	1:1	1:2	1:1	1:0.60	1:1.2

Once the best two mixtures of each fuel were determined, two more precursors were prepared. The aim was to retain the optimal fuel to salt proportions but now with a minimal amount of water. The saturated solutions prepared in this fashion were about twice as concentrated as the previously used ratio of 1.8 g salt/g of water (B2 for glycine and D2 for alanine), i.e. 3.9 g salt/g of water.

The thermal decomposition analyses were done using the Pyris Thermogravimetric Analyzer from PerkinElmer in air. A small drop of the precursor sample was placed within the crucible. Two different heating rates were investigated: 5°C/min and 10°C/min. The X-Ray diffraction analysis on the residue was done using a PHILIPS PW1710 powder X-ray diffraction system equipped with a copper X-ray source operated at 800 W. Finally, the synthesized powders were analyzed using a Hitachi 4700 Field Emission Scanning Electron Microscope (FE-SEM).

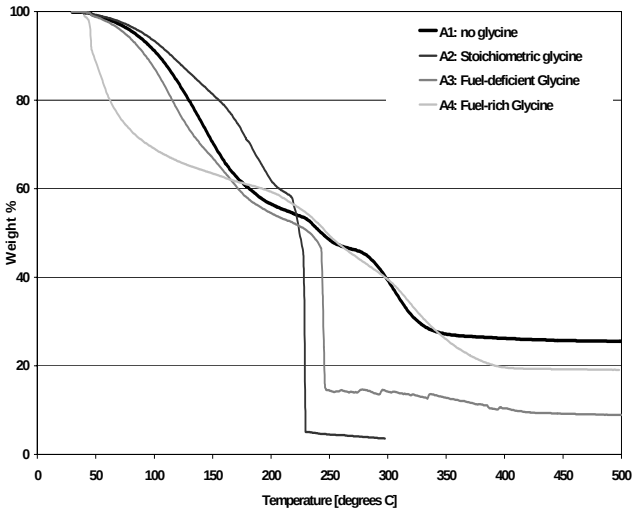
4. Results

4.a) Thermal decomposition and optimum ratio of nitrates, fuel and water

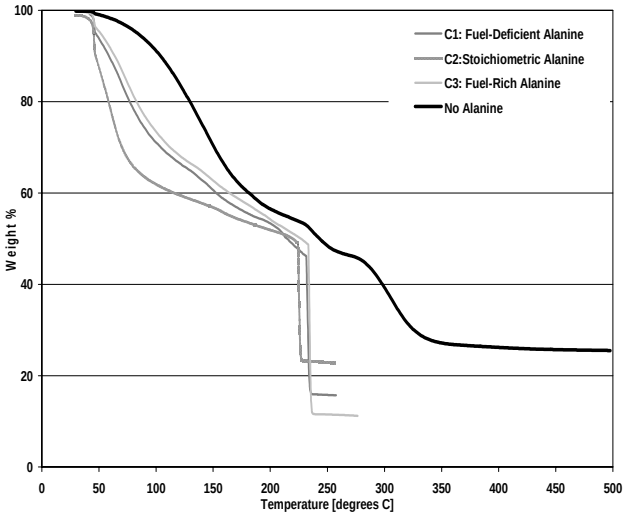
The A and C series were analyzed using a heating rate of 10°C/min on the TGA. It was found that complete nitrate decomposition was obtained at different temperatures depending on the amount of glycine added. The fuel deficient and the stoichiometric fuel mixtures formed the oxides at ~225 °C, whereas the fuel rich and no-fuel mixtures formed the oxides at temperatures close to ~350 °C (Fig. 1a). It was observed that there was an *auto-ignition* of the samples forming oxides at lower temperatures. Auto-ignition effectively decreases the temperature of oxide formation as previously reported [7].

For the C series, auto-ignition occurred for all mixtures regardless of the amount of alanine added. Complete decomposition of the salt into cerium oxide was found to be at ~225 °C (Fig. 1b). Both glycine and alanine decreased the temperature at which the oxides are formed by approximately 125 °C and the most favorable case was when stoichiometric amounts were added. Less fuel per salt is needed to produce the same effect in the case of alanine, and thus it is a more efficient fuel source.

For the twice as concentrated solutions (B2 and D2) of stoichiometric alanine and glycine; it was found that *only* the concentrated alanine mixture further reduced the oxide formation temperature (~200 °C) (Fig. 2). This could be attributed to the higher combustion energy of alanine (5,000 J/g more than glycine), which is sufficiently large to promote auto-ignition at a lower temperature.

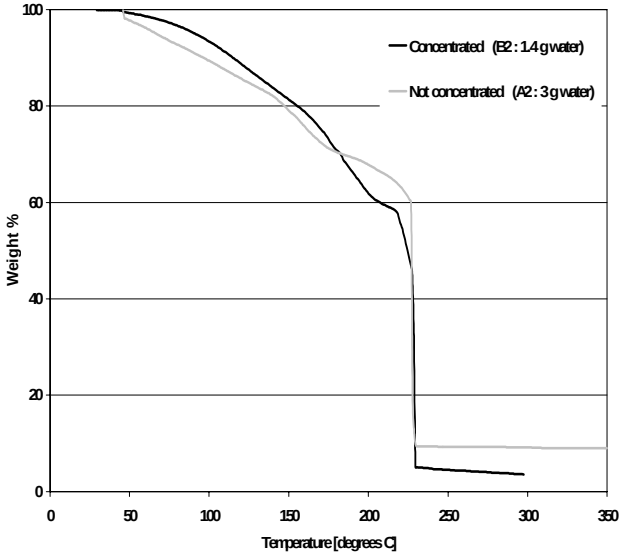


a. glycine

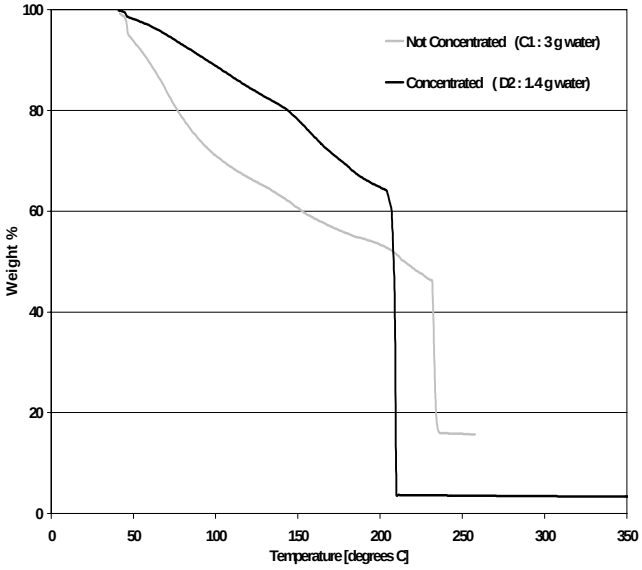


b. alanine

Figure 1. Thermal decomposition of the Series A and C mixtures obtained using TGA (heating rate: 10°C/min).



a. glycine

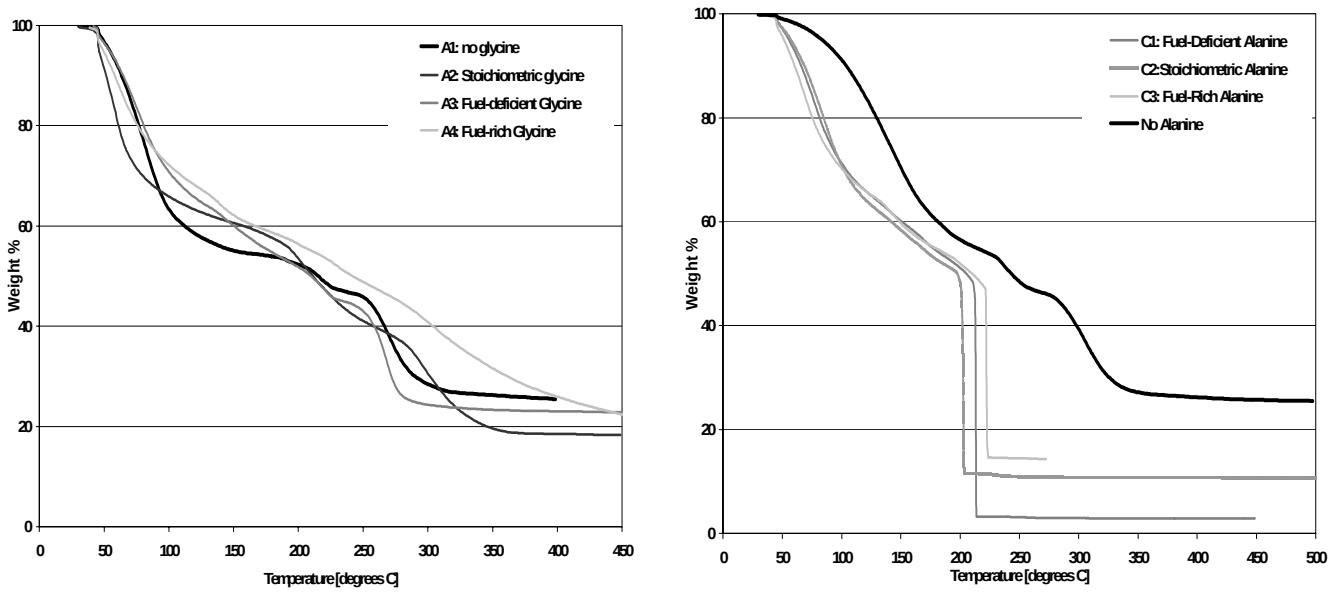


b. alanine

Figure 2. Effect of concentrating the mixture containing cerium nitrate and stoichiometric

The A and C series were re-analyzed at a lower heating rate of 5°C/min. It was found that there was *no* auto-ignition in *any* of the glycine-containing mixtures. Conversely, auto-ignition was encountered in all of the alanine-containing mixtures (Fig. 3a and 3b). This shows that the higher combustion energy of alanine is sufficient to promote auto-ignition of the nitrates even at a lower heating rate.

Based on the TGA results where the heating rate was fixed at 10°C/min, there appears to be an optimum ratio of nitrates, water and fuel that results in the formation of the CeO_2 powders at the lowest temperature. This optimum composition corresponds to the mixture D2 containing stoichiometric amounts of alanine. On a mass basis, this mixture is composed of 68% $Ce(NO_3)_3 \cdot 6H_2O$, 14% alanine and 18% water.



a. glycine b. alanine

Fig. 3. Thermal decomposition of the Series A and C mixtures obtained using TGA (heating rate: 5°C/min)

4. b) Crystallinity and purity of the oxides

The X-ray diffraction patterns of selected oxides powders produced from the TGA experiments showed that pure cerium oxide was produced. Also, the choice of glycine and alanine did not impact the crystallinity nor the purity of the oxides. However, the addition of fuel seemed to produce oxides with larger crystals judging from the narrower peaks observed when autoignition occurred.

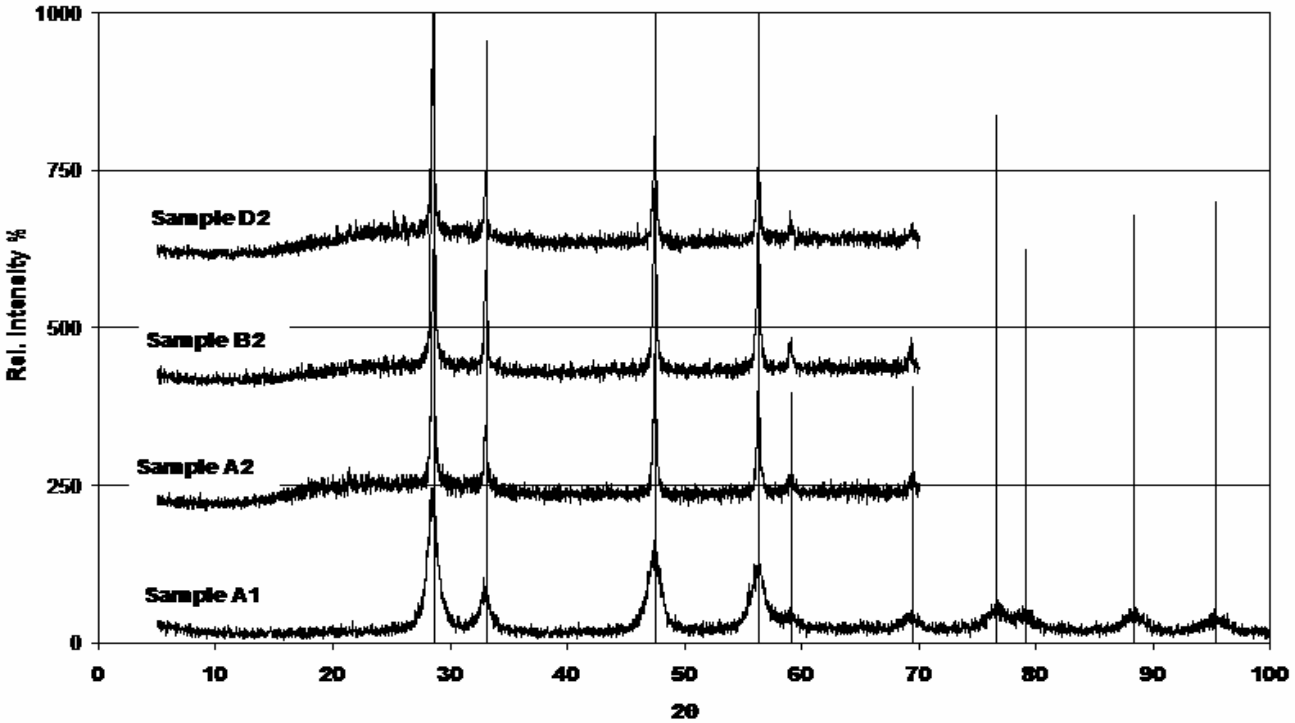


Figure 4. X-ray diffraction patterns of four CeO_2 powders synthesized from the TGA experiments. SD2=Stoich. conc. alanine, SB2=Stoich. conc. glycine; SA2=Stoich. glycine, SA1=No fuel

4. c) Powder morphology

Two different types of powder morphologies were observed from SEM micrographs. Porous-coral-like structures when auto auto-ignition was present, and dense-paste-like morphologies in its absence. This confirms the results obtained from the X-ray diffraction patterns which showed a difference in crystal size between mixtures that auto-ignite and those which do not. The foamy-coral-like structure is due to the evolution of gaseous materials during ignition.

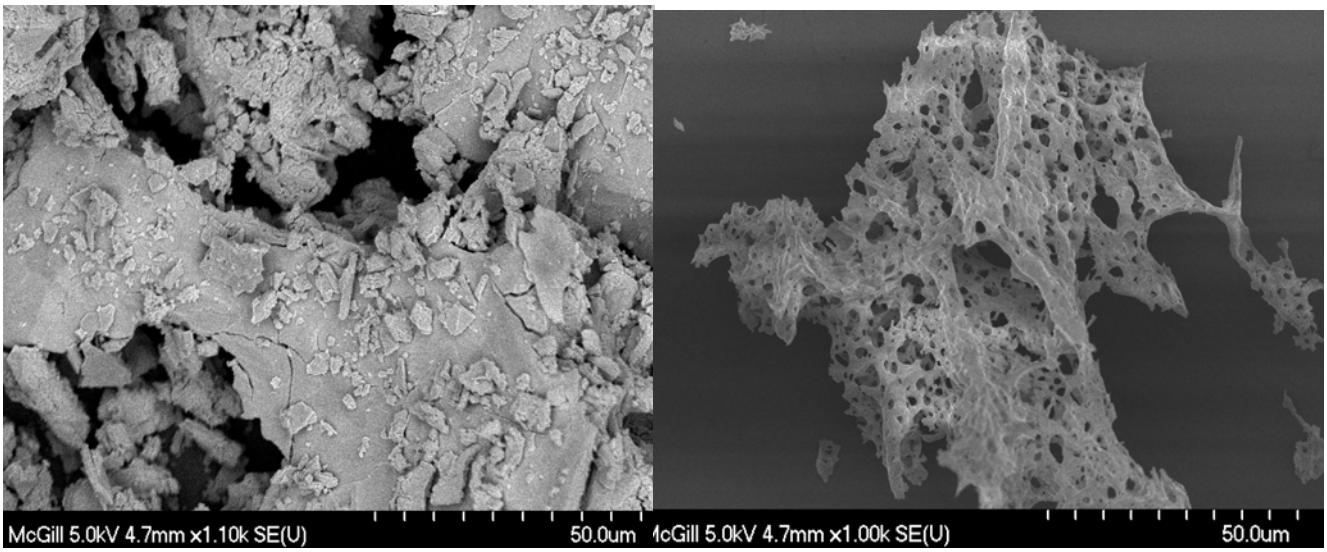

Figure 5. (a) SEM micrograph of powder produced from a mixture containing only $Ce(NO_3)_3 \cdot 6H_2O$ and water (no auto-ignition observed) (b) SEM micrograph of a powder produced from a mixture containing $Ce(NO_3)_3 \cdot 6H_2O$, water and stoichiometric alanine (auto-ignition observed)

5. Conclusions

The effect of adding glycine and alanine as fuel sources to precursor solutions of salt and water was investigated. Alanine is the preferred fuel based on the thermal decomposition results of the prepared mixtures. A smaller mass of alanine is required to achieve a similar reduction of the calcination temperature of cerium nitrate salts. Furthermore, concentrating the precursor mixture by removing water leads to an additional drop in the temperature at which the oxides are formed. The optimum composition of the precursor mixture has been found to be 68% $Ce(NO_3)_3 \cdot 6H_2O$, 14% alanine and 18% water (by mass). Auto-ignition of this mixture led to the production of the oxides at approximately 200°C (as opposed to ~350°C when no fuel is present).

The X-ray diffraction analysis results determined that the powders produced in the TGA were in fact the desired CeO_2. Lastly, the morphology of a few selected powders was characterized using SEM. Powders where auto-ignition had not occurred were found to be dense and of flaky appearance. The oxide powders obtained following auto-ignition were found to be porous and of foamy texture. This morphology can be attributed to the large amount of gases evolved during auto-ignition

Abstract

High quality transparent conductive ZnO thin films were deposited on quartz glass substrates using pulsed laser deposition (PLD). We varied the growth conditions such as the substrate temperature and oxygen pressure. Crystallographic structures, electrical and optical properties of the as-grown doped ZnO films were mainly investigated. In general, the study indicates that doped ZnO films show electrical and optical properties comparable with that of ITO films and emerging as a potential good challenger to ITO films.

1. Introduction

Zinc oxide (ZnO) is a Ⅱ-Ⅵ semiconductor, highly transparent in the visible region with a wide and direct band gap of about 3.37 eV at room temperature and a high exciton binding energy of 60 meV [1]. This material is very attractive because it has many applications such as transparent conductive contacts, solar cells, laser diodes, ultraviolet lasers, thin films transistors and other [2,3]. Generally, undoped ZnO thin films typically exhibit *n*-type conduction with a background electron concentration as high as 10^{21} cm^{-3}. ZnO is an oxide that can be grown as a thin film by many deposition techniques including chemical vapor deposition, radio frequency sputtering, magnetron sputtering, sol–gel, ion-beam-assisted, molecular-beam epitaxy, and pulsed laser deposition [4, 5]. Among the several fabrication techniques, pulsed laser deposition (PLD) has attracted much attention because the fabrication process is quite suitable for optoelectronic devices using the ZnO transparent electrode. The composition of films grown by PLD is quite close to that of the target, even for a multi component target. PLD films may be crystallized at lower deposition temperatures relative to other physical vapor deposition techniques due to the high kinetic energies of the ionized and ejected species in the laser plumes [6]. However, it is difficult to make the transparent layer on the optoelectronic devices because the electrical and optical properties of doped ZnO films very drastically depending on the PLD condition. In this work we report results obtained from nominally undoped ZnO, Al doped ZnO (AZO) and Ga doped ZnO (GZO) films grown by KrF excimer (λ=248 nm, 25 ns pulse width) pulsed laser deposition (PLD) at different substrate temperatures and background pressure of oxygen gas. The crystallographic structure and the electrical and optical properties of the films prepared at different growth parameters will be discussed.

2. Experimental

Fig.1 shows a schematic diagram of the PLD system. Transparent conductive ZnO films were prepared by pulsed laser deposition on quartz glass substrates. The pulsed laser was the KrF excimer laser (λ=248 nm, 25

ns pulse width) and energy fluence of 2 J/cm^2. The nominally undoped ZnO films were deposited by ablating a 99.99% pure ZnO target. The AZO and GZO films were produced by ablating ZnO targets containing 2 wt. % Al_2O_3 and 5 wt. % Ga_2O_3, respectively. A substrate was placed at 40mm away from the target and could be heated up to 1000°C. The typical grown run consisted of 9,000 laser shots with a repetition rate of 10 Hz. All of the films were also deposited on quartz glass cleaned in an ultrasonic bath acetone and then ethanol for 5 min. The deposition chamber was initially evacuated to 4×10^{-5} Torr and during deposition, oxygen gas was introduced into the growth chamber and the pressure was controlled to be 1~100 mTorr by using a conductance valve and a turbo molecular pump. The as-grown doped ZnO films were characterized by X-ray diffraction (XRD: Rigaku, RINT 2100/PC). The surface morphology was observed by atomic force microscopy (AFM: Seiko Instrument, SPI 3800N). The growth rate and the thickness of the sample were determined by cross-sectional scanning electron microscopy (SEM: JEOL JSM-T200). The transmission through the films was measured using UV-visible spectrophotometer in the wavelength range from 200~800 nm. Electrical properties of the AZO films were measured by van der Pauw method at room temperature.

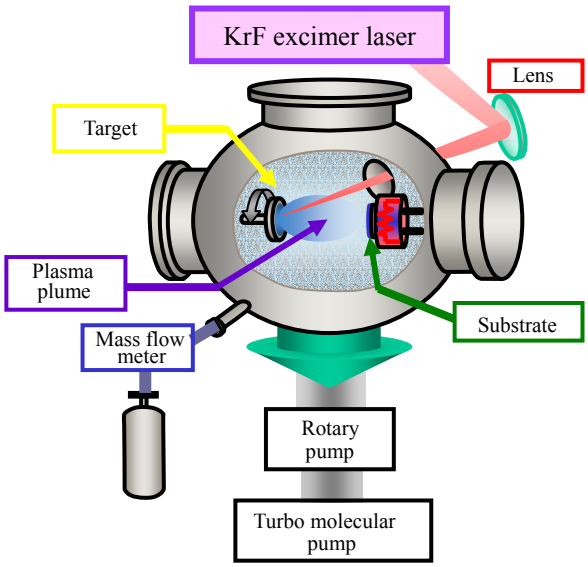

Fig. 1 Schematic diagram of PLD system

3. Results and discussion

Fig. 2a shows effect of oxygen pressure (pO_2) on the crystallinity of the AZO films. The ambient oxygen pressure was changed from 1 mTorr to 100 mTorr at substrate temperature of 500°C. XRD 2θ scans in the vicinity of the ZnO (002) reflection were performed on these films. The strong peak signal of the (002) diffraction was observed for the 5 mTorr film, while the film prepared at 1 mTorr shows fine evidence of crystallinity. Similar sets of samples were deposited using the Ga containing targets and XRD 2θ scans were carried out on these films, also. These results are not presented here but showed the same trend with pO_2 as the Al doped ZnO films. Table 1 show that the crystal size of the AZO films increases from 10.15 nm at 1 mTorr to 34.02 nm at 5 mTorr and then decreases gradually for samples prepared up to 100 mTorr. The facts suggest that the crystalline quality of the AZO films degraded from single-oriented crystal to polycrystalline with the increase of the oxygen content. The excess oxygen might induce defects in the films, which influenced the nucleation and growth of the films, and resulting in the degradation of the crystalline quality (see also Table 1). These results also confirm that a pressure of 5 mTorr will give the better epitaxy (as seen from 2θ scan), better texture, and larger crystal size (34 nm using Scherrer's formula) of the AZO films. Fig. 2b shows effect of substrate temperature on the crystallinity of the GZO films. Two diffraction peaks corresponding to (002) and (004) reflections are predominant and indicate that the film has a c-axis direction with an out-of-plane lattice parameter around 5.2 Å. At higher substrate temperatures the intensity of (002) peaks increased. The FWHM values decreased from 0.36 to 0.198º as the growth temperature increased from

100 to 500ºC.

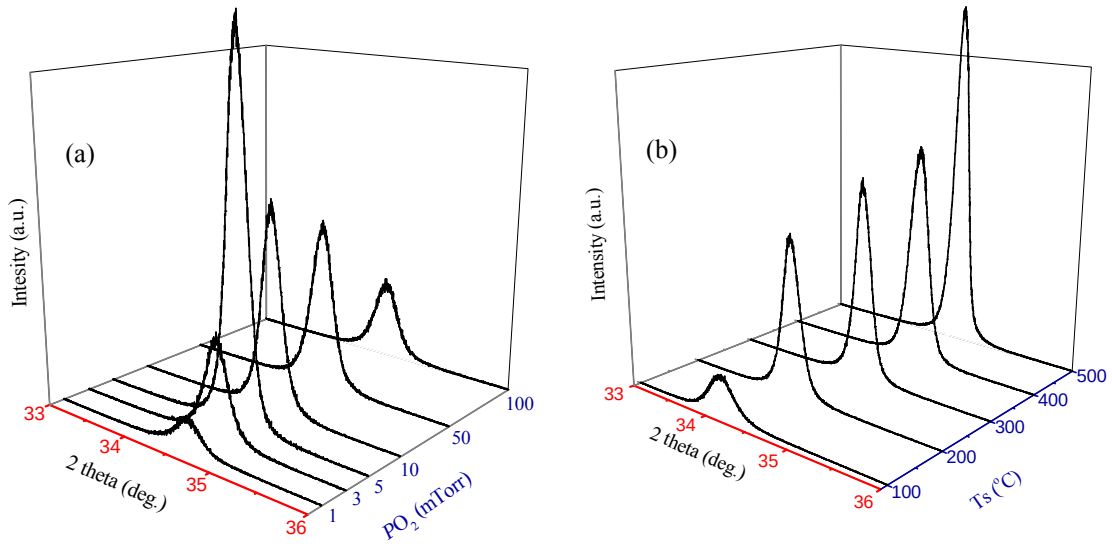

Fig. 2 XRD 2 theta scans of ZnO films grown on quartz substrates in the vicinity of ZnO (002) peaks. (a) AZO films as a function of pO_2. (b) GZO films as a function of Ts.

Table 1

Properties of AZO films on quartz glass substrates at 500°C as a function of oxygen pressure.

pO_2 (mTorr)	Crystal size (nm)	c-axis length (Å)	Roughness (nm)	T (%) (400-800 nm)	Band gap (eV)	Resistivity (Ωcm)	Carrier concentration (cm^{-3})	Carrier mobility (cm^2/Vsec)
1	10.15	5.178	7.062	88.66	3.36	5.14×10^{-4}	1.25×10^{21}	9.74
3	22.8	5.173	7.142	90.97	3.36	4.97×10^{-4}	1.16×10^{21}	10.87
5	34.02	5.176	7.97	93.37	3.35	3.92×10^{-4}	1.14×10^{21}	14.03
10	25.3	5.182	7.354	95.46	3.34	7.5×10^{-4}	1.04×10^{21}	8.01
50	23.5	5.187	7.227	94.63	3.32	1.78×10^{-3}	9.92×10^{20}	3.55
100	21.3	5.185	6.834	95.14	3.26	5.22	1.25×10^{19}	0.1

The morphology and the surface roughness determined by AFM measurement are shown in Fig. 3. The roughness seems to increase with the increase of substrate temperature and in the same time, the grain size on the surface is varied. For the film grown at low temperature (100°C), the grain size is around 90 nm. Furthermore, the roughness of this film is about 9 nm. On the contrary, the film grown at higher temperature (300°C) the grain size of around 115 nm and the roughness of the film slightly decrease to about 8 nm. Sample prepared at up to 500°C shows the grain size of around 230 nm and the roughness of about 8 nm.

Fig. 4 shows optical transmittance of the ZnO, AZO and GZO thin films prepared at a substrate temperature of 500°C and at an oxygen pressure of 5 mTorr. The transmittances obtained are around 90% at the wavelength from 400 to 800 nm. We also find the transmission edge shift around 350-390 nm toward lower energies either by doped material. This shift is confirmed by representing absorbance squared versus the excitation energy *hv*. The optical absorption coefficient α is related to the threshold absorption energy (Eg) by $\alpha = A\bullet (hv - Eg)^{1/2}$ (A is a constant). The band gap energy Eg can be determined by extrapolation of the

linear part of the plot of α^2 versus, *hv*. The band gap of ZnO, AZO and GZO films are 3.23, 3.36 and 3.51 eV, respectively. The high-energy shift of the optical band gap of GZO and AZO films compared to the ZnO films are due to the much higher carrier concentration of these doped films and filling of electronic states of the conduction band (Burstein-Moss-Shift) [7]. According to this Burstein-Moss-Shift, the band gap would increase with increasing carrier concentration.

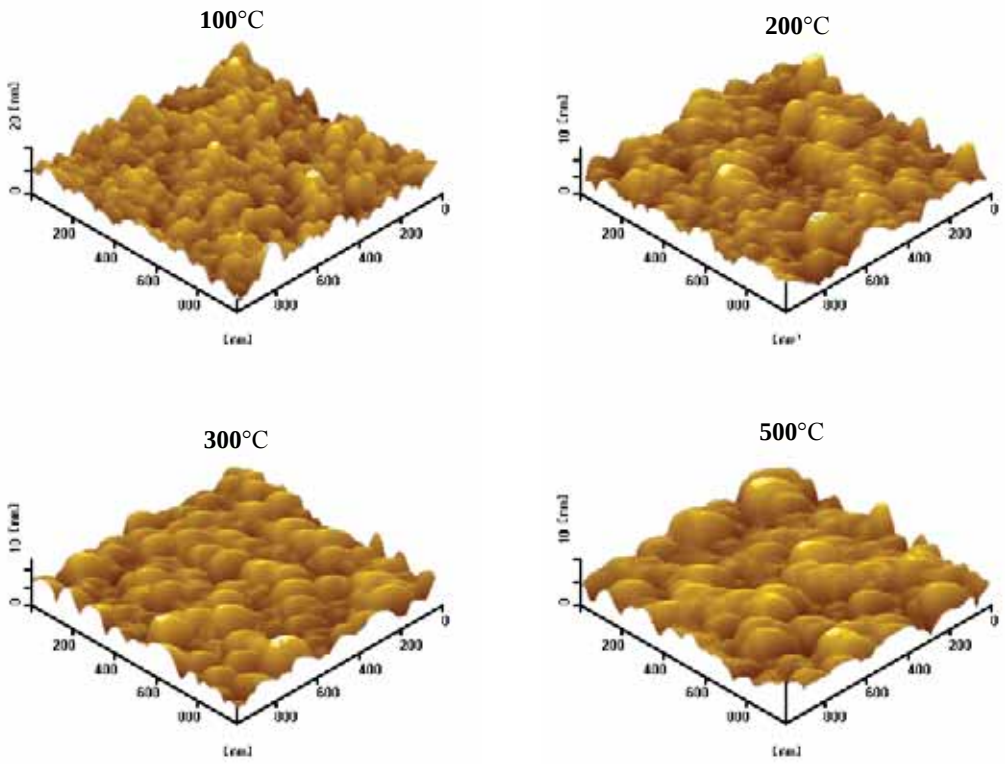

Fig. 3 AFM images of GZO films over 1μ×1μ area grown under 5 mTorr of O_2 at various substrate temperatures.

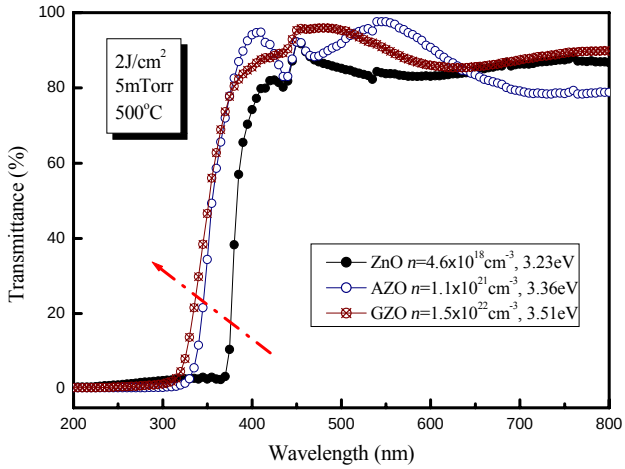

Fig. 4 Optical transmittance of the ZnO, AZO and GZO thin films prepared at a substrate temperature of 500°C and at an oxygen pressure of 5 mTorr.

The carrier concentration in the AZO films was observed to gradually decrease from 1.36×10^{21} to

9.92×10^{20} cm^{-3} as the oxygen pressure was increased (see also Table 1). A maximum in the carrier mobility was observed for an oxygen pressure of 5 mTorr. For the lower ratio O and Zn (oxygen flow rates of 1-5 mTorr) incorporation of interstitial Zn lead to a worsening of crystalline quality and creation of electron scattering centers. Consistent with this, the carrier mobility was found to increase with increasing oxygen flow rate below the optimum oxygen pressure of 5 mTorr. For ratios O and Zn higher than the optimum oxygen pressure of 5 mTorr, excess oxygen on the growth surface presumably induces changes in growth mode and crystal quality, resulting in increased carrier scattering and lower mobility. Carrier mobility thus decreases with increasing oxygen pressure of 5 mTorr.

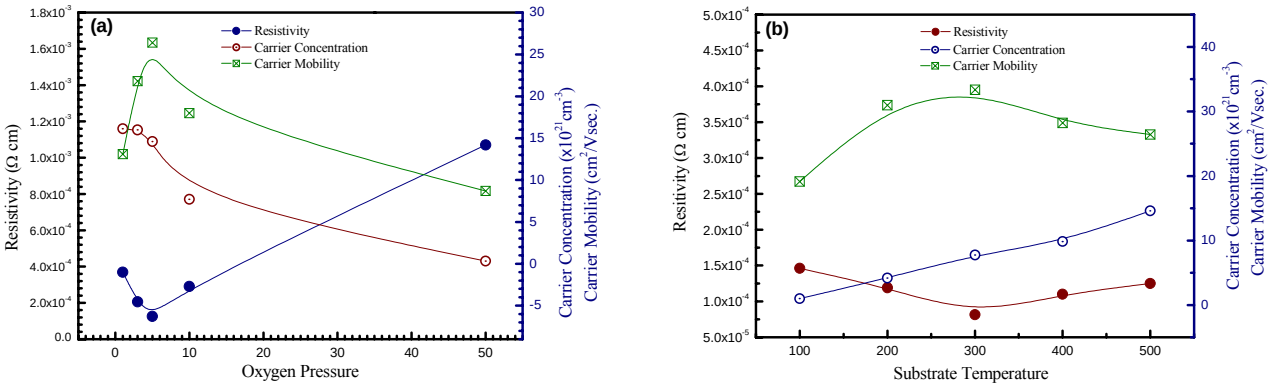

Fig. 5 Variation of the resistivity, the carrier concentration, and the carrier mobility as a function of the pO_2 for the GZO films deposited at the deposition temperature of 500°C (a) and as a function of the Ts for the GZO films deposited under the oxygen pressure of 5mTorr (b).

Fig. 5 (a) shows the variation of resistivity, carrier concentration and carrier mobility as a function of the oxygen pressure of the GZO films grown at the deposition temperature of 500°C. Films thickness was about 2000Å for all films. The resistivity of the GZO films decreases from 3.69×10^{-4} to 1.25×10^{-4} Ωcm as the pO_2 was increased from 1 mTorr to 5 mTorr. A drastically increases in the resistivity is observed as the pO_2 is further increased from 5 mTorr to 100 mTorr. Electrical property of GZO films has close relationship to oxygen content in the film. GZO is an oxide semiconductor having *n*-type conduction. High conductivity of the GZO might be resulted from Ga-doped effect. Since electrons in the AZO films are supplied from oxygen vacancy and aluminum atoms in the film, it can be though that increase of oxygen content might cause decrease of the oxygen vacancy, resulting in increase of resistivity. Fig. 5 (b) shows the variation of the resistivity, carrier concentration, and carrier mobility as a function of the deposition temperature of the GZO films grown at an oxygen pressure of 5mTorr. As the substrate temperature increases from 100°C to 300°C, the resistivity decreases from 1.46×10^{-4} to 8.12×10^{-5} Ωcm and then increases again. The decrease of the resistivity is due to the increase of both carrier concentration and carrier mobility. As the substrate temperature increases to 500°C, the corresponding resistivity becomes 1.25×10^{-4} Ωcm. The slight increase in resistivity of the films grown at higher substrate temperature from 300°C to 500°C may be due to contamination of the alkali ions from quartz glass substrates [8]. The carrier concentration in the GZO films was observed to gradually increase as the deposition temperature was increased. This increase in carrier concentration may be due to an increase in diffusion of Ga atoms from interstitial locations and grain

boundaries into the Zn cation sites [9]. The carrier mobility increases from 19.12 cm^2/Vsec at 100°C to 33.36 cm^2/Vs at substrate temperature 300°C, then decreases to 26.42 cm^2/Vsec. Moreover, the finding that the 1.46×10^{-4} Ωcm at 100°C suggests that film deposition into the semiconductor devices is possible.

4. Conclusion

High quality transparent conductive doped ZnO thin films were grown using the PLD technique on quartz glass substrates starting from ZnO target containing 2 wt.% of Al_2O_3 and 5wt.% of Ga_2O_3, respectively. The growth was performed under wide oxygen pressure range of 1-100 mTorr in the different substrate temperature range 100-500°C. We have studied the influence of the growth conditions (oxygen pressure, substrate temperature) on the structural properties that are directly related to essence of films, such as out of plane alignments, in plane epitaxy, crystal size, grain size, and so on. The resistivity and the carrier concentration of the films were decreased due to the decrease of the oxygen vacancy with increasing the oxygen pressure. With increasing the deposition temperature, the resistivity of the films was decreased and the carrier concentration was increased due to the grain growth and the enhancement of the impurity diffusion. The GZO films formed at a substrate temperature of 300°C showed low electrical resistivity of 8.12×10^{-5} Ωcm, carrier concentration of 7.73×10^{21} cm^{-3} and carrier mobility of 33.36 cm^2/Vsec at an oxygen pressure of 5 mTorr. In general, the study indicates that AZO and GZO films show comparable electrical and optical properties comparable with that of ITO films and emerging as a potential good challenger to ITO films. We suggest that, although Al is a better dopant for producing high quality n-type ZnO, Ga maybe economically viable as lower process temperatures can be used and the conductivity of the films can be expected to be more reproducible.

CO_2 Reforming of Methane with Nonthermal Plasma

S. Futamura and G. Annadurai

National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan

Abstract
Reaction behavior of CH_4 and CO_2 in nonthermal plasma was investigated with a ferroelectric packed-bed reactor at 298 to 433K. CH_4 conversion increased with reaction temperature, while CO_2 reactivity was not affected by temperature. No chemical interaction was observed between these substrates. The composition of synthesis gas was affected by the molar ratio of CO_2 to CH_4 and reaction temperature.

Keywords Nonthermal plasma, CO_2, reforming, CH_4, temperature, mechanism

1. Introduction

It is estimated that CO_2 contributes to ca. 64 % of global warming according to the 2nd Assessment Report of Intergovernmental Panel of Climate Change in 1997. Recognition of CO_2 as the major culprit in the global warming stimulated researches relevant to the development of environmentally friendly technologies for CO_2 utilization: photochemical CO_2 reduction, catalytic CO_2 hydrogenation, and CO_2 reforming. Application of the former two processes will be limited because of the low efficiency and the high cost of H_2, respectively. Catalytic CO_2 reforming of natural gas also has drawbacks such as high reaction temperature and clogging caused by coke formation.

On the other hand, CO_2 can act as an oxidant in nonthermal plasma because its deoxygenation proceeds rapidly in the absence of O_2 [1]. CO_2 reforming of CH_4 is a significant reaction because this process contributes to the co-processing of ubiquitous global warming compounds such as CO_2 and CH_4. From the chemical viewpoint, the in situ concentrations and reaction behavior of the radical species such as H and O released from CH_4 and CO_2 determine the substrate conversions and the yields of H_2 and CO. Reaction temperature is one of the important parameters because the downstream reactions would not be accelerated by nonthermal plasma.

Hitherto, dielectric barrier discharge reactors have been applied to fuel reforming reactions, and the effects of reactor type [2], feed gas composition [3], [4], gas pressure [3], specific energy density [4], reaction temperature [3], and energy efficiency [5] have been investigated. The authors have been exploring the potential of nonthermal plasma in the processes of H_2 production from water, CH_4, and CH_3OH [6], CH_3OH reforming [7], steam reforming of CH_4 [8], [9], and reforming of H_2O-CO_2 [10]. Compared to catalytic processes, similar compositions of synthesis gas have been obtained from the corresponding reaction systems in nonthermal plasma.

This paper presents the reaction behavior of CH_4 and CO_2 with different compositions, product distribution, temperature effect, and reaction mechanism relevant to CH_4 conversion, H_2 formation, and the role of CO_2 as an oxidant.

2. Experimental

In this research, a ferroelectric packed-bed reactor (**FPR**) was used because **FPR** worked much better than a silent discharge plasma reactor in the reforming reactions under the same conditions with 50 Hz ac and a neon transformer [8]-[10]. **FPR** was a coaxial reactor whose reaction length and gap distance were 127 mm and 15.4 mm, respectively. $BaTiO_3$ pellets (ε = 5000 at ambient temperature, 1 mm in diameter) were packed between the two concentric electrodes in **FPR**.

CH_4 and CO_2 balanced with N_2 in standard gas cylinders were introduced to **FPR** in an oven through a Teflon tube by adjusting their concentrations and flow rates with sets of mass flow controllers and a gas mixer. All the reactions were carried out in N_2 in the temperature range of 298K to 433K. The oven temperature was controlled within ± 2K. After each run, O_2 was passed through **FPR** at 7.6 kV for 20 min. With this operation, the concentrations of CO and CO_2 were correctly determined because the carbonaceous materials deposited on the inner reactor walls and on the $BaTiO_3$ surface were oxidatively removed as CO and CO_2 after reforming reactions.

Plug-in power consumptions and applied voltages for **FPR** were measured with a digital powermeter and a digital wavemeter, respectively. The volatile byproducts were identified by GC-MS. The substrates and the major products were quantified by gas chromatographs equipped with FID and TCD. The conversions of CH_4 and CO_2 and the yields of H_2, CO, and C_2 hydrocarbons (C_2H_x, x = 2, 4, 6) are defined according to eqs. (1) to (5), respectively.

CH_4 conversion (mol%) = 100 X {1 – [CH_4 concentration (%)] / [Initial CH_4 concentration (%)] } (1)

CO_2 conversion (mol%) = 100 X {1 – [CO_2 concentration (%)] / [Initial CO_2 concentration (%)] } (2)

H_2 yield (mol%) = 100 X [H_2 concentration (%)] / [2 X Initial concentration of CH_4 (%)] (3)

CO yield (mol%) = 100 X [CO concentration (%)] / [Initial concentration of CO_2 (%)] (4)

C_2H_x Yield (mol%) = 100 X [C_2H_x concentration (%)] / [0.5 X Initial concentration of CH_4 (%)] (5)

3. Results and Discussion

Increase of CO_2 concentration from 0 to 2.0 % at the fixed CH_4 concentration of 1.0 % decreased CH_4 conversion at 298K (Fig. 1). These facts suggest that the kinetic energies of high-energy electrons in nonthermal plasma are partitioned to CH_4 and CO_2 in proportion to their initial concentrations. CO_2 conversion was also decreased with an increase in the initial CH_4 concentration. No chemical interaction was observed between CH_4 and CO_2 even at elevated temperatures.

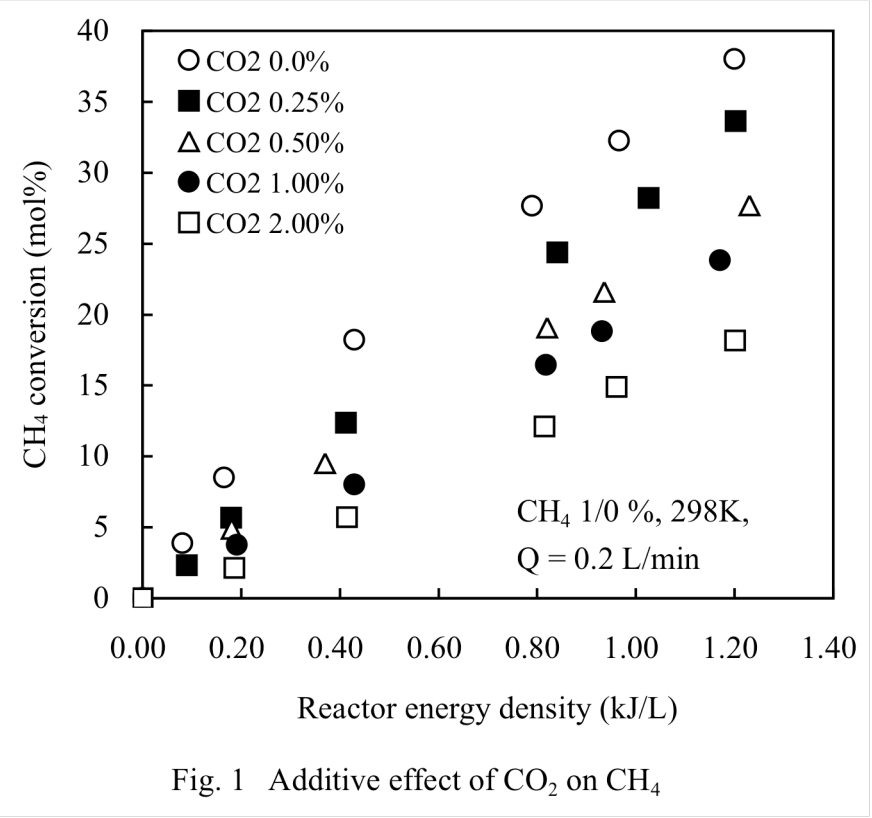

Fig. 1 Additive effect of CO_2 on CH_4

The temperature effect on CH_4 conversion (Fig. 2) suggests that CH_4 decomposition is promoted by some species at elevated temperatures. On the other hand, CO_2 conversion increased proportional to reactor energy density (RED, kJ/L) irrespective of reaction temperature. Fig. 3 shows the effects of temperature and CH_4 addition on CO_2 conversion. At 298K, CO_2 conversion was not affected by the presence of CH_4. At 433K, CO_2 conversion tended to be lower at higher REDs in the presence of CH_4. It is suggested that CO is oxidized back to CO_2 under hydrogen-deficient conditions.

H_2 and CO were obtained as the major products in the CO_2 reforming of CH_4. In the absence of CH_4, CO_2 deoxygenation was a clean reaction, and CO was almost quantitatively produced from CO_2. Since CO is stable in nonthermal plasma, further cleavage of carbon to oxygen bond in CO is unlikely under the reaction conditions. At 298K, no C_2 hydrocarbons were detected by GC in the range of 0.125% to 1.0 % of initial CH_4 concentration. At 433K at 1.0 % of CH_4, C_2 hydrocarbons were obtained, but their yields were approximately 1/20 of H_2 yields and 1/30 to 1/100 of CO yields, respectively. It is unlikely that recombination of methyl radicals occurs under the reaction conditions.

Fig. 4 shows a temperature effect on H_2 yield. At fixed REDs, higher H_2 yields are obtained at lower temperatures. At 298K, the maximum H_2 selectivity was 26 % (Figs. 2 and 4). At higher temperatures, H_2

would be consumed in the reactions with oxygen atoms from CO_2 because the yields of C_2 hydrocarbons are much lower and poor carbon recoveries are obtained.

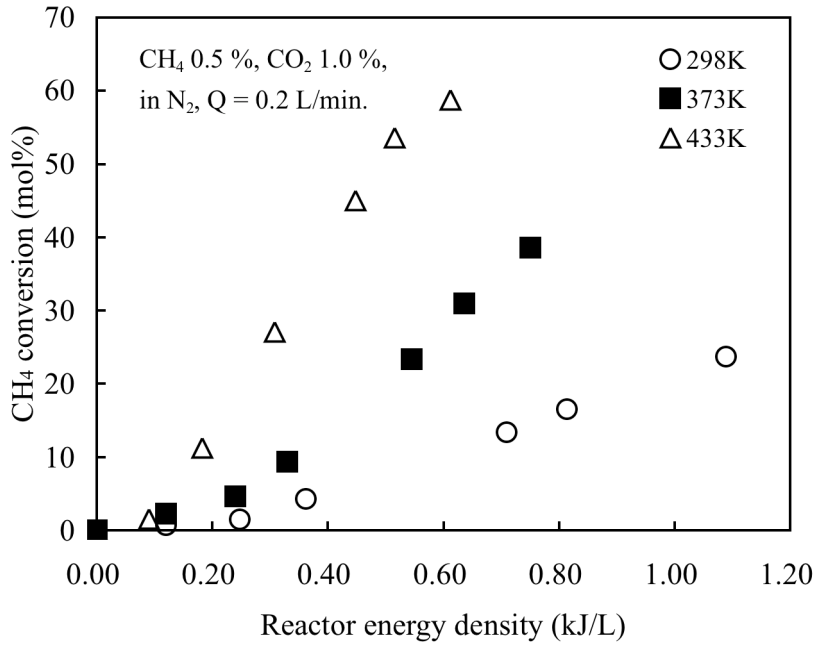

Fig. 2 Temperature effect on methane conversion

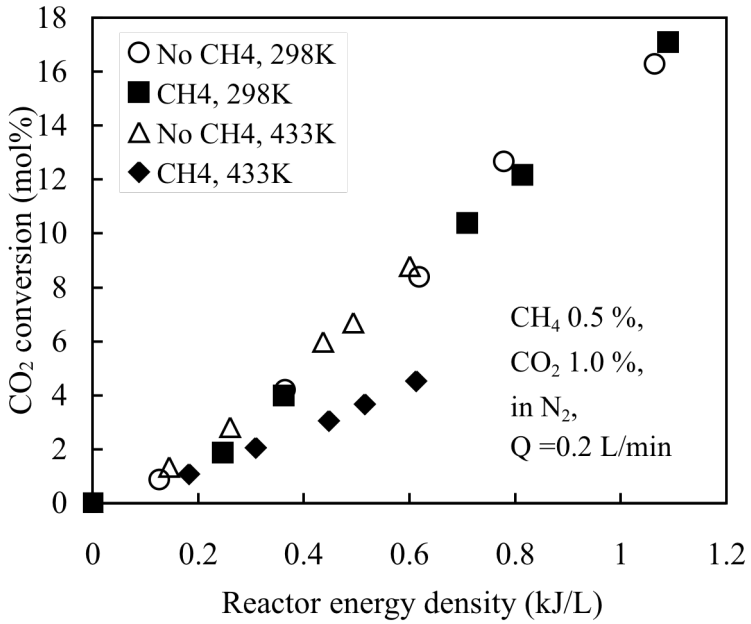

Fig. 3 Effects of temperature and CH_4 addition CO_2 conversion

Fig. 5 shows a temperature effect on the composition of synthesis gas. The molar ratio of H_2 to CO {[H_2] / [CO]} is lower than unity, and it decreases with an increase in temperature at fixed REDs. [H_2] / [CO] tended to decrease with an increase in RED and level off at higher REDs. This ratio can be flexibly controlled by changing the molar ratio of CH_4 to CO_2.

Fig. 6 shows a temperature effect on the carbon balance in the CO_2 reforming of CH_4. The x-axis stands for the total concentration of the carbon atoms consumed in CH_4 and CO_2. Data points are on the dotted line if all the carbon atoms in consumed CH_4 and CO_2 are recovered as CO. As discussed above, CO_2 deoxygenation is a clean reaction (Fig. 3), missing carbon atoms are ascribed to those in consumed CH_4. At

298K, a fairly good carbon balance is obtained, but carbon recovery decreases with an increase in reaction temperature. As in the case of synthesis gas composition, carbon balance can be improved by decreasing the molar ratio of CH_4 to CO_2. Thus, reaction conditions should be optimized depending on compositions of target synthesis gases.

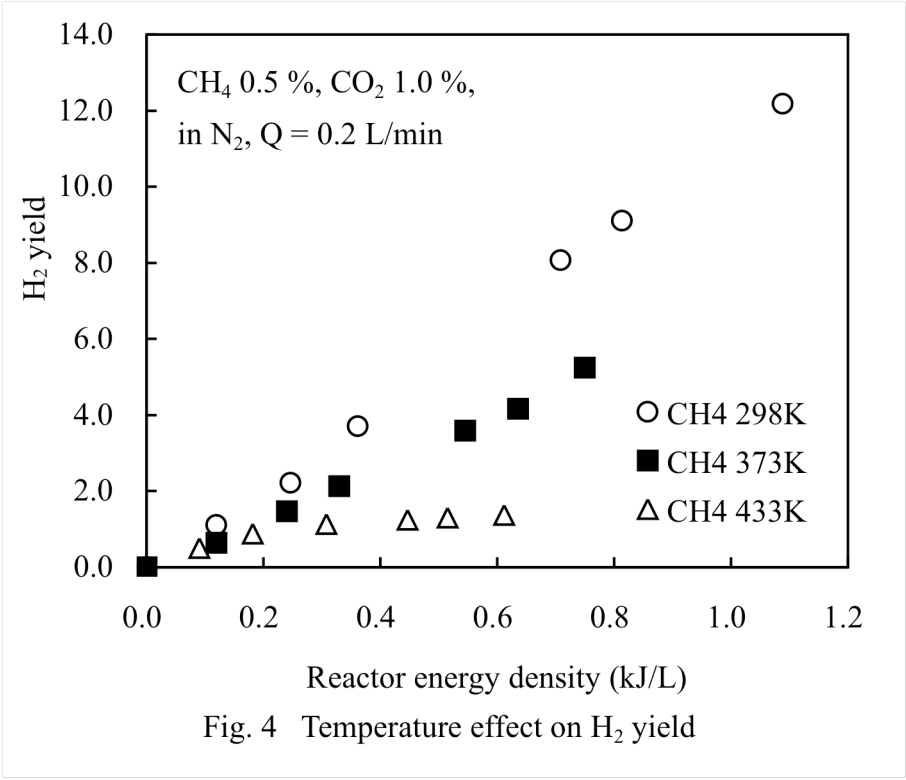

Fig. 4 Temperature effect on H_2 yield

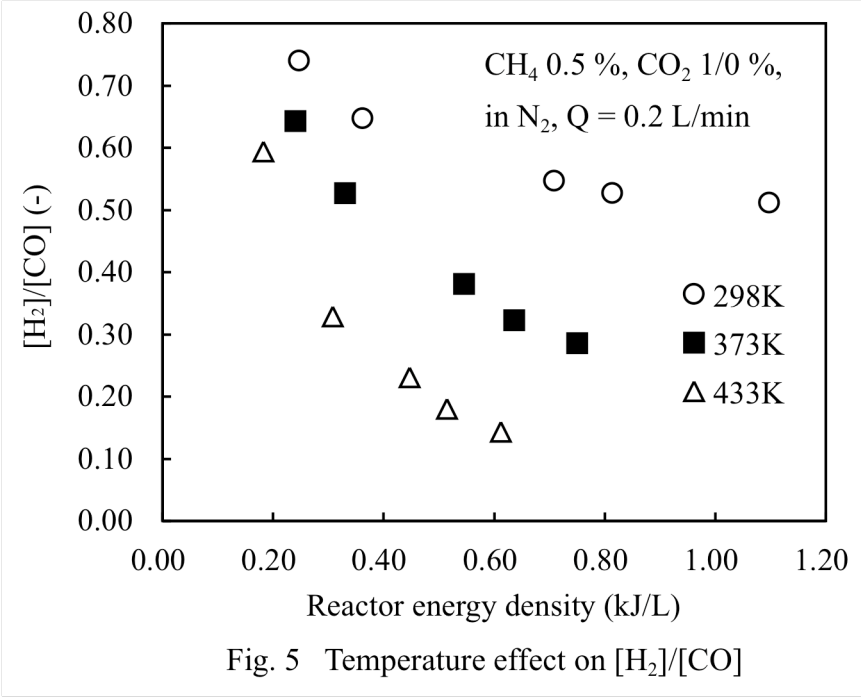

Fig. 5 Temperature effect on $[H_2]/[CO]$

Fig. 7 shows plausible pathways for the CO_2 reforming of CH_4. Eqs. (1) and (2) are the initial reactions occurring between high-energy electrons and the substrates. A hydrogen atom and a methyl radical is produced from CH_4, and CO and an oxygen atom is produced from CO_2. H_2 is produced from the hydrogen atom abstraction from CH_4 by the hydrogen atom [eq. (3)]. The reaction of the oxygen atom and CO is slow in nonthermal plasma, and the major pathway for this species should be the reaction with CH_4, giving OH and methyl radicals [eq. (4)]. OH radical also reacts with CH_4 to give water and a methyl radical [eq. (5)].

Due to the low concentrations of the substrates, recombination of methyl radicals can be neglected under our reaction conditions. This radical further undergoes oxygenation and dehydrogenation to give CO [eq. (6)]. At lower temperatures, cleavage of the C-H bond in CH_4 is rate-limiting. The temperature effect observed in this research suggests that secondary decomposition of only CH_4 is accelerated at elevated temperatures according to eqs. (4) and (5).

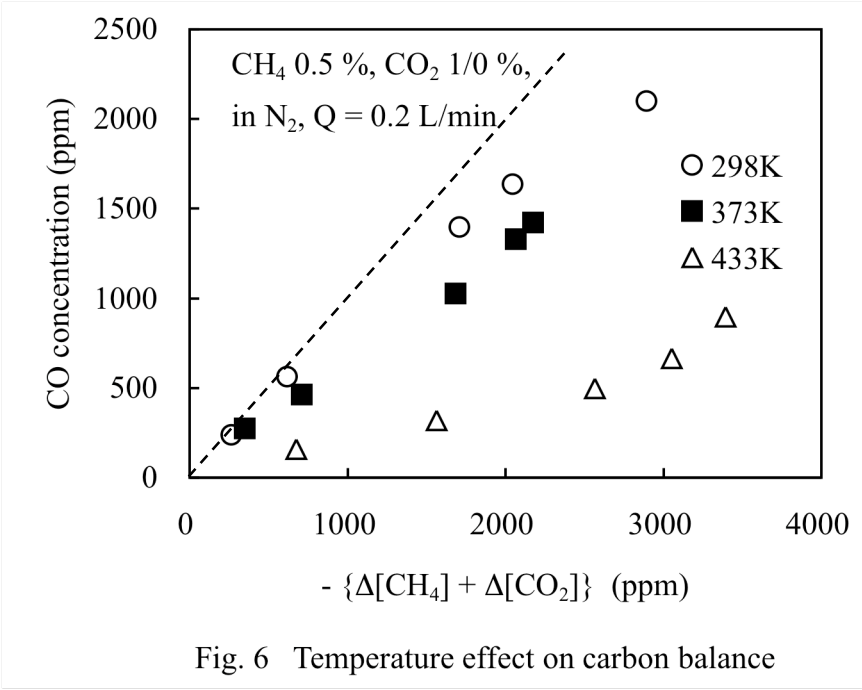

Fig. 6 Temperature effect on carbon balance

$$CH_4 + e^* \longrightarrow \bullet CH_3 + H\bullet + e \quad (1)$$

$$CO_2 + e^* \longrightarrow CO + O\bullet + e \quad (2)$$

$$H\bullet + CH_4 \longrightarrow H_2 + \bullet CH_3 \quad (3)$$

$$O\bullet + CH_4 \longrightarrow \bullet OH + \bullet CH_3 \quad (4)$$

$$\bullet OH + CH_4 \longrightarrow H_2O + \bullet CH_3 \quad (5)$$

$$\bullet CH_3 \xrightarrow{O} \xrightarrow{-H} CO \quad (6)$$

Fig. 7 Plausible pathways for CO_2 reforming of CH_4

4.Summuary

Temperature affects CH_4 conversion, but not that of CO_2 in the CO_2 reforming of CH_4. H_2 yield and the molar ratio of H_2 to CO are flexibly varied by controlling initial gas composition and temperature. Better carbon balances are obtained at lower temperatures.

Covalent immobilization of biological molecules on various plasma modified polymers

L. C. Lopez[1], R. Gristina[2], P. Favia[1,2], R. d'Agostino[1,2]

[1] *Department of Chemistry, University of Bari, Bari, Italy*
[2]*Institute of Inorganic Methodologies and Plasmas IMIP-CNR,, Bari, Italy*

Abstract

Different polymeric substrates were modified by means of plasma deposited coatings in order to functionalise the surfaces with tuneable density of functional groups (i.e. –COOH; C-O-C; etc.) to be used as anchor groups for biomolecules immobilization. Modified surfaces were employed in cell culture experiments to verify the effect of biomolecules immobilization in improving the biological response of Polyethylene terephthalate, in terms of adhesion, growth and metabolic function of different cell types.

Keywords: plasma deposition, functional groups, RGD, carbohydrates, cell behaviour.

1. Introduction

The ability of any biomaterial to regulate cell behaviour requires control over bulk and surface chemistry, topography and properties in general. Among the principles driving the development of biomaterials reducing to a minimum the immune response from the organism to the foreign biomaterial body and to increase their capacity in providing specific functionality to the desired target tissue/organ can be considered of paramount importance. Most of the existing biomaterials are limited because they represent a clear compromise. For instance, living tissues normally respond to changing physiological loads and biochemical stimuli providing the basic factors of the homeostasis; synthetic materials instead, cannot have control of such biological activities. This limits development and lifetime of biomedical materials used to replace body parts or promote tissue repair and regeneration. The engineering of polymeric materials tailored to activate cell proliferation and differentiation represent a shift toward a more biologically based method for the repairing and regeneration of tissues.

One promising strategy to control the interaction between biomaterials and cells involves covalent grafting of biological molecules to polymers that hardly support cell adhesion and growth. To provide a stable linking those molecules should be covalently attached to the polymer surface, e.g. via functional groups like hydroxyl-, amino-, or carboxyl groups or others. Since many polymers do not present such groups on their surface, these have to be introduced with a chemical or physical treatment. Plasma surface modification of polymers represents one of the more versatile process to functionalize material surfaces without interfering with its bulk properties. PE-CVD (plasma enhanced chemical vapour deposition), Plasma Etching, and Plasma Treatment processes are nowadays extensively used to tailor the surface of materials to be utilized in contact with biological systems, *in vitro*, *ex vivo*, and *in vivo*, in a wide number of biomedical applications.

Surface properties like free energy, wettability, electric charge, surface chemistry and morphology, that might all affect cell attachment and behaviour either indirectly, e.g., by controlling protein adsorption, or directly, e.g., by guiding cell spreading with surface topography, can all be easily tuned by means of surface modifications in plasma processes [1, 2]. Modification of polymeric surface by plasmas, alone or followed by immobilisation of proper biomolecules, could be particularly advantageous because surface modified polymers offer the advantage to have a material with selective properties, defined geometry and stability with intelligence to activate specifically a given metabolic cell pathway.

More advanced and recent plasma-based surface modifications deal with the immobilization of biomolecules (i.e., heparine, heparine-like, peptides, enzymes, antibodies, etc.) on biomedical surfaces, to induce the growth of primary cells, or to act as sensors in immunodiagnostics, or to exhibit blood compatibility [3]. PE-CVD and Plasma Treatments are utilized as patterning techniques to develop biomedical surfaces characterized by cell-adhesive micro-domains alternated with cell repulsive ones. Such an approach is devoted to drive the

behaviour of cells on biomedical surfaces (e.g., on biodegradable scaffolds) to be utilized in Tissue Engineering [4].

In this work different plasma-processed surfaces were utilized for cell growth experiments as it, or functionalized with RGD peptides or with carbohydrate-based molecules. Galactose, in particular, was shown to selectively bind hepatocytes via the asialoglycoprotein receptor when immobilised to polymer surfaces. The immobilization was performed through wet chemical reactions, in order to develop surfaces more suitable to support the growth of primary cells. The biomolecules were immobilized through proper hydrophilic "spacer arm" molecules, that leave the highest conformational freedom to the immobilized molecules, or directly to the surface. Modified surfaces were investigated by means of WCA (Water Contact Angle) and XPS (X-ray Photoelectron Spectroscopy) analysis after each step of modification. Hepatocyte and fibroblast cell lines were used to verify the cell behaviour on modified substrates with respect to unmodified polymers.

2. Materials and Methods

2.1 Materials

Polyethylene terephthalate (PET, Goodfellow UK) (10 to 14 mm dia disks) were used as substrates. Acrylic acid (AA), RGD (Arginine- Glycine- Aspartic acid), morpholine ethane sulfonate (MES) and 1-Ethyl-3-(3-dimethylamino-propyl) carbodiimide (EDC) were supplied by Sigma-Aldrich. O,O'-bis-(2-aminopropyl)-polyethylene glycol 500 (bNH_2PEG) was supplied by Fluka. Ar was supplied by Air Liquid. All reagents were used without further purification.

2.2 Surface plasma modification

Plasma deposited acrylic acid (pdAA) coatings were deposited in a stainless-steel parallel plate plasma reactor (internal steel electrodes), with the upper electrode shielded and connected, through a matching network, to a 13.56 MHz RF generator. The bottom electrode, grounded, was used as substrate holder. Two different type of pdAA coated samples were prepared by regulating the AA vapour flux rate (3 or 6 sccm). RF power was supplied for 5 min in continuous wave mode (CW) with 100% duty cycle (DC) at 100, thus leading to a high AA fragmentation. All discharges were fed with AA vapours (3 sccm or 6 sccm) and Ar (20 sccm). AA degassed with freeze-thaw cycles, was fed through a needle valve from a liquid reservoir and a steel line. Pressure was kept at 150 mTorr. Very thin pdAA coatings (< 30 nm) were always deposited; the thickness of the coatings was measured with an Alpha-Step® 500 KLA TENCOR Surface Profiler.

2.3 Biomolecules covalent immobilization

To covalently immobilise RGD on both pdAA films, PET coated substrates were first immersed in 7,5 ml of a EDC solution in MES buffer (100 mg EDC; pH 5.5; 1h at 4°C; mild stirring) to activate -COOH groups. After activation, samples were rinsed and sonicated three times in distilled water. After achieving the formation of an amide bond between the COOH groups and a NH_2 group of the RGD molecule, the substrates were reacted in 7,5 ml of MES (pH 5.5; 24h at 4°C; mild stirring) with 20 µl of a 1,44 $x10^{-2}$ M RGD solution and 100mg of EDC. RGD modified substrates were rinsed three times in distilled water.

The immobilization of galactose units on the surface of pdAA coatings, was accomplished on pdAA 6 sccm coating. Galactose was oxidized to galactonic acid according to ref [5] then it was immobilized at the surface of pdAA coatings by following the same step described for RGD. The oxidation to galactonic acid was necessary to create COOH groups available on the molecule for the immobilization.

2.4 Surface diagnostic

XPS analyses were carried out with a PHI ESCA 5300 equipped with a non-monochromatized MgK_α X-ray source (1253.6 eV). Survey (0-1150 eV Binding Energy (BE)) and high resolution spectra (C1s, O1s, N1s)

were recorded at pass energy of 160eV and 20eV, respectively. All spectra were recorded at a take off angle of 45°. Sample charging was corrected by positioning the hydrocarbon peak component of the C1s signal at 285.0 eV of BE. Chemical composition value were obtained from high resolution spectra after a linear background subtraction, using sensitivity factors provided by the software.
Static WCA measurements were carried out soon after each plasma process with a Ramé-Hart NRL 100 goniometer, using 2 µl drops of bidistilled water (five measures per sample, in triplicate).
XPS and WCA were performed also after at least one week of water soaking at 37°C. After the immersion period, samples were air dried for 12 hours and analysed.

2.5 Cell culture experiments

3T3 fibroblast and HepG2 hepatocyte cell lines were utilized for cell culture experiments, obtained from stocks routinely grown in Dulbecco's Modified Eagle Medium (DMEM), supplemented with 10% fetal bovine serum, 50 IU/ml penicillin, 50 IU/ml streptomycin and 200 mM glutamine, under 5% CO_2/ 95% air atmosphere at 37°C.
PET and TCPS (tissue culture polystirene) were used as control substrates. Plasma-processed, biomolecules modified and control samples were placed, modified side up, in Iwaki 24 well culture plates. Cells, obtained after trypsinization of confluent or near-confluent culture, were seeded at $2x10^4$ cells/well in 1 ml of DMEM and incubated at 37°C under 5%CO_2 atmosphere. Cell attachment and morphology were determined (at least 10 areas of 0.8 mm^2 per sample) at various time intervals acquired with a phase contrast microscope (Leica DM IL). Unpaired Student's t-test was used to evaluate statistical significant differences among tests (four repeated samples per experiment). Data were considered significant when $p<0.01$ was obtained.

3. Results and Discussion

Two different pdAA films were deposited on PET from different feeds of AA (3 and 6 sccm) and Ar in order to obtain functionalised surfaces with different density of COOH groups. XPS C1s signals and WCA analysis (Fig. 1) show that pdAA 6 coating resulted more hydrophilic and with an higher COOH/R density than pdAA 3 films.

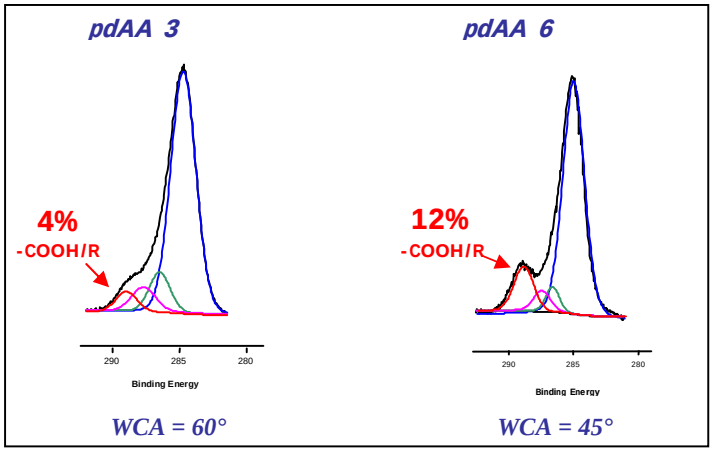

Figure 1: C1s XPS signals and WCA values of pdAA3 and pdAA6 coatings.

Particular care was devoted to investigate the stability of the coatings in water after at least 1 week of soaking. It was already known that pdAA 3 coatings are very stable in water [6]. PdAA 6 coatings presented an higher amount of COOH groups but were found less stable after water soaking as shown in Figure 2.

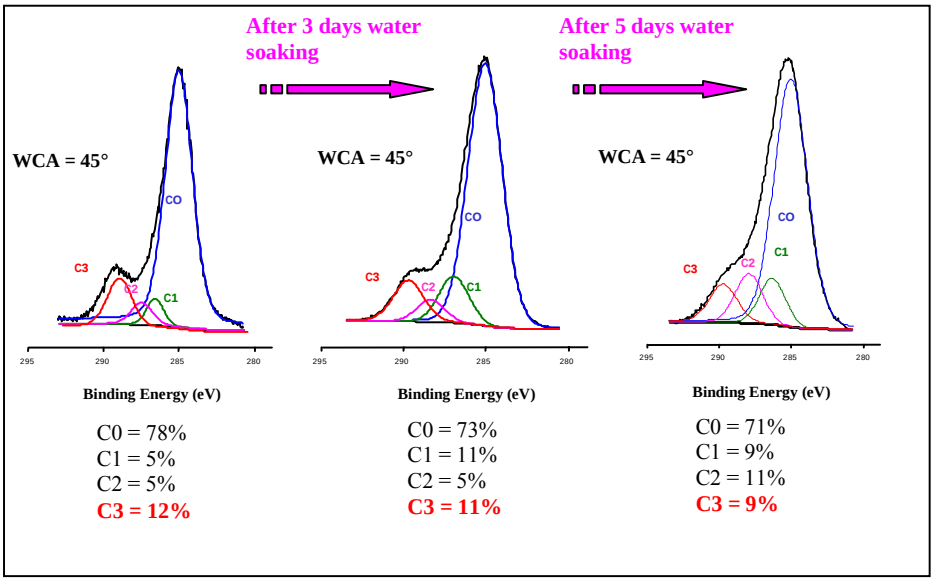

Figure 2: C1s XPS peaks of pdAA 6 coatings and best fittings after 3 and 5 days of water soaking.

PET samples coated with pdAA 3 and pdAA 6 were used for immobilization of the RGD peptide. Interestingly, pdAA 6 coatings, unstable to water soaking, resulted stabilized after the covalent immobilization of RGD involving surface COOH anchor groups and this is shown by the XPS analysis in Figure 3. This very interesting result suggests that the instability of the coatings, mainly due to surface groups, can be overwhelmed when surface groups are involved in stable bond with molecules.

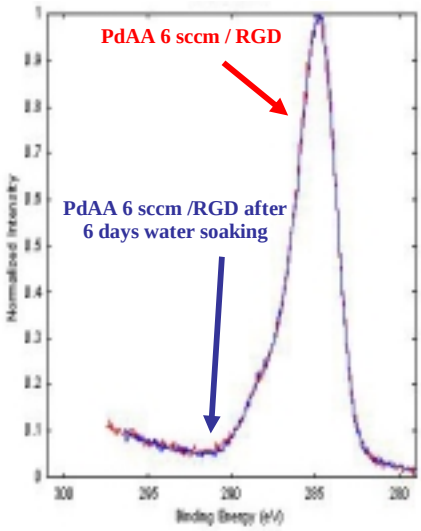

Figure 3: C1s XPS peaks of pdAA 6sccm coated PET samples after RGD immobilization before (blue) and after (red) six days of water soaking.

Plasma modified surfaces with and without immobilised RGD were tested in cell adhesion and growth experiments with 3T3 fibroblasts. After 7 hours of cell culture cell adhesion was dramatically increased on pdAA 6-RGD samples as shown in Figure 4, with respect to the other substrates. It was also seen that the adhesion is higher respect to pdAA 3-RGD surface, probably due to the higher density of surface RGD on the first kind of surfaces. Surface analysis are being performed to confirm this hypotheses.

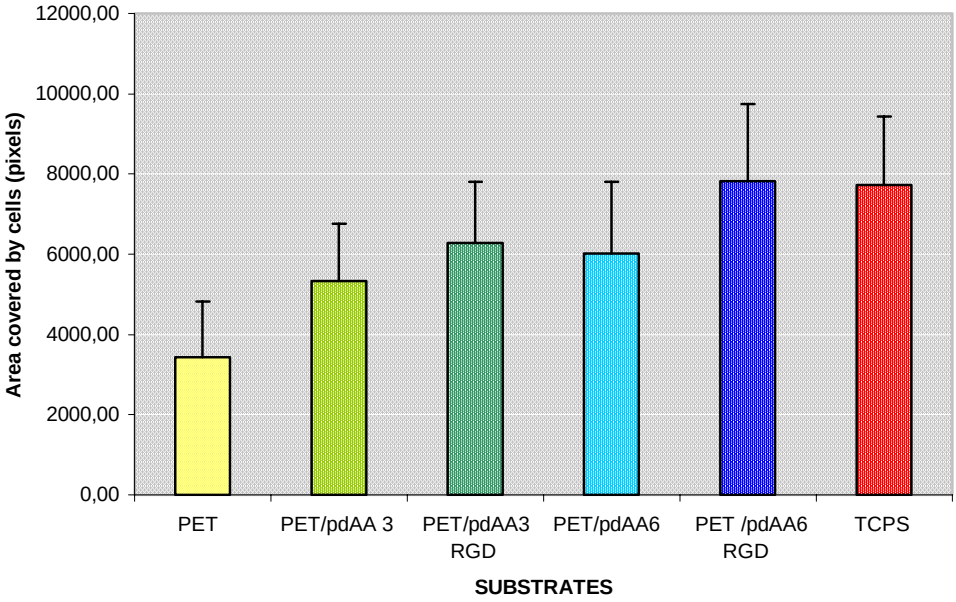

Figure. 4: Means (+ SD) of the area covered by 3T3 on different substrates after 7 hours of cell culture.

In another set of experiments PET substrates coated with the pdAA 3 sccm, were used to immobilize galactose moieties for cell adhesion experiments with HepG2 hepatocyte cell line. XPS spectra [7] showed the occurred immobilization. When HepG2 cells were seeded on galactose immobilised substrates a very different cell behaviour was found with respect to cells seeded on the other substrates. As it is shown in figure 5 an higher aggregation of Hep G2 cells was present on galactose immobilised on PET with respect to the other substrates.

4. Conclusions

In this paper cell adhesion and spreading in the first hour of cell culture was increased on different pdAA coated PET that were used as substrates for biomolecules immobilization. Those results show that the presence of biomolecules further increases cell adhesion and spreading on coatings that were already shown to be cell adhesive [6]. It is very important to note that coupling the capacity of plasma processing of tuning the chemical composition of surfaces with the specificity of immobilized biomolecules offers formidable tools for the study of cell substrates interaction.

Frequency analysis of arc voltage, light intensity and stagnation pressure fluctuations of DC laminar/turbulent plasma jets

Xian Meng, Wenxia Pan, Teng Li, Chengkang Wu

Institute of Mechanics, Chinese Academy of Sciences, Beijing, China

Abstract
The time-resolved arc voltage in plasma generation, related responses of light intensity and local stagnation pressure of DC pure argon laminar/turbulent plasma jets have been measured, and the frequency distributions have been obtained by using Fast Fourier Transform method to treat the measured signals. Results show that these parameters fluctuate with the similar oscillatory characteristics as the power supply, while there exists a high frequency component in turbulent state, indicating different arc-flow interactions.

Keywords DC plasma jet, fluctuation characteristics, frequency, laminar flow, turbulent flow

1. Introduction

Thermal plasma jets are widely used to heat materials difficult to melt by ordinary heating sources [1] because of their high temperature and high power density. Commonly used non-transferred DC plasma jets at atmospheric pressure operate in turbulent flow state, characterized by strong fluctuations with sharp noise. Up to now, the turbulent plasma jets have been widely used in plasma spray technology [1,2], but its inherent fluctuating characteristics cause difficulties in process control, and limit its application to low precision and less reproducible processing. The fluctuation characteristics of electric arc and turbulent jets have been much discussed these years [3-7]. Z. Duan etc. identified three different arc operating modes in a DC plasma torch, i.e., the restrike mode, the takeover mode and the steady mode, through arc voltage measurements; and suggested that the thickness of the cold gas boundary layer between the arc column and the anode surface was the most important variable influencing the arc mode occurrence and transition [3]; J. -L. Dorier etc. investigated the fluctuating behavior of a commercial DC plasma spraying torch at various working conditions, and found that the time dependence voltage signals for pure argon operation fluctuated with weak amplitude, which suggested the arc experienced the so-called “take-over mode”, while the voltage signals for the H_2/Ar mixture showed a clear sawtooth pattern, which was typical of “restrike mode” [4]; W. H. Zhao etc. presented three main factors for the jet fluctuation, i. e., the fluctuation of the power supply output, the arc root motion on the anode and the fluid dynamic process of the jet，and considered that the power supply characteristic was the dominant fluctuation source for the argon plasma jet [5].
There are several reports about the generation of laminar plasma jets [8-11]. Long laminar plasma jets have the characteristics of stable flow condition, reduced entrainment of surrounding gas, low temperature and velocity gradients along the jet axis and low working noise, and preliminary work shows favorite reproducibility for re-melting hardening of cast iron surfaces and in the stainless-steel surface cladding using laminar plasma jets, while turbulent jets are difficult to use in these material processing for their violent fluctuation and high stagnation pressure [8]. There are no detailed reports on fluctuating characteristics of laminar plasma generation and jet flow, and on comparisons between laminar and turbulent jets. So it is meaningful to compare laminar and turbulent plasma jet characteristics, for a better understanding of laminar jets and for developing novel material processing methods using them.
Both laminar and turbulent jets can be generated with the same plasma torch by changing the working parameters [9]. In this paper, the time-resolved arc voltages in plasma generation have been measured directly by using an oscilloscope, and related responses of light intensity and local stagnation pressure of the DC pure argon laminar and turbulent plasma jets have been measured by using a spectrometric system and a pressure probe respectively; the frequency distributions of these parameters have been obtained by using Fast Fourier Transform method (FFT) to treat the measured signals.

2. Experimental details

The plasma torch is the same as used in our former work [8, 9]. Both laminar and turbulent jets can be

generated with the same plasma torch by changing the working parameters, such as the gas flow rate and arc current. Plasma jets were generated with pure argon gas at gas flow rate of 2.2×10^{-4} kg/s to 5.5×10^{-4} kg/s and arc currents of 160 A to 200 A, and issued into the atmosphere after leaving the torch nozzle.

Fig. 1 shows the schematic diagram of experimental setup. Three parts are included in this experimental setup, i.e., the oscilloscope is used to measure directly the time-resolved arc voltage signals in generating plasma jets, with sampling rate of 125 kHz, and each group of signal contains 5000 points, which can be transferred to a computer at the same time; the pressure probe is used to measure the local stagnation pressure in laminar and turbulent jets; and the spectrometric system is applied to measure the spectral line intensity of ArI 750.4 nm in laminar and turbulent jets; the oscilloscope is also applied to collect the signals of light and pressure.

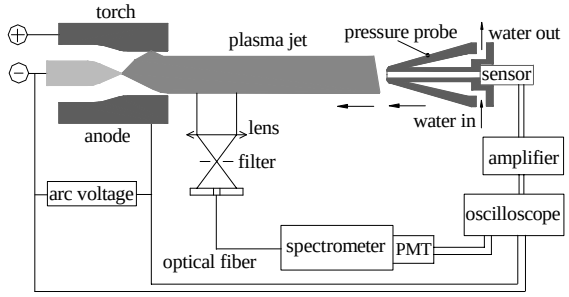

Fig. 1 The schematic diagram of experimental setup.

A tapered small size water-cooled probe is designed to connect a pressure sensor of 40 kHz in response ability. In order to get the actual fluctuation amplitude values and high system response frequency, a 0.6 mm hole is opened in the tip center of the probe, and the tip size is 3 mm. The pressure sensor can transfer the pressure signals into milli-voltage signals, and an amplifier without frequency loss is employed to enlarge the original signal values to 100 times, and then the signals are recorded by the oscilloscope with the same sampling rate as the arc voltage.

The spectrometric system consists of a lens with focal length of 120 mm, a line-type optical fiber of 10mm×1mm in dimension which can receive the whole light signals of a jet cross section, a spectrometer with focal length of 550 mm, a photo-multiplier tube (PMT) and the oscilloscope. The 1:1 image of plasma jet is formed on one side of the optical fiber through the lens, and light signals at the jet cross section are transferred to the slit of the spectrometer by the fiber. Spectral line of ArI 750.4 nm is selected by the spectrometer and transferred to the PMT by which the spectral line intensity can be detected and outputted as voltage signals. Similarly, the outputted voltage signals are collected by the oscilloscope with the same sampling rate as the arc voltage.

Fast Fourier Transform method (FFT) is applied to treat the measured signals, and then to find out the frequency distributions of laminar and turbulent plasma jets.

3. Results and discussions

Fig. 2(a) shows the voltage signals across a fixed resistance at current of 180 A, and Fig. 2(b) shows the FFT result of the voltage. It can be seen that the output of the rectified DC power supply includes obviously alternating components. The amplitude spectrum shows that 300 Hz is the prominent frequency, which is the characteristic frequency of the three-phase full-wave rectified power supply. The 100 Hz peak is due to the imbalance of the commutating circuit for three-phase AC input.

Fig. 3(a) plots the time-resolved arc voltages in generating laminar and turbulent plasma jets at arc current of 180 A and gas flow rate of 2.2×10^{-4} kg/s for laminar jet and 5.5×10^{-4} kg/s for turbulent jet, and the related local stagnation pressures of laminar and turbulent jets at the distance of 20 mm from the torch exit are presented in Fig. 3(b). The signals of arc voltage and local stagnation pressure for laminar jet and turbulent one are sampled at the same time respectively. One can see from Fig. 3(a) that the alternating components are included in the voltage signals in generating the laminar and turbulent jets, which could suggest that the characteristic of the power

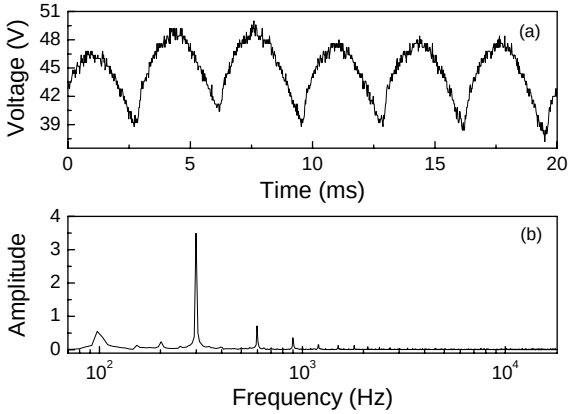

Fig. 2 Measured time-resolved voltages on resistance (a) at current of 180 A and the FFT result of the voltages (b).

supply affects the arc voltages in generating the laminar and turbulent jets in almost the same way. There is an apparent high frequency component added to the low frequency wave affected by the power supply in the case of turbulent plasma generating. The local stagnation pressures for laminar jet and turbulent one plotted in Fig. 3(b) show the similar fluctuating characteristics as the arc voltages. It is clearly seen that there are high frequency fluctuations of stagnation pressure in turbulent jet. The measured pressure is related to the gas density and flow velocity at the measuring point according to the Bernoulli's equation, where gas density value is a function of the gas temperature. At the same working parameters, the maximum stagnation pressure P_{max} can reach 28000 Pa, while the minimum pressure P_{min} is just over 8000 Pa within the time interval of 20 ms. The pressure change of laminar jet at the same measurement point is just 1500 Pa. Though the mean stagnation pressure of turbulent jet (about 19200 Pa) is larger than that of laminar jet (about 4300 Pa), where "mean stagnation pressure" is defined as the averaged time-resolved pressure signals, the ratio of the variation of stagnation pressure (P_{max} - P_{min}) to the mean pressure of turbulent jet (about 104.2%) is also larger than laminar jet (about 34.9%), which suggests the much more stable flow filed characteristics in the laminar jet. The fluctuation characteristics of spectral line intensity of ArI 750.4 nm have been studied. A high frequency component also exists in the waveform of turbulent jet. The fluctuations of stagnation pressure and spectral line intensity could represent the flow filed fluctuations of the plasma jet. This unstable property is related to the arc power fluctuation in generating plasma jets. For the convenience of later description and discussion, the word "fluctuation" is defined as the varying component added to the low frequency wave and the word "mean" refers to the average value of the related parameters, which is averaged out from time-resolved total signal data.

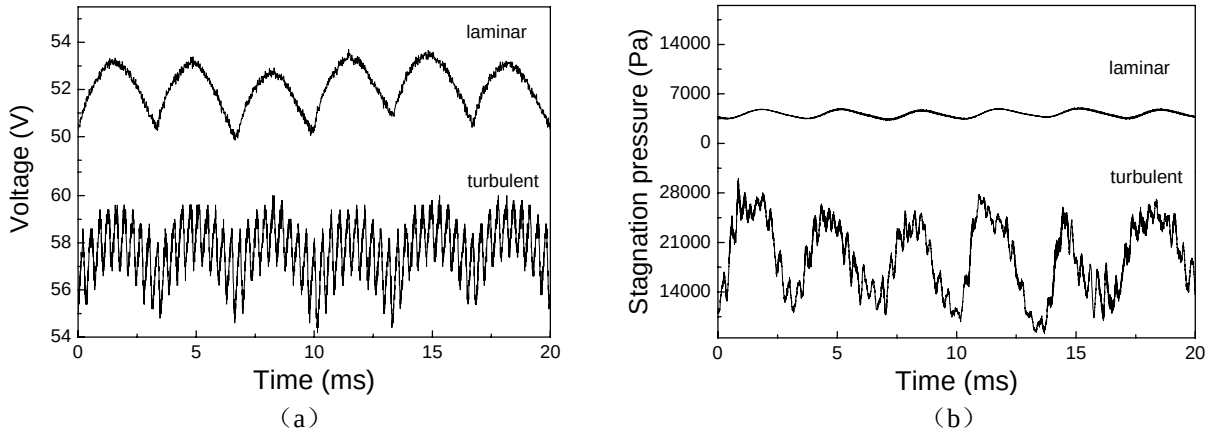

Fig. 3 Measured time-resolved arc voltages (a) in generating plasma jets and stagnation pressures (b) at the distance of 20 mm from the torch exit at arc current of 180 A and gas flow rate of 2.2×10^{-4} kg/s for laminar jet and 5.5×10^{-4} kg/s for turbulent jet.

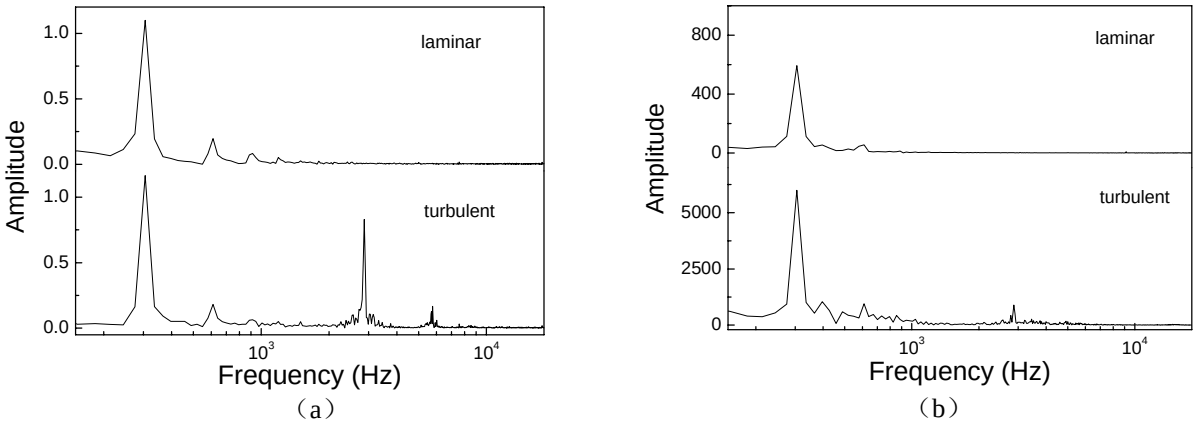

Fig. 4 FFT results for arc voltages (a) in generating plasma jets and stagnation pressures (b) at the distance of 20 mm from the torch exit at arc current of 180 A and gas flow rate of 2.2×10^{-4} kg/s for laminar jet and 5.5×10^{-4} kg/s for turbulent jet.

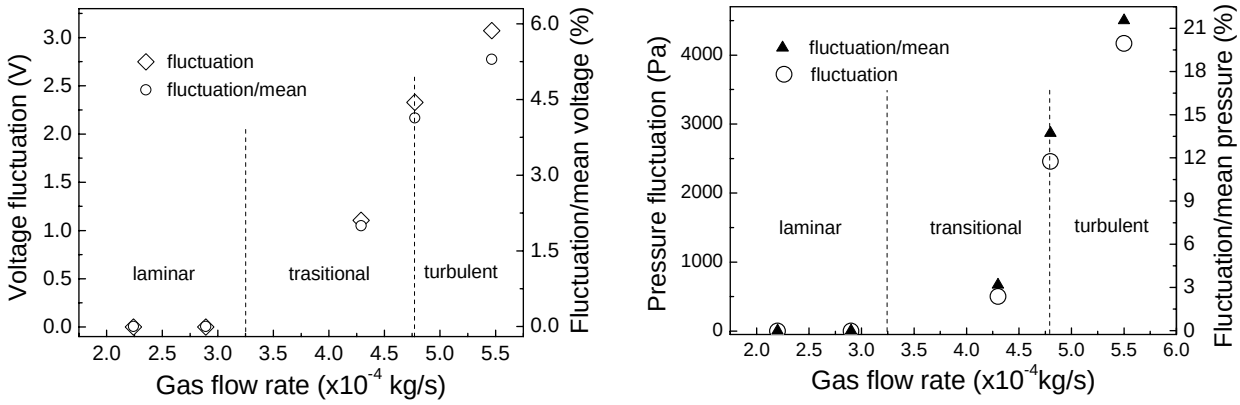
By using the FFT method, the amplitude spectra of the arc voltages and local stagnation pressures of Fig. 3(a) and 3(b) can be obtained, the results are shown in Fig. 4(a) and 4(b) separately. One can see that the peak of 300 Hz appears in all these spectra, similar to the spectrum of the voltage across the fixed resistance, which could prove that the characteristics of the power supply have apparent influence on the arc voltage and plasma jet flow. The amplitude spectrum of arc voltage also shows that there exists a high frequency peak close to 3 kHz in the turbulent state, which could indicate the rapid movement of the arc root on the anode surface in the generation of the turbulent plasma jet. And the value of the high frequency peak in the stagnation pressure spectrum is the same as that of the arc voltage, which indicates that the motion of the anode arc root attachment can affect the fluctuation characteristics of plasma jet. From the waveforms of Fig. 3(a) and the FFT results of Fig. 4(a), it could suggest the different moving behaviour of arc root attachment spot on the anode surface for laminar and turbulent jets generation. The arc motion in generating turbulent plasma jets seems to be similar to the “takeover mode”, since the scale of the voltage fluctuation is relatively low compared with the situation of conventional “restrike mode” [3].



(a) (b)

Fig. 5 Voltage fluctuation and fluctuation/mean voltage (a), pressure fluctuation and fluctuation/mean pressure (b) change with gas flow rate at arc current of 180A. The words “laminar”, “transitional” and “turbulent” represent different jet flow regime.

Fig. 5(a) and 5(b) show the voltage fluctuation and the ratio of voltage fluctuation to mean voltage, and local stagnation pressure fluctuation at 20 mm from the torch nozzle and the ratio of pressure fluctuation to mean pressure at arc current of 180A and with the increase of gas flow rate from 2.2×10^{-4} kg/s to 5.5×10^{-4} kg/s separately. The words “laminar”, “transitional” and “turbulent” in these figures represent three different jet flow regimes, i.e., in the laminar flow regime, jet length increases apparently with gas flow rate and arc current; at a certain arc current, there exists a maximum gas flow rate where the jet length shows its maximum value and keeps the laminar flow state; and then the jet flow changes into the transitional regime, the jet length fluctuates heavily, and the mean jet length decreases with the increase of gas flow rate; while in the turbulent regime, the jet length is very short and almost independent of gas flow rate and arc current [12]. The values of voltage fluctuation and the ratio of voltage fluctuation to mean voltage for laminar jet are zero, for there is no high frequency fluctuation from the FFT results. It is clearly seen from these figures, the arc voltage fluctuations and the ratio of fluctuation to the mean voltage increase with the increase of gas flow rate, and the stagnation pressure has the similar characteristics, which could indicate that the flow regime of the plasma jet is directly corresponding to the arc voltage fluctuation characteristics. The ratio of the voltage fluctuation to mean voltage at the gas flow rate of 5.5×10^{-4} kg/s is about 5.3%, while that of the stagnation pressure fluctuation to mean stagnation pressure is about 20.8%, it could caused by the strong fluctuations of temperature and velocity of the turbulent plasma jet.

Similarly, the voltage fluctuation and the ratio of voltage fluctuation to mean voltage change with the increase of arc current are plotted in Fig. 6, at gas flow rate of 2.2×10^{-4} kg/s for laminar plasma jet and 5.5×10^{-4} kg/s for turbulent one. The voltage fluctuations increase a little from 3 V to 3.2 V with the increase of arc current from 170 A to 200 A for the turbulent jet, and the ratios of voltage fluctuation to mean voltage decrease a little with the increase of arc current. The increase of arc current can lead to the increase of arc voltage, though the voltage fluctuation increases a little, the net effect may lead to the decrease of the ratio.

The stagnation pressure and the ratio of pressure fluctuation to mean pressure with the increase of arc current have the same trend as that of the arc voltage, which is shown in Fig. 7. The decrease of the ratio could suggest that there is a stabilizing effect on the turbulent jet as the arc current increases.

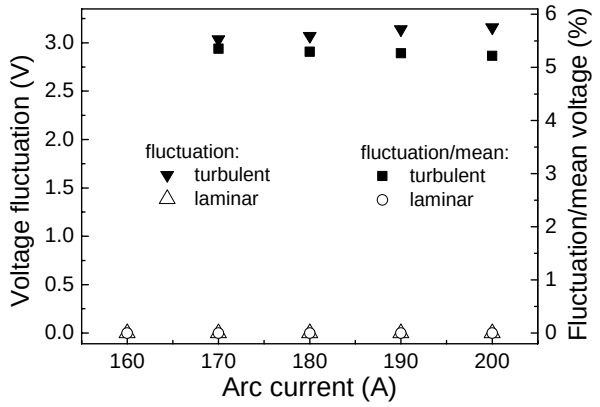


Fig.6 Voltage fluctuation and fluctuation/mean voltage change with the increase of arc current at gas flow rate of 2.2×10^{-4} kg/s for laminar plasma jet and 5.5×10^{-4} kg/s for turbulent jet.

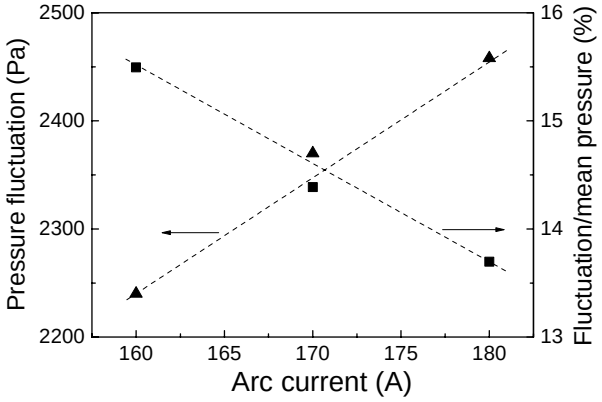

Fig. 7 Stagnation pressure fluctuation at 20mm from the torch exit and fluctuation/mean pressure change with the increase of arc current at gas flow rate of 4.8×10^{-4} kg/s for turbulent jet.

4. Conclusions

Experimental results show that the fluctuations of arc voltage in generating plasma jet, and related spectral line intensity and local stagnation pressure in a plasma jet have similar characteristics. The power supply affects the arc voltages in generating the laminar and turbulent jets in almost the same way; A high frequency component, close to 3 kHz, exists in the arc voltage in generating turbulent jet and in the corresponding stagnation pressure signals. At the same working parameters, the ratio of stagnation pressure fluctuation to the mean pressure is much larger than that of the arc voltage. Both the ratios of arc voltage fluctuation to mean voltage and the stagnation pressure fluctuation to the mean pressure decrease with the increase of arc current.

ABSTRACT

A calculation of plasma parameters in RF ICP torch was made using a non-equilibrium model. The RF ICP torch for spectrochemical analysis works at a frequency of 27.12 MHz; the plasma power is 2 kW; the inner diameter of the torch is 24 mm and the plasma gas is argon. The plasma torch has three axial gas flows: the transport gas flow is G_1=3.0 l/min, the plasma gas flow is G_2=2.5 l/min, the sheath gas flow is G_3=20 l/min.

Two cases were calculated: without and with the transport gas flow. The results calculated using the Saha and Potapov equations were compared. The results of calculation using an equilibrium (LTE) model are also given for comparison.

1. INTRODUCTION

The features of plasma in RF ICP torches such as a high purity due to the absence of electrode and large volumes of plasma have resulted in a wide range of applications. Main technologies based on RF ICP torch application are the following: powder spheroidization, synthesis of ultra-fine powder, plasmachemical technologies, material treatment at reduced pressures etc. One of the most widespread applications of ICP torches is a spectrum source for spectrochemical analysis.

The particularity of spectrochemical ICP torch is the feeding of the investigated material into the axial plasma zone through a central tube by a transport gas flow. This material evaporates and the elements contained in this material emit spectra. These spectra are recorded and analyzed by spectral instruments. The transport gas flow leads to the formation of a cold channel in the axial zone of the plasma.

The numerical modeling of plasma parameters in RF ICP torches is widely used to analyze the plasma processes and to select the optimal operating conditions of the torch. A review of early articles on RF ICP torch modeling was carried out in the book of S. Dresvin [1]. Reviews of recent articles on this topic are contained in articles of M. Boulos, R. Barnes and J. Mostaghimi [2, 3].

The first two dimensional (2D) models of plasma were developed assuming equilibrium, see for example [4]. Non-equilibrium effects in Ar atmospheric plasma were showed in the sixties [5], but the first 2D model of a non-equilibrium Ar plasma only appeared in 1987 [6].

To calculate non-equilibrium plasma parameters in RF ICP torch, it is necessary to use data on thermodynamic and transport properties of non-equilibrium argon plasma. The calculation of non-equilibrium plasma composition is the basis of thermodynamic and transport properties calculation.

At present time, in most of works, non-equilibrium plasma composition is calculated using either non-equilibrium Saha equation [7, 6] or Potapov equation [8, 9]. The present work is devoted to the calculation of non-equilibrium Ar plasma parameters in ICP torch for spectrochemical analysis and the comparison of the results obtained using Saha and Potapov equations.

2. MATHEMATICAL MODEL OF NON-EQUILIBRIUM AR PLASMA

The model is based on the following assumptions:

- plasma is axisymmetric, fields of temperature, velocity and electromagnetic values are two dimensional;
- gas flow is laminar, stationary, at atmospheric pressure;
- plasma is optically thin;
- only the following species are present in plasma: Ar atoms, Ar+ positive ions and e electrons;
- temperatures of heavy species (Ar atoms and Ar+ ions) are equal;
- electron temperature T_e can differ from temperature of heavy species T_h (thermal non-equilibrium);
- the ionization equilibrium is present in the plasma;

- viscous dissipation and pressure work in the energy equation, gravity force and displacement current are neglected.

The non-equilibrium model of plasma involves the following equations:

- equation of energy balance for electrons:

$$\mathrm{div}\left(\left(\frac{5}{2}kT_e + E_i\right)n_e\vec{v}\right) = \mathrm{div}\left(\lambda_e \mathrm{grad}T_e\right) + \sigma_e E_\varphi^2 - u_{rad} - b_{eh}\cdot\left(T_e - T_h\right), \quad (1)$$

- equation of energy balance for heavy species:

$$\mathrm{div}\left(\frac{5}{2}kT_h\left(n_i + n_a\right)\vec{v}\right) = \mathrm{div}\left(\lambda_h \mathrm{grad}T_h\right) + b_{eh}\cdot\left(T_e - T_h\right), \quad (2)$$

- continuity equation:

$$\mathrm{div}\left(\rho\vec{v}\right) = 0, \quad (3)$$

- momentum transfer equations for axial and radial components of velocity:

$$\mathrm{div}\left(\rho\vec{v}v_z\right) = -\frac{\partial p}{\partial z} + \frac{\partial}{\partial z}\left(2\mu_h\frac{\partial v_z}{\partial z}\right) + \frac{1}{r}\frac{\partial}{\partial r}\left[r\mu_h\left(\frac{\partial v_r}{\partial z} + \frac{\partial v_z}{\partial r}\right)\right] + F_z, \quad (4)$$

$$\mathrm{div}\left(\rho\vec{v}v_r\right) = -\frac{\partial p}{\partial r} + \frac{\partial}{\partial z}\left[\mu_h\left(\frac{\partial v_r}{\partial z} + \frac{\partial v_z}{\partial r}\right)\right] + \frac{1}{r}\frac{\partial}{\partial r}\left(2r\mu_h\frac{\partial v_r}{\partial r}\right) - 2\mu_h\frac{v_r}{r^2} + F_r, \quad (5)$$

- equation of electromagnetic problem:

$$\frac{\partial^2\dot{E}_\varphi}{\partial z^2} + \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\dot{E}_\varphi}{\partial r}\right) - \left(\frac{1}{r^2} + j\mu_0\omega\sigma_e\right)\dot{E}_\varphi = 0. \quad (6)$$

It is necessary to notice that the 2D electromagnetic problem was developed and solved for the vector potential $\dot{A}_\varphi$ [10, 11]. But in the articles [12, 13], it has been showed that this problem can be solved for electric field intensity $\dot{E}_\varphi$ with the exception of intermediate value – vector potential $\dot{A}_\varphi$ (see (6)). Moreover, contrary to most of the works, the complex equation (6) was not decomposed into two real ones but was solved in complex numbers [14]. This system of non-linear differential equations (1) – (6) was solved using the SIMPLER algorithm [15].

To solve the system (1) – (6) it is necessary to calculate the thermodynamic and transport properties of non-equilibrium Ar plasma which depend on two temperatures: electron temperature T_e and temperature T_h of heavy species.

The following system of equations was used for the calculation of plasma composition:

- quasi-neutrality equation:

$$n_e = n_{Ar+}, \quad (7)$$

- Dalton's law of partial pressures:

$$p = n_e kT_e + \left(n_{Ar} + n_{Ar+}\right)kT_h, \quad (8)$$

- Potapov equation:

$$n_e\left(\frac{n_{Ar+}}{n_{Ar}}\right)^{T_h/T_e} = g_e\frac{Z_{Ar+}\left(T_e\right)}{Z_{Ar}\left(T_e\right)}\left(\frac{2\pi m_e kT}{h^2}\right)^{3/2}\exp\left(-\frac{E_i}{kT_e}\right), \quad (9a)$$

or non-equilibrium Saha equation:

$$n_e\frac{n_{Ar+}}{n_{Ar}} = g_e\frac{Z_{Ar+}\left(T_e\right)}{Z_{Ar}\left(T_e\right)}\left(\frac{2\pi m_e kT}{h^2}\right)^{3/2}\exp\left(-\frac{E_i}{kT_e}\right). \quad (9b)$$

Data from reference [16] were used to calculate the partition functions $Z_{Ar}\left(T_e\right)$, $Z_{Ar+}\left(T_e\right)$. The calculation of plasma composition using Potapov equation (solving of system of equations (7), (8) and (9a)) and Saha equation (solving of system of equations (7), (8) and (9b)) was carried out by Newton method for increment of logarithm of unknown values [17].

As the plasma composition is known, its thermodynamic properties can be calculated using simple formulas [1]. The transport properties of plasma were calculated by the Chapman-Enskog method [18, 19]. In this calculation, the data for collision integrals recommended in works [20, 21] were used.

3. DATA FOR CALCULATIONS

The plasma torch for spectrochemical analysis operated at a frequency of 27.12 MHz, the electrical power in plasma was 2 kW and the gas was argon. The plasma torch had three axial gas flows: transport gas flow G_1, plasma gas flow G_2, sheath gas flow G_3. The torch geometry is given in Fig. 1.

Two cases were calculated:

- without the injection of transport gas: G_1=0;
- with the injection of transport gas: G_1=3.0 l/min.

The plasma gas flow rate was G_2=2.5 l/min and the sheath gas flow rate was G_3=20 l/min. A non-uniform grid system of (r,z)=(40,50) points was used for the calculation.

Both cases were calculated using 3 different models:

- non-equilibrium model using Potapov equation;
- non-equilibrium model using Saha equation;
- equilibrium model.

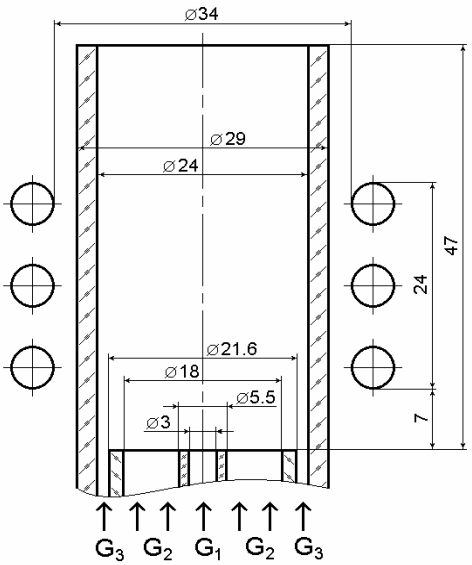

Figure 1. The torch geometry (dimensions are given in mm)

4. RESULTS AND DISCUSSION

The results of the calculations are shown in Figs. 2 – 4.

Comparing the results from the different models, one can notice the following:

1. The electron temperature T_e in the model using Potapov equation is higher by about 1000 K than the electron temperature predicted with the model using Saha equation.

2. In the case of two gas flows the heavy species temperatures T_h of concerned non-equilibrium models are equal near the torch wall but in the axis zone the heavy species temperature of the model using Potapov equation is higher by 1000 K and more. The transport gas flow G_1 (the case with three gas flows) leads to the formation of a cold channel in which the heavy species temperatures T_h predicted by the both models are equal.

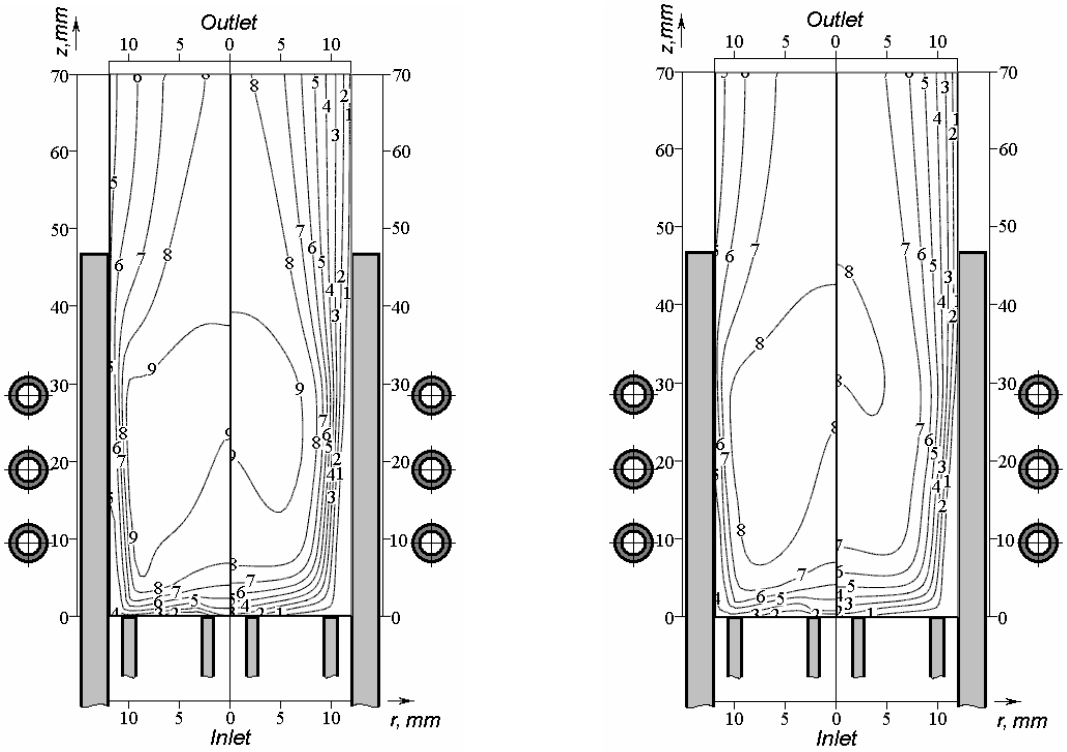
3. In the case of the two gas flow a substantial deviation from LTE is observed near the wall of the torch (the difference between T_e and T_h can reach 6000 K) but near the axis, plasma is close to LTE. The deviation from LTE is observed also near the inlet of the torch. The transport gas flow leads to a substantial deviation from LTE on the torch axis.

4. The comparison of the equilibrium temperature with the heavy species temperature T_h shows that the equilibrium temperature is lower near the wall. This fact can be explained as follows: the heavy species have an additional source of energy resulting from the energy exchange with electrons due to the high electron temperature in this region. This source of energy can not be taken into account in the equilibrium model.

The equilibrium temperature is higher than the heavy species temperature near the axis of the torch. This fact can be explained as follows: the zone of power dissipation is smaller for the equilibrium model; therefore, the plasma temperature has to be higher in the equilibrium model to dissipate the same electrical power as for non-equilibrium plasma [3].

a) non-eq, Potapov, T_e (left) and T_h (right)

b) non-eq, Saha, T_e (left) and T_h (right)



c) non-eq, ψ, Potapov(left) and Saha(right)

d) equilibrium, T (left) and ψ (right)

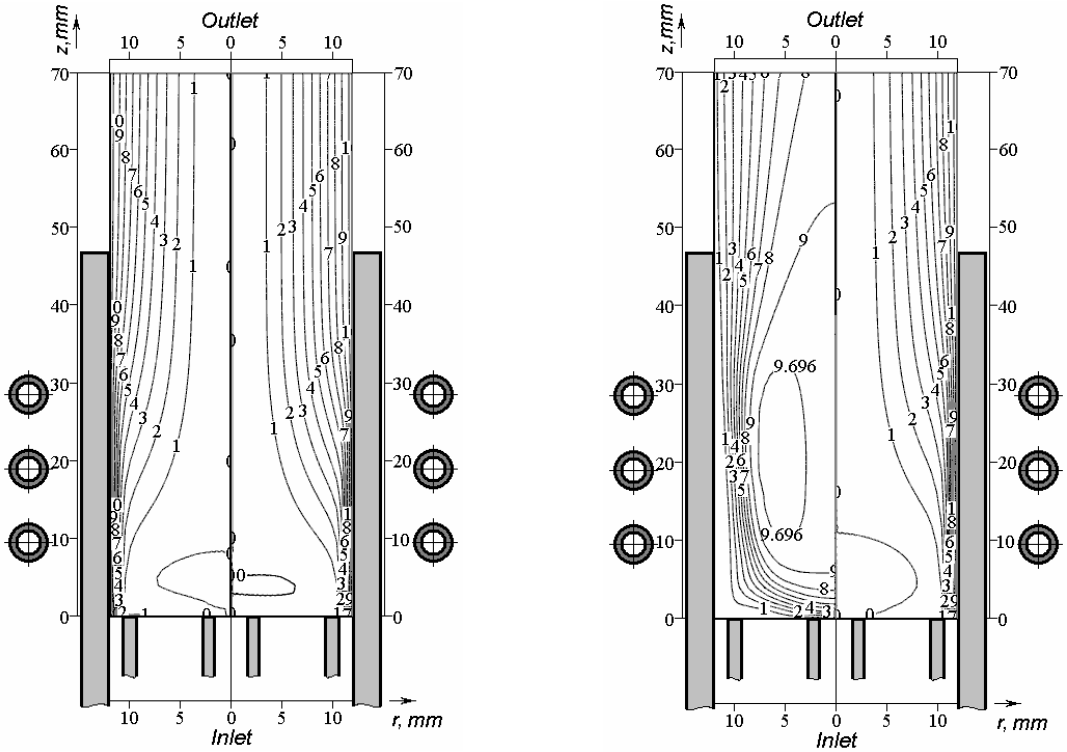


Figure 2. Temperature (in 10^3 K) and flow (in 10^{-5} kg/s) fields for concerned models in case of two gas flows

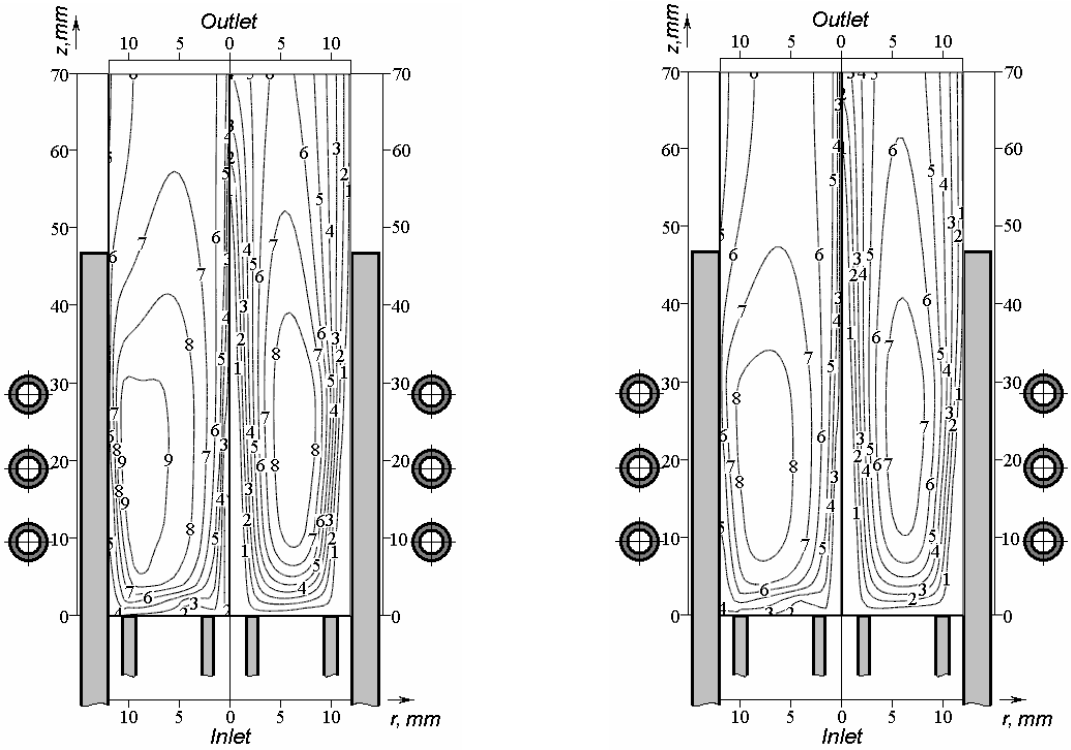
a) non-eq, Potapov, T_e (left) and T_h (right)

b) non-eq, Saha, T_e (left) and T_h (right)



c) non-eq, ψ, Potapov(left) and Saha(right)

d) equilibrium, T (left) and ψ (right)

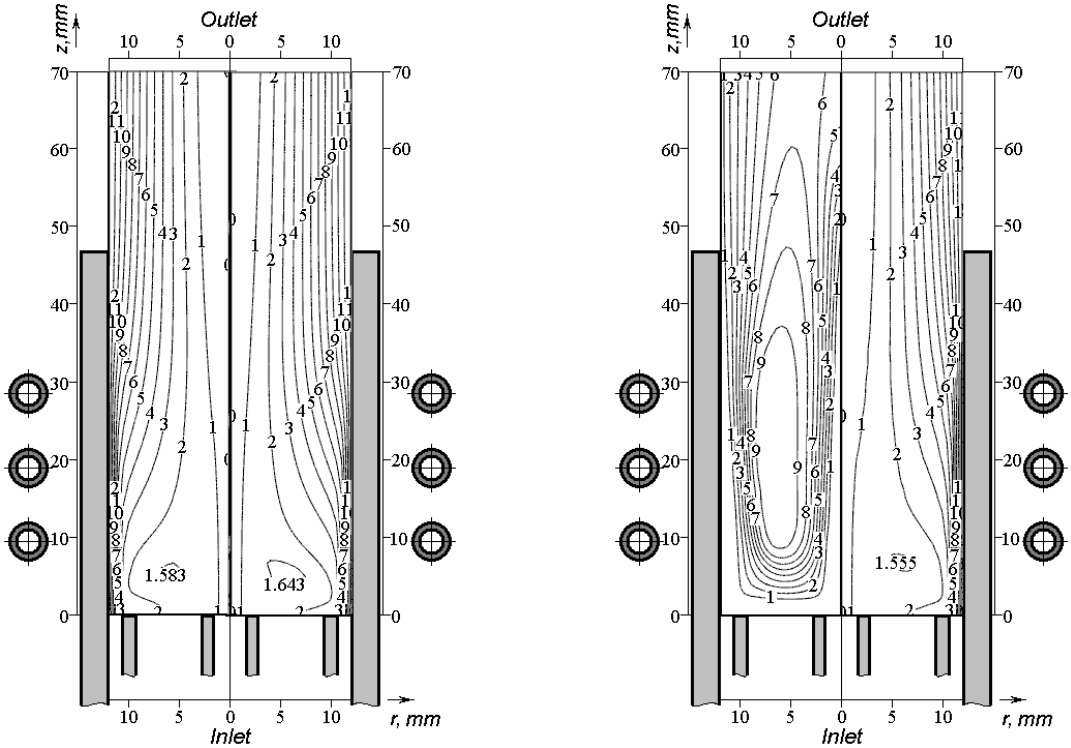


Figure 3. Temperature (in 10^3 K) and flow (in 10^{-5} kg/s) fields for concerned models in case of three gas flows

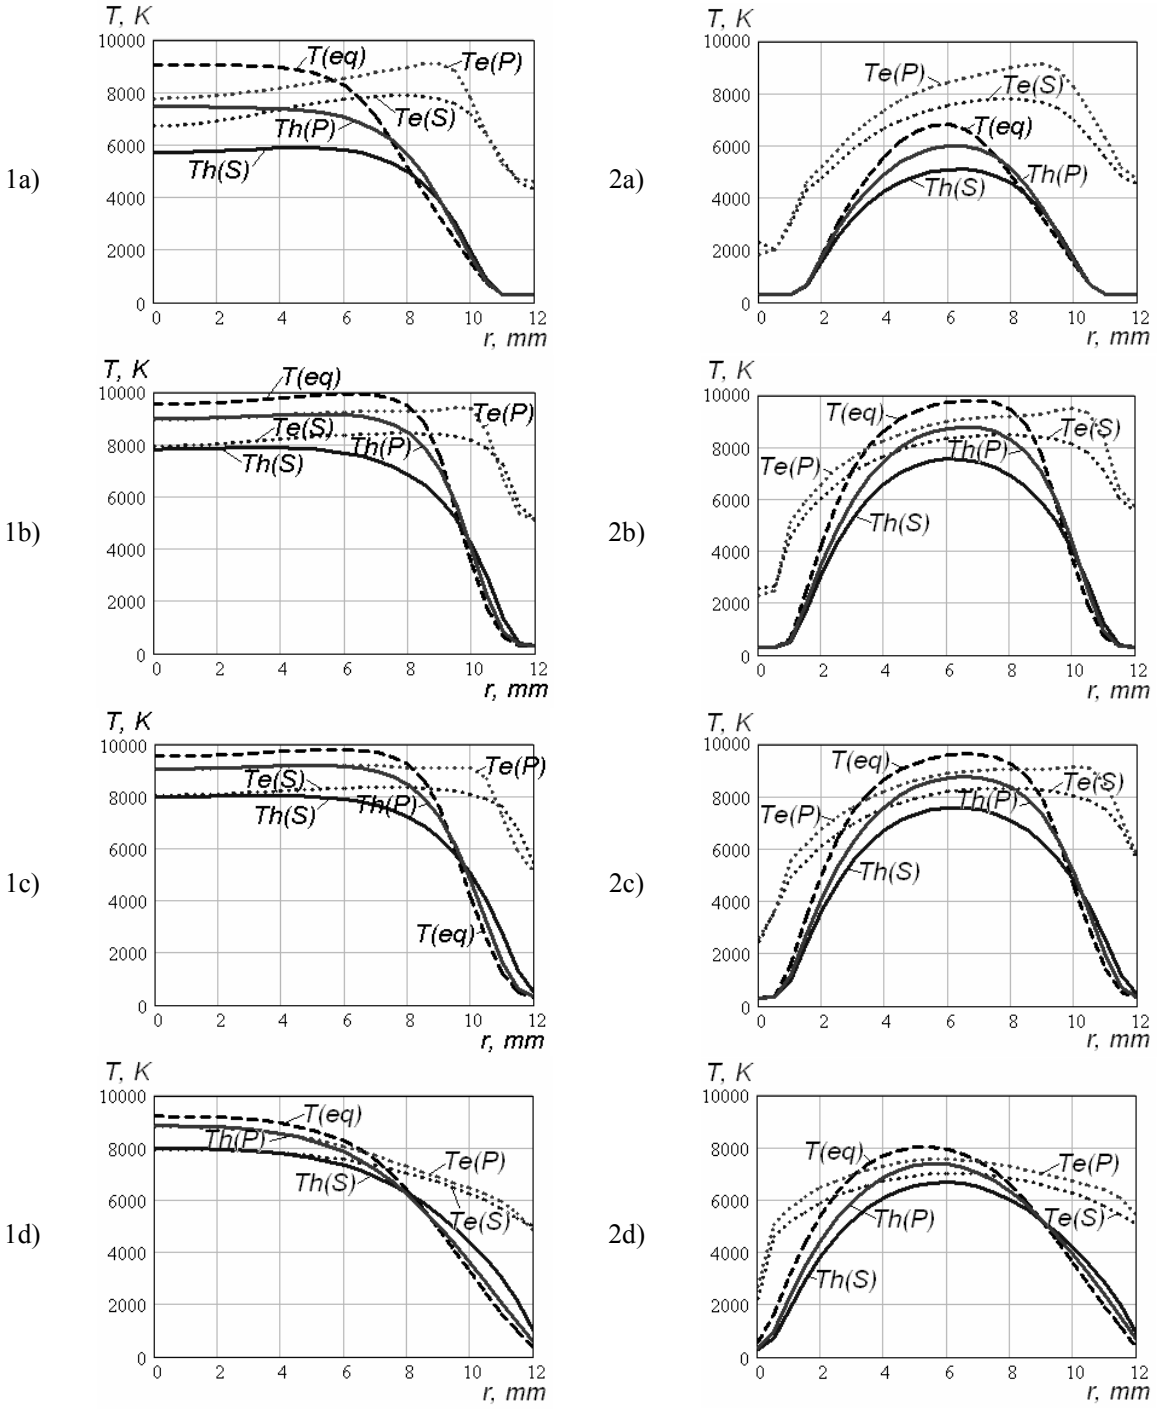

Figure 4. Radial distributions of electron temperature T_e, temperature T_h of heavy species and equilibrium temperature in various cross sections: a - z =6 mm, b - z =20 mm, c - z =30 mm, d - z =47 mm; 1 (left) – case of two gas flows, 2 (right) – case of three gas flows. Symbols in the graphs: T(eq) – equilibrium temperature, Te(P) and Th(P) – electron and heavy species temperatures in model with Potapov equation, Te(S) and Th(S) – the same with Saha equation

5. The peak of temperature is located near the axis according to the equilibrium model. Meanwhile plasma has an obvious skin effect at a frequency of 27.12 MHz. Therefore, the results of the non-equilibrium

models are closer to the reality because the peak of electron temperature is located noticeably closer to the wall of the torch.

It is necessary to notice that the transport gas does not change the position of the peak of electron temperature.

6. The plasma flows predicted with the two non-equilibrium models are the same. The comparison of the plasma flows obtained using equilibrium and non-equilibrium models shows that the gas penetrates faster into the plasma core in the case of the non-equilibrium model.

5. CONCLUSIONS

The results of the calculations have shown that the non-equilibrium model is closer to experimental data comparing to the equilibrium one when mathematical modeling of RF ICP torch for spectrochemical analysis. The basic features of the plasma torches of this kind are the following ones: small size, small plasma power, high frequency – not lower than 27 MHz, feeding of material into the axial zone of plasma.

The non-equilibrium models have shown that most part of plasma in the ICP torch is far from LTE. In the case of two gas flows, the substantial deviation from LTE is observed near the wall and inlet of the torch but near the axis of the torch plasma is close to LTE. Feeding of the transport gas flow leads to a substantial deviation from LTE on the axis.

Differences between the non-equilibrium model with Potapov equation and the one with Saha equation were shown. The final choice between these two models can be done only on the basis of experimental data.

SYMBOL LIST

b_{eh}, W/(m^3·K) - coefficient of energy exchange from the electrons to the heavy species

E_i, J - ionization potential of Ar atom

$\dot{E}_\varphi$, V/m - electric field intensity

F_z, F_r, N/m^3 - axial and radial components of the Lorentz force

f, Hz - frequency

$g_e = 2$ - statistical weight of electron

h, J·s – Plank's constant

k, J/K – Boltzmann's constant

$n_a = n_{Ar}$, m^{-3} - Ar atom density

n_e, m^{-3} - electron density

$n_i = n_{Ar+}$, m^{-3} - Ar ion density

p, Pa - pressure

T_e, K - electron temperature

T_h, K - temperature of the heavy species

u_{rad}, W/m^3 - radiation power

$\vec{v}$, m/s - vector of plasma velocity

v_z, v_r, m/s - axial and radial components of velocity

$Z_{Ar}(T_e)$, $Z_{Ar+}(T_e)$ - partition functions of Ar atom and Ar ion

λ_e, W/(m·K) - electron heat conductivity

λ_h, W/(m·K) - heat conductivity of the heavy species

μ_0, h/m - permeability of the free space

μ_h, kg/(m·s) - viscosity of the heavy species

ρ, kg/m^3 - mass density of plasma

σ_e, mho/m - electron electrical conductivity

$\omega = 2\pi f$, radian/s - pulsation

ψ, kg/s - plasma flow

Abstract

One of the most widespread areas of plasma technology is a treatment of fine-dispersed materials in plasma jets. Complexity of an experimental research of system «plasma flow – particles» has caused the creation of the mathematical models describing movement, heat transfer and physical and chemical transformations of dispersed materials in plasma. Researches of heat transfer in high-temperature flows are of significant interest as heat transfer from plasma to particles of powder is the determining factor.

A number of studies of particle heat transfer in thermal plasmas give the following expression for Nusselt number: $Nu=2+A\cdot Re^{0.5}\cdot Pr^{0.33}$, where A is constant. However, this expression overestimates Nu in comparison with experimental data. In this connection authors offer the criterial expression for calculation of particle heat transfer in plasma taking into account the correction for conductive term: $Nu=2\cdot(V_s/V_p)+A\cdot Re^{0.5}\cdot Pr^{0.33}$. Introduction of correction namely V_s/V_p obviously explains mechanism of influence of heat transfer conductive component on particle conductive-convective heat transfer in thermal plasma and result in sufficiently good agreement of calculations with numerous experimental data.

Key words

Plasma, solid particle, calculation, heat transfer, experimental data.

Symbol list

«p»	Plasma index	Pr	Prandtl number
«s»	Solid particle index	Re	Reynolds number
«f»	Boundary layer average value index	Nu	Nusselt number
T	Temperature	d	Diameter
H	Enthalpy	μ	Viscosity
V	Velocity	ρ	Density
α	Heat transfer coefficient	q	Specific power
c_p	Specific heat at constant pressure	λ	Heat conductivity

1. Introduction

In most cases a heating of fine-dispersed materials is determined by intensity of particles heat transfer in thermal plasmas. So depending on sizes, one of particles are have time to heat up to a certain temperature, others are melt and super-dispersed particles are evaporate completely. Therefore particles and thermal plasmas heat transfer investigation is necessary for understanding of plasma technologies of dispersed materials treatment.

2. Investigation of criterial dependences of heat transfer

A body placed into a flow of ionized gas is received a heat by a heat conductivity, a convection and a radiation. Here it is meant that the heat transfer is carried out by the all kind of processes: atomic, molecular, electron, recombinational, dissociational and chemical processes.

An analytic solution of differential equations can not be obtained for complex conditions of heat transfer in plasma. Therefore to understand complex physical phenomena in plasma a method of modeling is used. That method is based on the theory of similarity. The Newton model of the heat transfer underlies of the method:

$$q = \alpha \cdot \Delta T . \qquad (1)$$

A heat transfer coefficient α is a complex function. It depends on different parameters and both the body and plasma properties.

A relationship between the heat transfer coefficient and the mentioned parameters is usually defined by a criterial dependence:

$$\mathrm{Nu} = \alpha \cdot \frac{d_s}{\lambda_p} = f(\mathrm{Re}, \mathrm{Pr}) . \qquad (2)$$

There are a big number of semi-empirical criterial dependences that differ considerably from each other for the same conditions of a streamline of the spherical model [1–3].

By now a lot of coefficients and corrective modifications for Reynolds and Prandtl numbers were proposed by a series of authors on the basis of an analysis of experimental data of small bodies heat transfer in plasma [4–16].

In most cases they use the following formula [17]:

$$\mathrm{Nu} = \underbrace{2}_{\text{conduction}} + \underbrace{0.6 \cdot \mathrm{Re}^{0.5} \cdot \mathrm{Pr}^{0.33}}_{\text{convection}}, \qquad (3)$$

where the first item «2» characterizes the process of heat transfer by a thermal conductivity through the boundary layer and the second one «$0.6 \cdot \mathrm{Re}^{0.5} \cdot \mathrm{Pr}^{0.33}$» expresses a convective heat transfer from an incident plasma flow.

It is necessary to notice important features in a point of view of different authors to a taking into account of a strong temperature change in a thermal boundary layer of a streamlined body. For example, as the defining temperature to calculate plasma properties in the papers [11, 12, 18] they use the temperature of an incident flow, in the papers [6, 7] – mass averaged temperature, in the paper [10] they recommend to use the averaging temperature of the boundary layer. The authors of the paper [12] calculate a flow viscosity using the temperature $T_s + 0.19 \cdot (T_p - T_s)$, but a heat conductivity – using the temperature of the particle surface T_s, in the paper [9] they calculate properties using the temperature of the particle surface T_s. Different points of view also exist to a calculation of heat fluxes, in the papers [7, 10–12, 18] they use the temperature difference $\Delta T = T_p - T_s$, but in the papers [4, 5, 9] – the enthalpy one $\Delta T = (H_p - H_s)/c_p$. Some authors suppose that as the defining temperature it is necessary to use a temperature that was found experimentally.

Thus, the differences between the criterial dependences of different authors lie in a choice of the defining temperature to calculate plasma properties – the flow temperature (T_p), the particle surface temperature (T_s) or the average value of the flow and particle surface temperatures (T_f), and in a using of different temperature corrections. In addition each of authors introduces the correction in a form of an additional item in one's own way on the basis of one or another reason [18]. That fact makes difficulties for the heat transfer analysis.

3. Heat transfer experimental data

A big number of formulas to calculate the Nusselt number exist. Those criterial dependences are correct for narrow ranges of temperatures and conditions at which they were obtained. Therefore their using often leads to errors that are difficult to evaluate (an error of the heat flux calculation may exceed a hundred per cent). In this connection it seems to be important to compare the most generally used formulas with existing experimental data in a wide range of the temperature.

To have a total notion of the process of heat transfer it is necessary to measure at the same time the following values: the heat flux to a model, the plasma temperature and velocity in a local point. Such investigation is complex to realize; therefore data does not exist in large quantities. Figs. 1 and 2 present practically all well-known experimental data of a heat transfer research in high temperature flows and plasma jets for models of metal water-cooled spheres with a diameter of 25.4 mm and for moving ceramic particles with diameters of 330-820 μm.

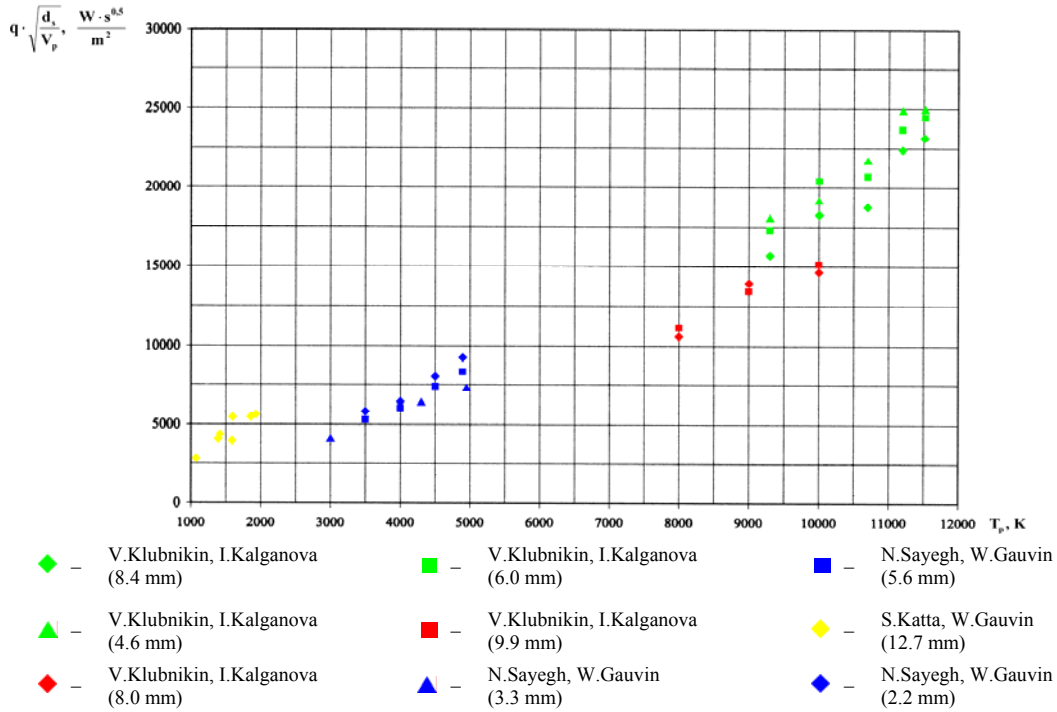

Fig. 1. Experimental data of a heat transfer research in argon plasma jets for copper models

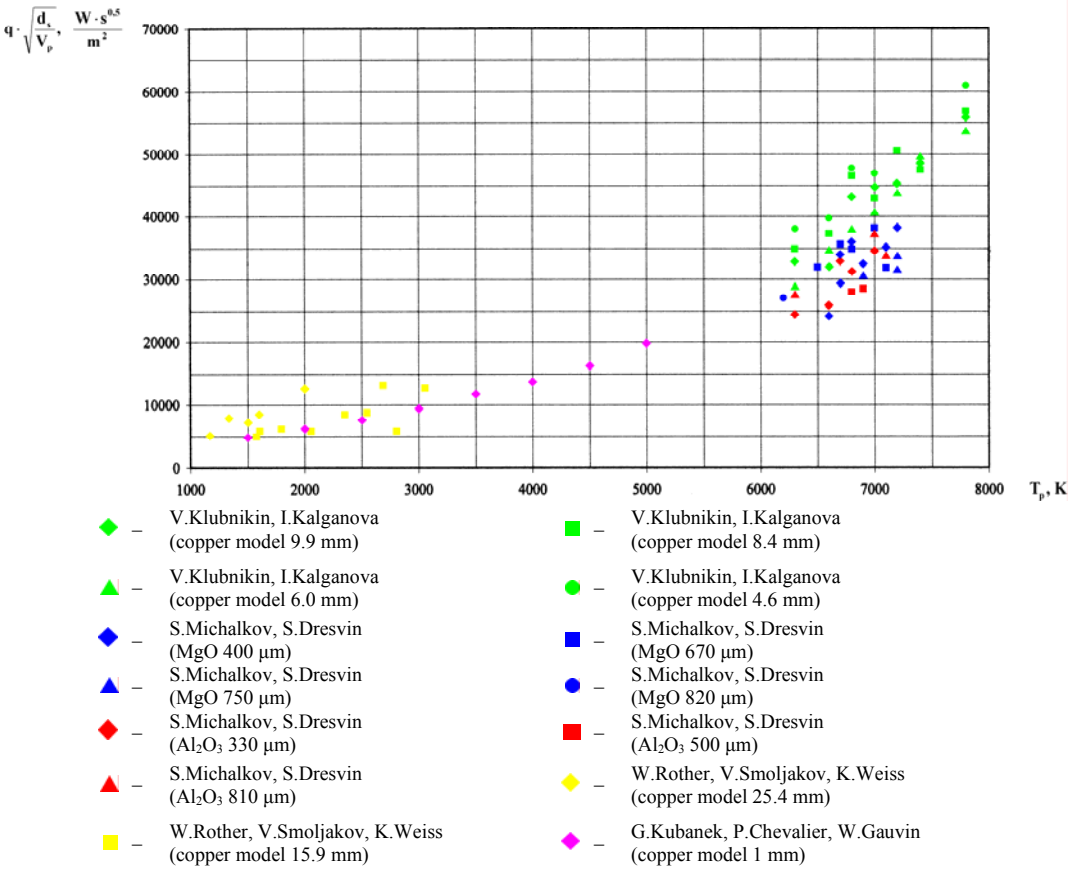

Fig. 2. Experimental data of a heat transfer research in air plasma jets for different models

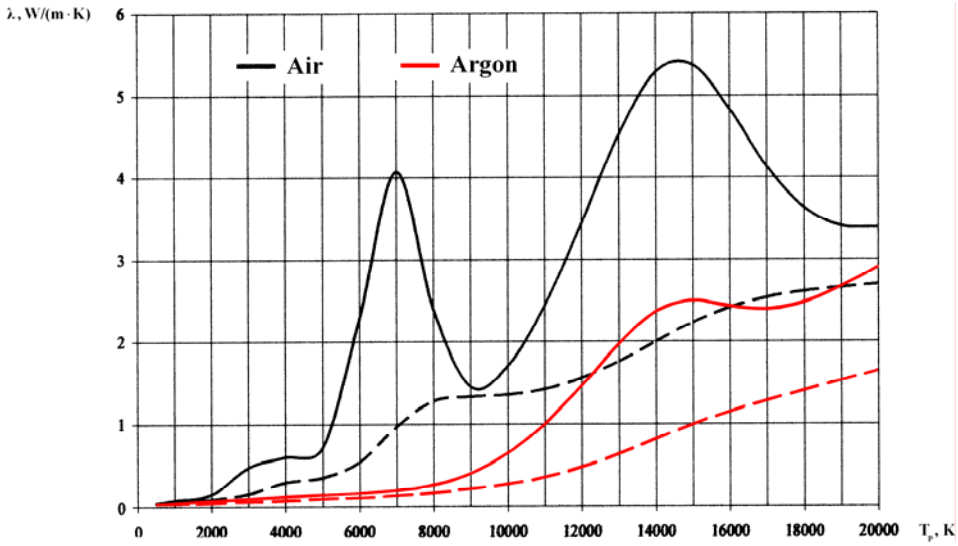
On the basis of that experimental data the authors of the paper [19] made temperature dependences of heat flux for argon and air plasma, here those dependences had been calculated using the different criterial formulas and reduced to the same conditions: d_s = 6 mm, V_p = 25 m/s, T_s = 300 K. There was shown that all dependences of the heat flux in argon plasma on the temperature have a monotonic character. A character of those dependences in a case of air plasma is more complex. That difference for argon and air plasma connects to the dependence on temperature of the plasma heat conductivity (see Fig. 3).



– Plasma heat conductivity from the paper [20];

– Plasma heat conductivity averaged through the particle boundary layer

Fig. 3. Dependence on temperature of the heat conductivity for air and argon plasma

If they use the temperature of the plasma flow to calculate the heat conductivity of air plasma that is necessary to estimate a heat flux, it leads to a disturbance of dependence on temperature monotonicity for high temperatures (higher than plasma dissociation takes place) and to an appearance of sharp decreasing of heat fluxes. Some doubts are cast upon it because an experimental confirmation of that fact has not been obtained up to now. Dependences on temperature of the heat flux have a smooth increasing character when using the heat conductivity averaged through the boundary layer:

$$\overline{\lambda}_p = \frac{1}{T_p - T_s} \cdot \int_{T_s}^{T_p} \lambda_p \cdot dt . \qquad (4)$$

A comparison of different criterial dependences given in the paper [19] shows a considerable variation of heat flux values for argon plasma and especially for air one. For example, the heat flux has values from 0.7 to 2 MW/m^2 for argon plasma at the temperature of 8000 K, and for air plasma at the same conditions – from 2 to 14 MW/m^2. Therefore a recommendation to use some of them can be made only as a result of a comparison of that criterial dependence with experimental data given in the paper [19].

However the direct comparison of experimental data with calculated curves is not possible as different experimental data were obtained for different model spheres (fixed copper water-cooled models or ceramic particles moving in a plasma flow) at different conditions that vary by the velocity and the temperature of plasma flows.

4. Method of D-function

To compare experimental data that had been received at different values of an incident flow velocity, a model sphere diameter and its temperature, it is convenient to use a method of D-function considering only the convective part of heat transfer.

That method allows to compare experimental data received at different conditions and to connect parameters of plasma itself with values of a heat flux to a spherical model [4].

The method of D-function is realized by the following way: the equation of the heat flux

$$q_s = Nu \cdot \frac{\lambda_p}{d_s} \cdot \left(T_p - T_s\right) = \left[A \cdot Re^{0.5} \cdot Pr^{0.33}\right] \cdot \frac{\lambda_p}{d_s} \cdot \left(T_p - T_s\right) \qquad (5)$$

is rearranged so that the right side of that equation consists of items that are dependent on the temperature only, the other items are carried to the left side.

By substituting of the formulas of definition of Reynolds and Prandtl numbers into the expression (5) of heat flux, we have:

$$q_p = A \cdot \sqrt{\frac{\rho_p \cdot V_p \cdot d_s}{\mu_p}} \cdot \sqrt[3]{\frac{\mu_p \cdot c_p}{\lambda_p}} \cdot \frac{\lambda_p}{d_s} \cdot \left(T_p - T_s\right). \qquad (6)$$

Let the equation (6) is rearranged by the following way: the left side consists of items that were measured during experiments, and the right side – ones that are dependent on the plasma temperature only:

$$\underbrace{q_p \cdot \sqrt{\frac{d_s}{V_p}}}_{\text{Experimental data}} = \underbrace{A \cdot \sqrt{\frac{\rho_p}{\mu_p}} \cdot \sqrt[3]{\frac{\mu_p \cdot c_p}{\lambda_p}} \cdot \lambda_p \cdot \left(T_p - T_s\right)}_{\text{D-function}}. \qquad (7)$$

Then the right side of the equation (7) that is dependent on the temperature only can be denoted as D-function:

$$D(T) = A \cdot \sqrt{\frac{\rho_p}{\mu_p}} \cdot \sqrt[3]{\frac{\mu_p \cdot c_p}{\lambda_p}} \cdot \lambda_p \cdot \left(T_p - T_s\right). \qquad (8)$$

Thus, the D-function connects a value of the heat flux q_p to the spherical model with the values of the sphere diameter d_s, the plasma temperature T_p and velocity V_p by the following way:

$$q_p \cdot \sqrt{\frac{d_s}{V_p}} = D(T). \qquad (9)$$

Using the D-function, it is very convenient to make a criterial treatment of results of different experiments. Then it is possible to present practically all experimental data in an only graph. Figs. 4 and 5 present dependences on temperature of the D-function for argon and air plasma correspondingly that had been created for different values of the semi-empirical coefficient A and with using of the plasma heat conductivity averaged through the boundary layer. Experimental data of different authors expressed by a universal complex $q_p \cdot \sqrt{\frac{d_s}{V_p}}$ are shown in the same figures.

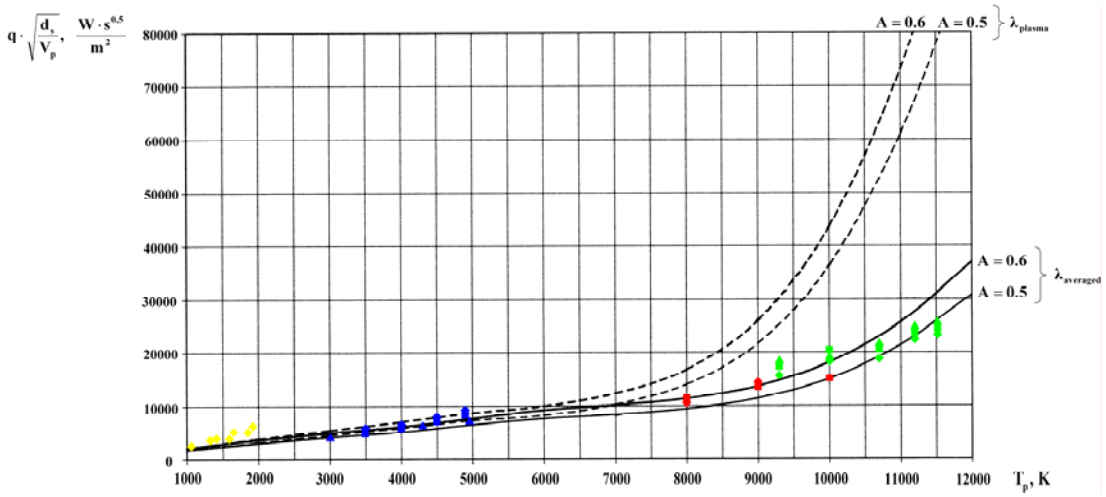


Fig. 4. Dependence on temperature of the D-function and experimental data for argon plasma

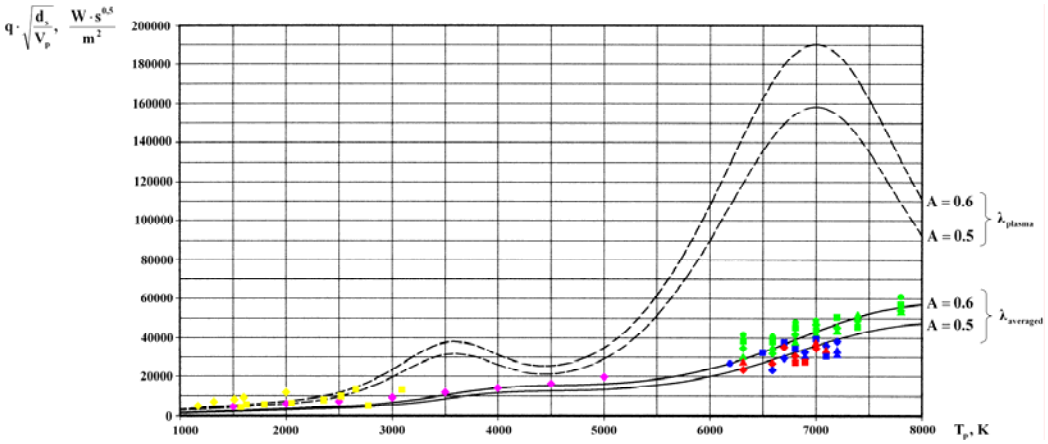

Fig. 5. Dependence on temperature of the D-function and experimental data for air plasma

A comparison by the D-function of different experimental data with the convective part of the heat transfer has shown a good agreement for the both argon and air plasma when the coefficient A is in the range of 0.5-0.6 – for metal particles, and 0.4-0.5 – for ceramic particles.

Thus, an analysis and a comparison of different experimental data with a big number of criterial formulas of spherical model heat transfer in plasma flows as well as a quantity of calculations of dynamics and heat transfer of particles of different powdered materials in plasma jets of RF plasma torches [21] let make the following conclusions:

1) When the plasma flow velocity is much more than the particle velocity – $V_p > V_s$, the conductive part does not play a noticeable role in the heat transfer;

2) When a particle is accelerated and its velocity becomes comparable with a plasma jet velocity – $V_p \approx V_s$, that is typical for small particles (less than 50 μm) and especially for fine-dispersed ones, the convective part of the heat transfer becomes equal zero $0.6 \cdot Re^{0.5} \cdot Pr^{0.33} \to 0$ because the Reynolds number becomes equal zero $Re = \frac{\rho_p \cdot \left|\vec{V}_p - \vec{V}_s\right| \cdot d_s}{\mu_p} \to 0$, and the conductive part becomes the main part of the heat transfer.

5. Correction proposal

A using of the criterial formula that takes into account the both conductive part and convective one (5) of the heat transfer under the condition that $V_p > V_s$ leads to an overestimation of the heat flux value in 2-3 times and to considerable errors in results due to the conductive part $Nu = 2$ presence. That fact is confirmed as well as calculations that had been carried out in the paper [19].

Thus, there are the following types of the criterial formulas of the particle heat transfer in plasma for different proportions of their velocities:

$$Nu = A \cdot Re^{0.5} \cdot Pr^{0.33}, \qquad \text{if} \qquad V_p > V_s;$$

$$Nu = 2, \qquad \text{if} \qquad V_p \approx V_s.$$

The goal is to find a universal criterial formula that is agreed in a satisfactory degree of accuracy with experimental data of heat fluxes from plasma to particles (Figs. 1 and 2) as well as takes into account the feature of a calculation of dynamics and heat transfer of different particles in plasma jets when the heat transfer may be changed from the convective nature to the conductive one.

As shown above, a dominance of the conductive part ($Nu = 2$) or the convective one ($Nu = A \cdot Re^{0.5} \cdot Pr^{0.33}$) of the heat transfer is determined by a proportion between the particle velocity and plasma one. That fact let us to propose a correction to the conductive part of the heat transfer ($Nu = 2$) that is a ratio $\frac{V_s}{V_p}$ of the particle velocity to the plasma one (in the current point of time). Then for heat flux calculations we recommend the following criterial formula that takes into account the features of the heating of different particles in plasma:

$$\mathrm{Nu} = 2 \cdot \frac{V_s}{V_p} + 0.6 \cdot \mathrm{Re}^{0.5} \cdot \mathrm{Pr}^{0.33}. \qquad (10)$$

Here the classical formula without any other corrections is taken as the basis because different correction factors of other authors result in correction of the heat flux of no more than 15 %. The simplest expression (3) is the most reasonable for the heat transfer analysis especially because an investigation of the convective part of that expression with using of D-function and taking into account the heat conductivity averaged through the boundary layer has shown a good agreement with experimental data (see Figs. 4 and 5). And the formula to an estimation of the heat flux from plasma to the particle has the following form:

$$q_p = \mathrm{Nu} \cdot \frac{\overline{\lambda}_p}{d_s} \cdot \left(T_p - T_s\right). \qquad (11)$$

Here as the plasma heat conductivity $\overline{\lambda}_p$ we recommend to use that one averaged through the boundary layer, but to calculate other plasma properties, using the temperature of the incident plasma flow (at the external border of the boundary layer).

The formula (10) takes automatically into account above mentioned disadvantages that take place when changing of the nature of the heat transfer from plasma to the particle. If the plasma velocity is higher than treated particles velocities $V_p > V_s$ then the formula (10) takes into account only convective part of the heat transfer, it is transformed into the following form:

$$\mathrm{Nu} = 0.6 \cdot \mathrm{Re}^{0.5} \cdot \mathrm{Pr}^{0.33}, \qquad \left(2 \cdot \frac{V_s}{V_p}\right) \to 0.$$

If treated particles velocities are comparable with the plasma velocity $V_p \approx V_s$ then the formula (10) takes into account only the conductive part of the heat transfer, it is transformed into the following form:

$$\mathrm{Nu} = 2, \qquad \left(0.6 \cdot \mathrm{Re}^{0.5} \cdot \mathrm{Pr}^{0.33}\right) \to 0.$$

Thus, there is the following universality of the formula (10) that provides changing of the nature of the heat transfer depending on the ratio of the particle velocity V_s to the plasma one V_p:

$$\mathrm{Nu} = 2 \cdot \frac{V_s}{V_p} + 0.6 \cdot \mathrm{Re}^{0.5} \cdot \mathrm{Pr}^{0.33}, \quad \begin{cases} \mathrm{Nu} = 0.6 \cdot \mathrm{Re}^{0.5} \cdot \mathrm{Pr}^{0.33} & \text{if } V_p > V_s \\ \mathrm{Nu} = 2 & \text{if } V_p \approx V_s \end{cases}$$

Conclusions

A result of a treatment of numerous experimental data on the particle heat transfer in plasma as well as the analysis of numerous criterial formulas described the heat transfer let to make the following conclusions:

1. A using of the enthalpy difference ΔH in the formula (11) for a calculation of the heat flux q leads to an overestimation of the last one in 3-5 times. Therefore the temperature difference $\Delta T = T_p - T_s$ is recommended to use for a calculation of the heat flux.

2. A calculation of the heat flux q with a using of the heat conductivity of the incident plasma flow (at the external border of the boundary layer) leads to an overestimation of the heat flux in comparison with experimental data in 2-3 times. Therefore the heat flux is recommended to calculate with a using of the heat conductivity averaged through the boundary layer (4). But the other plasma properties such as a specific heat c_p, a density ρ_p, a viscosity μ_p should be calculated with a using of the temperature of the incident plasma flow.

3. We propose to use the correction coefficient depending on the particle velocity and the plasma one in the criterial formula of the particle heat transfer in plasma jet. That coefficient regulates the value of a conductive part of the heat transfer according on the ratio of the particle velocity to the plasma one.

ABSTRACT

Our goal is to qualify the chemical reaction mechanisms which take place during the interaction between a RF air plasma and silicon particles.

The energy and mass transfer in the usual model take into account heat transfer from plasma by conduction and convection on the surface of the particle, radiation effect, melting, heating of vapor cloud and vaporization. So that heat and mass balance give us the possibility of modeling these processes. However exothermic reactions are able to appear between oxygen atoms and silicon which give SiO gas and strong enthalpy effect.

These mechanisms of chemical reactions between the air plasma and the silicon particles depend mainly of the plasma temperature and of the gas flow velocity. We propose to discuss the main results of this model in order to take into account the chemical mechanisms which appear on the surface plasma–powder.

1. INTRODUCTION

One of the main difficulties of plasma treatment of particles is to take into account the chemical mechanisms which appear during the heat and mass transfer phenomena.

Nevertheless the main applications are for plasma spraying, and because the usual material are oxides such as Al_2O_3, S, O_2, MgO, ZrO_2 … usual works don't take into account the stoechiometric modifications of the oxides. As we know for mixtures of oxides for examples perovskites of lanthanium manganese LaMnOx few works point out that manganese oxide is vaporized during the plasma spraying of such kind of material.

So in that work our goal is to qualify the mechanisms of heat and mass transfer in an air plasma of silicon particles of diameters between 100 to 300 μm. The main aspect is to point out the role of oxygen-silicon interaction during the residence time of the particle in the plasma and to identify the heat transfer which appear during the exothermic reaction between silicon and oxygen.

2. GENERAL PRESENTATION OF THE PROBLEM

Silicon powder is mainly characterized by its melting temperature 1712 K and its boiling temperature 3505 K, while its density in the liquid phase 2570 kg/m^3 is higher than in the solid phase 2340 kg/m^3, at last we have to remember that at high temperature 2500 K its viscosity is the same than the viscosity of water, while its reaction with oxygen is a strong exothermic one. From all the data we are able to summarize the main phenomena which are able to be taken into account for the simulation of heat and mass transfer between silicon particle and air plasma.

The heating of one particle is supposed to follow 4 sequential steps (Fig. 1).

1 – Heating of the solid particle up to the melting temperature T_{melt}
2 – Melting of the particle at constant temperature T_{melt}
3 – Heating of the liquid droplet up to the boiling temperature T_{boil}
4 – Boiling of the particle at constant temperature T_{boil}

These phenomena are correlated with the size of the spherical particle, we can said that its main evolution appears during the evaporation process (Fig. 1b).

Neglecting the heat propagation phenomenon within the particle, the energy balance in the boundary layer surrounding the particle can be written :

$$m_s c_{ps} \frac{dT_s}{dt} = \sum_i P_i \,, \qquad (1)$$

where $\sum_i P_i$ is the sum of the different heat fluxes corresponding to the steps presented in Fig. 1, each of them being expressed by a power P_i.

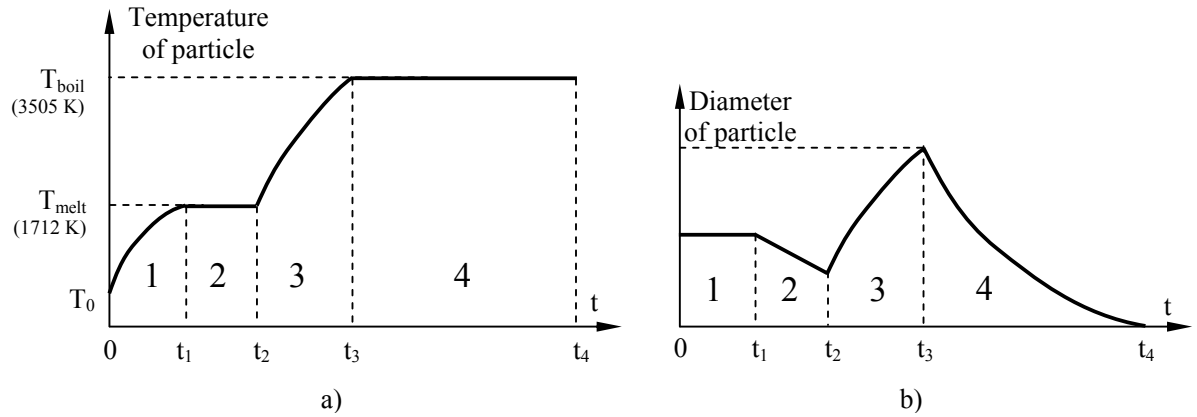

Figure 1. Steps of particle heating: a – change of particle temperature, b – change of particle diameter

These steps of particle heating by the plasma and the different mechanisms of heat and mass transfer were already described in details [1]. In the present paper, the different formulae allowing calculating those values are recalled in Tables 1 and 2.

Table 1. Equation for particle heating

Heating of the solid particle up to the melting temperature	$m_s c_{p_s} \frac{dT_s}{dt} = P_{pl} - P_{rad}$	(2)
Melting of the particle	$m_s c_{p_s} \frac{dT_s}{dt} = 0 = P_{pl} - P_{rad} - P_{melt}$	(3)
Heating of the liquid droplet up to boiling temperature	$m_s c_{p_s} \frac{dT_s}{dt} = P_{pl} - P_{rad} - P_{vap} - P_{cloud}$	(4)
Boiling of the droplet	$m_s c_{p_s} \frac{dT_s}{dt} = 0 = P_{pl} - P_{rad} - P_{boil} - P_{cloud}$	(5)

Table 2. Heat and mass transfer mechanisms

Conductive-convective heat transfer from plasma	$P_{pl} = \left(2 + 0.6 \cdot Re^{0.5} \cdot Pr^{0.33}\right) \cdot \frac{\lambda_p}{d_s} \cdot \left(T_p - T_s\right) \cdot S_{surface}$	(6)
Radiation of the particle	$P_{rad} = \varepsilon \cdot \sigma \cdot T_s^4 \cdot S_{surface}$	(7)
Melting of the particle	$P_{melt} = \Delta H_{melt} \cdot \dot{m}_{melt}$	(8)
Vaporization of the particle	$P_{vap} = \Delta H_{boil} \cdot \dot{m}_{vap}$	(9)
Boiling of the particle	$P_{boil} = \Delta H_{boil} \cdot \dot{m}_{boil}$	(10)
Heating of the vapor cloud	$P_{cloud} = \dot{m}_{\substack{vap \\ (boil)}} \cdot \bar{c}_{p_{vapor}} \cdot \left(T_p - T_{boil}\right)$	(11)
Mass losses by boiling	$\dot{m}_{boil} = \frac{P_{pl} - P_{rad}}{\Delta H_{boil} + \bar{c}_{p_{vapor}}\left(T_p\right) \cdot \left(T_p - T_{boil}\right)}$	(12)
Mass losses by vaporization	$\dot{m}_{vap} = h_m \cdot S_{surface} \cdot p_{pl} \cdot \ln\left(\frac{p_{pl}}{p_{pl} - p_v\left(T_s\right)}\right)$	(13)

3. CHEMICAL INTERACTION BETWEEN PLASMA GAS AND SILICON PARTICLES

If the silicon particle is heated in a reactive gas such as air we have to take into account the chemical reactions between silicon atoms and atoms or molecules of oxygen. These mechanisms can appear in the boundary layer between silicon vapor and oxygen atoms of the plasma, or on the surface of the silicon

melted particle and oxygen atoms. We consider that the thermal conduction in the particle is higher than the heat transfer by convection at the surface of the particle ; that mean that the temperature of the particle is constant during the melting phenomena. The boundary layer around the particle is not deformed by the plasma gas flow (no turbulence effect).

During heating of the liquid droplet up to its boiling temperature and the boiling of the droplet, the silicon is evaporated from the particle surface, resulting in a cloud of silicon vapor surrounding the particle. When the silicon vapor is oxidized in the air plasma with the formation of silicon oxide (SiO), energy is released through the reaction :

$$\text{Si (gas)} + \text{O (gas)} \leftrightarrow \text{SiO (gas)} - \Delta_r H_{SiO}(T), \tag{14}$$

where $\Delta_r H_{SiO}(T)$ is the enthalpy of the chemical reaction.

The heat flux P_{chem} due to the chemical reaction can be calculated using the following equation:

$$P_{chem} = \Delta_r H_{SiO}(T_{b.l.}) \cdot \dot{m}_{Si_{react}}. \tag{15}$$

This heat flux shall be subtracted from the right side of equation (1) when the third and fourth steps of particle hating are considered.

The model assumes that the speed of the chemical reaction is very high, much higher than the considered time intervals of heating (chemical kinetics is not taken into account). Also it is supposed that the whole energy released by the chemical reaction is absorbed by the particle.

The mass flow rate $\dot{m}_{Si_{react}}$ of silicon reacting with oxygen is defined by the following formula:

$$\dot{m}_{Si_{react}} = \frac{M_{Si}}{N_A} \cdot \frac{N_{Si_{react}}}{\Delta t}. \tag{16}$$

The quantity of silicon atoms that react with atomic oxygen during the time Δt can be defined using the law of action mass:

$$K_{SiO}(T_{b.l.}) = \frac{p^*_{SiO_{eq}}}{p^*_{Si_{eq}} \cdot p^*_{O_{eq}}}.$$

Here $p^*_{SiO_{eq}}$, $p^*_{Si_{eq}}$, $p^*_{O_{eq}}$ are the ratios of the partial pressures $p_{SiO_{eq}}$, $p_{Si_{eq}}$, $p_{O_{eq}}$ of species at thermodynamic equilibrium to the atmospheric pressure p_{atm}. These values can be expressed using the atom quantities $N_{SiO_{eq}}$, $N_{Si_{eq}}$, $N_{O_{eq}}$. For example :

$$p^*_{Si_{eq}} = \frac{p_{Si_{eq}}}{p_{atm}} = \frac{n_{Si_{eq}} \cdot k_B \cdot T_{b.l.}}{p_{atm}} = \frac{N_{Si_{eq}}}{V_{b.l.}} \cdot \frac{k_B \cdot T_{b.l.}}{p_{atm}}.$$

Taking into account the last expression, the law of action mass can be written in the following form :

$$\frac{K_{SiO}(T_{b.l.}) \cdot k_B \cdot T_{b.l.}}{V_{b.l.} \cdot p_{atm}} = \frac{N_{SiO_{eq}}}{N_{Si_{eq}} \cdot N_{O_{eq}}}. \tag{17}$$

It should be noted that $N_{Si_{eq}}$ is the quantity of silicon atoms at thermodynamic equilibrium. It means that during the time Δt, the quantity $N_{Si_{ini}}$ of silicon atoms was evaporated from the particle surface while a part $N_{Si_{react}}$ of those atoms have reacted with the atomic oxygen.

The initial quantity $N_{Si_{ini}}$ of silicon atoms, i.e. the quantity of atoms evaporated from the silicon droplet surface during the time Δt, is defined by:

$$N_{Si_{ini}} = m_{Si} \cdot N_A / M_{mol_{Si}}. \tag{18}$$

The partial pressure of oxygen atoms in the particle boundary layer is usually very low in comparison to that of evaporated silicon atoms, so that if we calculate the heat flux P_{chem} due to the chemical reaction, then the value obtained will be lower by several orders of magnitude than the heat transfer P_{pl} from

the plasma [2, 3]. However, the difference velocity between the plasma and the particle give blowing gas through the particle boundary layer (see Fig. 2).

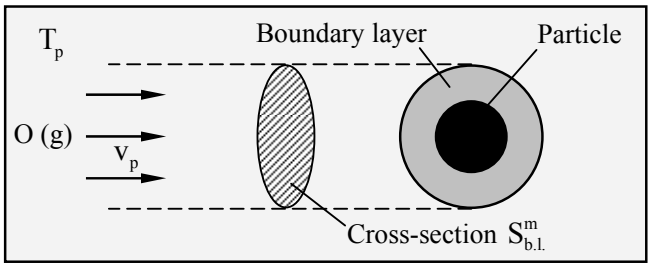

Figure 2. Evaluation of the number of oxygen atoms that takes part in the reaction

Therefore the quantity $N_{O_{ini}}$ of oxygen atoms in the particle boundary layer over Δt is defined using the following formula [3]:

$$N_{O_{ini}} = n_O \cdot \left|\vec{v}_p - \vec{v}_s\right| \cdot S^m_{b.l.} \cdot \Delta t \,. \tag{19}$$

To perform this calculation, it is the necessary to define the volume $V_{b.l.}$ and the middle cross section $S^m_{b.l.}$ of the boundary layer around the particle. For the sake of simplicity it has been assumed that the diameter of the boundary layer is twin the diameter of the particle: $d_{b.l.} = 2 \cdot d_s$.

4. DATA FOR CALCULATIONS

We first consider the reaction between silicon and molecular oxygen gases, to form SiO(g) (14). This can be taken into account for temperatures greater than melting temperature, for which we have some silicon gas either from evaporation or boiling.

We can either consider this reaction as a total reaction or as an equilibrium. Because oxygen is present in a very low concentration compared to the silicon one, the results will be similar. Nonetheless, if we want to be able to study the influence of oxygen concentration in that case where it is similar to the silicon one, it is better to consider an equilibrium.

We can calculate the thermodynamic parameters of this reaction bases on the enthalpy and entropy molar data available in [5] for the three compounds. These values are interpolated so that we can work at any temperature.

The dependence of the number density of atomic oxygen on temperature T in air plasma was drawn from reference [6]. Reference data of particle material are given in reference [1]. The thermo physical properties of air plasma were taken from reference [4].

5. RESULTS AND DISCUSSION

We start the simulation of heat transfer between air plasma (T = 5000 K) and a particle of silicon of 200 µm for a low difference of velocity between gas and plasma (Δv =1 m/s).

Fig. 3,a shows the different contributions of the heat transfer to the particle. It can be seen that the conductive-convective heat transfer P_{pl} from plasma to particle decreases with time, over the time interval 0 to about 25 ms the decrease is rather drastic, and then relatively smooth. That character can be explained by the fact that the particle temperature increases sharply over the time interval 0 to about 25 ms (see Fig. 3,b) resulting in a decrease in P_{pl} (see eq. (6)). After that, the particle temperature reaches the boiling point and ceases to change, while the lowering of P_{pl} takes place by the decreasing of the particle diameter (see Fig. 3,c).

Fig. 3, a shows that the main energy loss is the particle radiation P_{rad} (it is necessary to note that for particles of smaller diameter [1], the part of radiation in the energy balance decreases because of the reduction in the particle surface area – see eq. (7)), more over an important part of energy is lost because of vaporization and boiling. At last (Fig. 3,a) the heat flux P_{chem} due to the chemical reaction is small when the particle velocity relative to plasma is Δv =1 m/s.

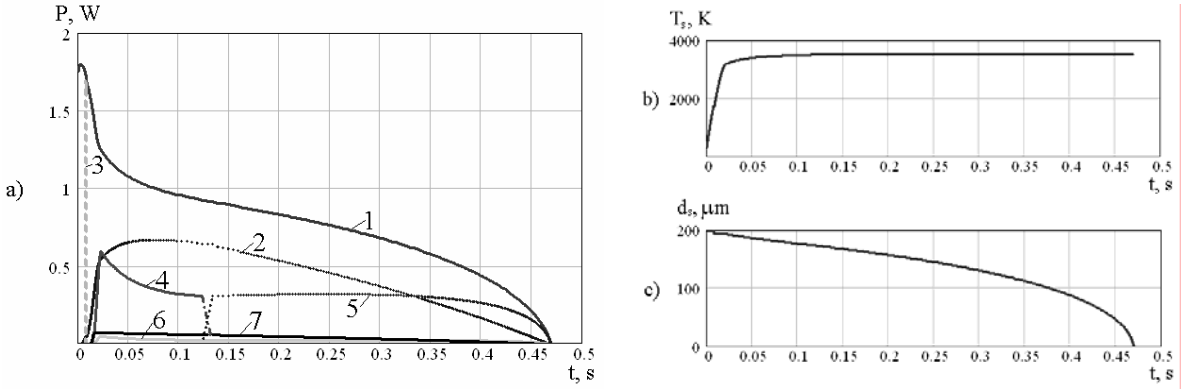

Figure 3. Evolution versus the heating time of the different energies received by the particle (a), the particle temperature (b) and its diameter (c) (particle velocity relative to plasma Δv=1m/s, particle diameter d_s =200 μm, and plasma temperature T_p = 5000 K). In Fig. 3a : 1 – P_{pl}, conductive-convective heat transfer from plasma 2 – P_{rad}, particle radiation 3 – P_{melt}, heat rate of melting 4 – P_{vap}, heat rate of vaporization 5 – P_{boil}, heat rate of boiling 6 – P_{cloud}, vapor cloud heating 7 – P_{chem}, heat flux due to the chemical reaction

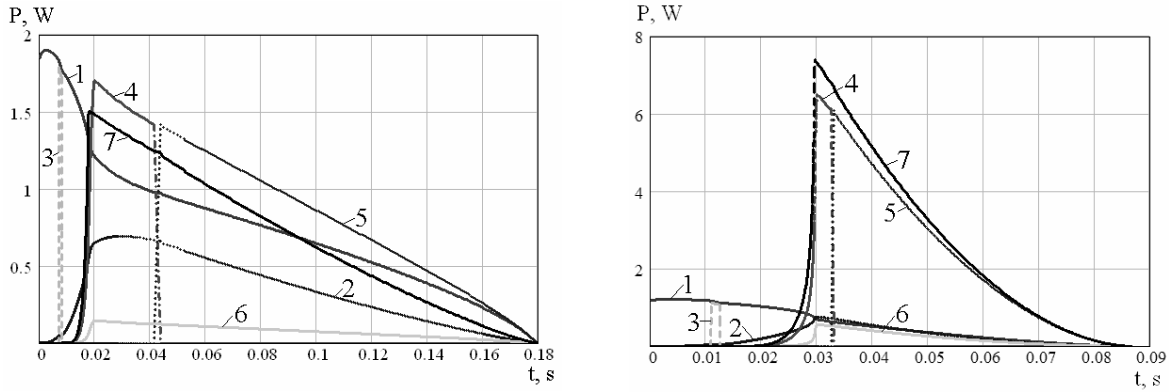
The calculation showed that the number density of silicon atoms in the boundary layer during the particle evaporation exceeds considerably the number density of oxygen atoms. Therefore the quantity of oxygen atoms that react with silicon atoms in the particle boundary layer is a limiting factor. That quantity increases with Δv.

Fig. 4 presents the energy balance for the particle in the cases when the particle relative velocity is equal respectively to Δv=20 m/s (a) and Δv=100 m/s (b), all other conditions being the same.



a) b)

Figure 4. Evolution with the heating time of the different energies of the particle for a particle velocity relative to plasma respectively of Δv=20 m/s (a) and Δv=100 m/s (b). The particle diameter is d_s =200 μm, the plasma temperature is T_p =5000 K. Different heat transfer : 1 – P_{pl}, conductive-convective heat transfer from plasma 2 – P_{rad}, particle radiation 3 – P_{melt}, heat rate of melting 4 – P_{vap}, heat rate of vaporization 5 – P_{boil}, heat rate of boiling 6 – P_{cloud}, vapor cloud heating 7 – P_{chem}, heat flux due to the chemical reaction

It can be seen that with high velocities the heat flux P_{chem} due to the chemical reaction plays an important role in the energy balance for the particle: P_{chem} is approximately equal to the heat transfer P_{pl} from the plasma when Δv=20 m/s, and P_{chem} is higher by several orders of magnitude than P_{pl} when Δv=100 m/s !

Thus, the heat flux due to the chemical reaction may be very important during the process of heating of a 200 μm silicon particle in a reactive plasma.

Therefore, we need to evaluate the effect of the different conditions on the power of the chemical reaction. For that purpose we propose to determine the integral value of energy received by the particle during the residence time at constant temperature : conductive-convective heat transfer from plasma and due to the chemical reaction :

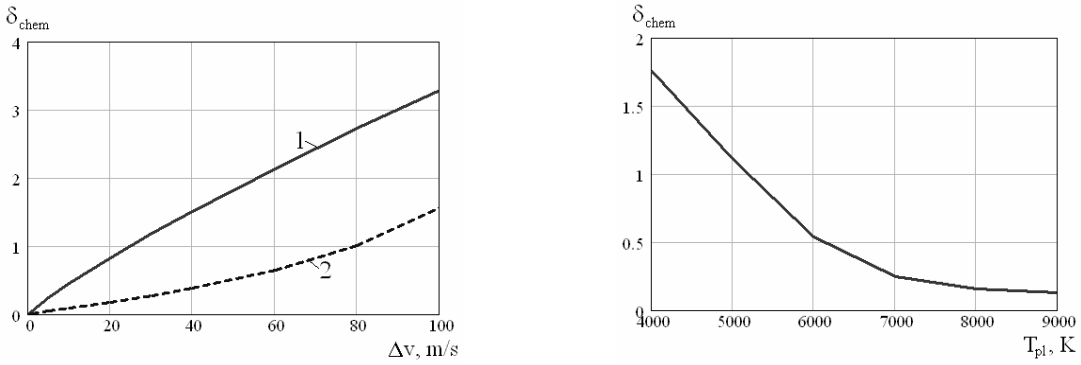
$$E_{pl} = \int_0^{t_{total}} P_{pl} dt, \qquad E_{chem} = \int_0^{t_{total}} P_{chem} dt .$$

A ratio of the chemical energy E_{chem} to the plasma energy E_{pl} can also be defined :

$$\delta_{chem} = \frac{E_{chem}}{E_{pl}} .$$

The parameter δ_{chem} is used for the definition of the conditions at which the chemical reaction plays an important role in the process of particle heating. Fig. 5,a shows the dependence of this parameter δ_{chem} on the relative particle velocity for two plasma temperature: T_p=5000 K and T_p=7000 K. It can be seen that δ_{chem} increases with Δv. At the plasma temperature T_p=5000 K, the parameter δ_{chem} is equal to 1 at $\Delta v \approx 25$ m/s. It means the energy received by the particle due to the chemical reaction is equal to that one received by the particle due to heat transfer from the plasma.

Fig. 5,a also shows that an increase of the plasma temperature T_p leads to a decrease of the parameter δ_{chem}, i.e. the effect of the chemical reaction onto the energy balance for the particle decreases. The dependence of the parameter δ_{chem} on the plasma temperature T_p is shown in Fig. 5,b in detail.



a) b)

Figure 5. Dependence of the parameter δ_{chem} on different parameters for the particle with diameter of 200 μm: a – dependence on the relative particle velocity Δv for different plasma temperatures : 1 – T_p= 5000 K ; 2 – T_p=7000 K; b – dependence on the plasma temperature T_p when the relative particle velocity is Δv=20 m/s

Fig. 6 shows the dependence of the parameter δ_{chem} on the particle diameter d_s. It can be seen that the parameter δ_{chem} increases when increasing d_s. It is due to the increase of the volume and correlatively of the midle cross section of the particle boundary layer. That fact in turn leads to an increase of the number of oxygen atoms that react with silicon atoms in the particle boundary layer.

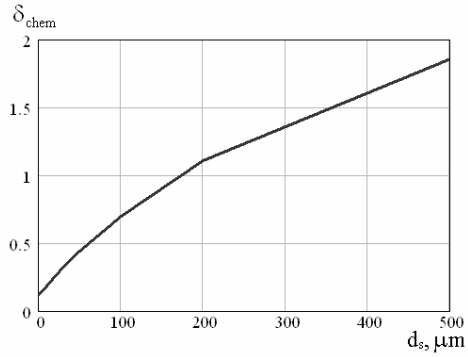


Figure 6. Dependence of the parameter δ_{chem} on the particle diameter d_s for the plasma temperature T_p = 5000 K and the relative particle velocity Δv=20 m/s

6. CONCLUSIONS

The heat and mass transfer between plasma gas (air) and spherical particles (d < 500 μm) of silicon were simulated with a model which take into account the evaporation of the silicon from the surface and its reaction with the oxygen atom.

The exothermic reaction of SiO oxide formation was taken into account in order to qualify the competitive phenomena which appear between thermal transfer and chemical heat transfer : under special condition the heat flux P_{chem} due to chemical reaction is several time higher than the conductive-convection heat transfer from the plasma gas.

To evaluate the effect of the chemical reaction onto the energy balance to the particle, the parameter δ_{chem} (characterizing the part of the power of the chemical reaction in the energy balance to the particle) was proposed. It increases under the following conditions : increase of the relative particle velocity Δv, decrease of the plasma temperature T_p, increase of the particle diameter d_s.

At last our experimental study[1] which was realized in an inductive RF plasma torch of 30 kW with a counter current injection of silicon powder of 200 μm gives a strong cloud of SiO/SiO_2 vapor with a strong deposition of SiO_2 amorphous powder on the wall of the reactor. The final diameter of the silicon particles was 159 μm (or 44 % of mass evaporation) for a residence time of 56 ms. In a second experimental study[2] we have a cocurrent axial injection of the Si particles (60 μm) in a RF plasma torch. On line Anemometric Doppler laser and optical measurement give a final diameter of 56 μm that mean an evaporation rate of 20 % for a 20 μs of residence time. Optical emission spectroscopy permits to control the evaporation zone from the injection point along the axial trajectory in the RF plasma torch.

SYMBOL LIST

$\bar{c}_{p\,vapor}$ – specific heat of vapor, averaged on the boundary layer (J/kg.K)

d_s – diameter of the particle (m)

$d_{b.l.}$ – diameter of the particle boundary layer (m)

h_m – mass transfer coefficient (W/m^2)

$K_{SiO}(T)$ – equilibrium constant of the reaction (-)

k_B – Boltzmann's constant (J/K)

M – molecular weight (kg/mol)

m_s – mass of the particle (kg)

$\dot{m}_{melt} = -\left(dm_{\substack{solid \\ core}} / dt \right)_{melt}$ – melting rate (kg/s)

$\dot{m}_{vap} = -\left(dm_s / dt \right)_{vap}$ – vaporization rate (kg/s)

[1] Experimental study was carried out together with S. Zverev in Electrotechnical and Electrothermal Laboratory for Plasma Applications, Saint Petersburg State Polythechnical University (Russia)

[2] Experimental study was carried out together with D. Morvan in Laboratoire de Genie des Procedes Plasmas et Traitements de Surfaces, Universite Pierre et Marie Curie Paris VI (France)

$\dot{m}_{boil} = -(dm_s/dt)_{boil}$ – boiling rate (kg/s)

N_A – Avogadro constant ($6.023.10^{23}$part/mol)

$N_{SiO_{react}}$, $N_{Si_{react}}$, $N_{O_{react}}$ – number of atoms (molecules) of species which react during a time interval Δt (-)

$N_{SiO_{eq}}$, $N_{Si_{eq}}$, $N_{O_{eq}}$ – number of atoms (molecules) of species at thermodynamic equilibrium (-)

$N_{Si_{ini}}$, $N_{O_{ini}}$ – initial number of species (-)

n_O – number density of oxygen atoms (m^{-3})

P_{pl} – conductive-convective heat transfer from plasma to particle (W)

P_{rad} – radiation from the particle (W)

P_{melt} – heat rate of particle melting (W)

P_{vap} – heat rate of particle vaporization (W)

P_{cloud} – heating of the vapor cloud (W)

P_{boil} – heat rate of particle boiling (W)

P_{chem} – heat flux due to chemical reactions (W)

p_{atm} – atmospheric pressure (p_{atm} =101325Pa)

p_{pl} – total pressure of plasma (Pa)

$p_{SiO_{eq}}$, $p_{Si_{eq}}$, $p_{O_{eq}}$ – the partial pressures of species at thermodynamic equilibrium (Pa)

$p^*_{SiO_{eq}}$, $p^*_{Si_{eq}}$, $p^*_{O_{eq}}$ – ratios of the partial pressures of species at thermodynamic equilibrium to the atmospheric pressure (-)

$p_v(T_s)$ – partial pressure of saturated vapor for the particle temperature (Pa)

$Pr = \mu_p \cdot c_{Pp}/\lambda_p$ – Prandtl number (-)

R – universal gas constant (8.32 J/mol.K)

$Re = \rho_p \cdot |\vec{v}_s - \vec{v}_p| \cdot d_s/\mu_p$ – Reynolds number (-)

$S_{surface} = \pi d_s^2$ – surface area of the particle (m^2)

$S^m_{b.l.} = \pi d^2_{b.l.}/4$ – middle area of the particle boundary layer (m^2)

T_{melt} – melting temperature (K)

T_{boil} – boiling temperature (K)

T_p – temperature of plasma (K)

T_s – temperature of the particle (K)

$T_{b.l.} = (T_s + T_p)/2$ – average temperature of the boundary layer (K)

t – time (s)

t_{total} – total time from the start of heating to full particle evaporation (s)

$V_{b.l.}$ – volume of the particle boundary layer (m^3)

$\vec{v}_p$ – velocity of plasma (m/s)

$\vec{v}_s$ – velocity of the particle (m/s)

ΔH_{melt} – heat of fusion of the particle material (J/kg)

ΔH_{boil} – heat of evaporation of the particle material (J/kg)

$\Delta_r H_{SiO}(T)$ – enthalpy of reaction of SiO formation (J/kg)

Δv – particle velocity relative to plasma (m/s)

δ_{chem} – parameter that characterizes the fraction of the power of the chemical reaction in the energy balance of the particle (-)

ε – emissitivity factor of the particle material (-)

K_p – thermal conductivity of plasma (W/m.K)

σ_s– Stephan-Boltzmann constant

($\sigma_s = 5.67.10^{-8}$ W/m^2.K^4)

Abstract

Optical lithography has been the key technology for manufacturing microprocessors or integrated circuits (ICs). To meet future manufacturing demands for smaller feature sizes, today's conventional optolithography will have to be replaced by a new system that operates in the extreme ultraviolet (EUV). In such a system, an efficient and reliable radiation source of adequate in-band power (〜115 W) is one of the major issues. This paper presents a numerical model that is qualitatively helpful in designing a pulsed current discharge-based radiation source.

1. Introduction

Over the last few decades, optical lithography has been the key technology for manufacturing microchips in semiconductor industries. The advances in this technology have been crucial in helping the semiconductor industries develop and market fast integrated circuits (ICs). The speed and performance of integrated circuits or the final product, for instance computer systems, are dictated by the lithographic minimum feature printing capability. With the miniaturization of feature size, lithographic systems have been required to work with light of shorter wavelength.

Today's state-of-the-art optolithographic tools use deep ultraviolet (DUV) light with a wavelength of 193 nm to allow the printing of a 90 nm minimum feature size. There are indications that light of 193 nm may be able to print features as small as 45 nm, however this limit will ultimately spell the end for the conventional approach to optolithography. According to the SIA (Semiconductor Industry Association) roadmap of 2000, the feature size will decrease to 30 nm at the middle of the next decade at which time a new lithographic system will become a must. Foreseeing the physical limits of current lithographic systems, the global semiconductor industries have made enormous efforts to develop a new system, which has been dubbed as the next generation lithography (NGL) system. Among several candidates for NGL, extreme ultraviolet lithography (EUVL) is the most prominent one. In EUVL, extreme ultraviolet (EUV) light with a wavelength band of 2%, centering at 13.5 nm, will be used.

In commercial EUVL systems, the generation of EUV light with adequate power at the intermediate focus point (~115 W) is one of many key issues. Plasma of very high temperature is necessary in order to obtain the desired EUV light. There are two possible approaches for generating the high-temperature plasma: either by laser or by

an electrical discharge. Currently, discharge produced plasma (DPP) for EUVL is in the lead in terms of radiation output power. Generation of DPP has been tried using several engineering techniques by different industrial and/or research and development organizations. Reported discharges include the conventional capillary discharge, hollow-cathode triggered capillary discharge, dense plasma focus and Z-pinch [1].

Mathematical simulations and computer-aided engineering (CAE) have been gaining significant importance in industries because they are a vital tool in expediting the development of new products and/or improving the performance of existing products. Modeling and CAE have also been shown to reduce the development cost and the time to launch new products. Likewise, the benefits of CAE in designing reliable and efficient EUV discharge source have been progressing [2].

We are working to simulate the discharge dynamics for the purpose of extracting phenomenological concepts that will allow the efficient and rapid development of new designs. In this paper, we discuss the details of a newly developed model that can predict the plasma dynamics of an EUV discharge generated using the combined scheme of capillary and Z-pinch discharges. Calculations are done for a discharge medium of xenon gas with mass flow-rates of 40 and 100 sccm. The discharge is heated using a 23.7 kA peak current with a pulse duration of 275 ns. The flow is considered as compressible and the P-1 radiation method is used to predict the radiative energy.

2. Model description

A time-dependent axisymmetric model consisting of the complete set of magnetohydrodynamic equations (MHD) assuming compressibility has been solved. Expressions for the MHD equation set are given below.

Mass continuity:

$$\frac{\partial \rho}{\partial t}+\frac{\partial}{\partial z}(\rho u)+\frac{1}{r}\frac{\partial}{\partial r}(r\rho v)=0\,. \tag{1}$$

Momentum conservation:

$$\frac{\partial}{\partial t}(\rho u)+\frac{1}{r}\frac{\partial}{\partial z}(r\rho uu)+\frac{1}{r}\frac{\partial}{\partial r}(r\rho uv)=-\frac{\partial p}{\partial z}+\frac{1}{r}\frac{\partial}{\partial r}\left[r\mu\left(\frac{\partial u}{\partial r}+\frac{\partial v}{\partial z}\right)\right]+\frac{1}{r}\frac{\partial}{\partial r}\left[r\mu\left\{2\frac{\partial u}{\partial z}-\frac{2}{3}(\nabla\cdot\mathbf{u})\right\}\right]+\mathbf{J}\times\mathbf{B}\big|_z \tag{2-a}$$

$$\begin{aligned}\frac{\partial}{\partial t}(\rho v)+\frac{1}{r}\frac{\partial}{\partial z}(r\rho uv)+\frac{1}{r}\frac{\partial}{\partial r}(r\rho vv)=&-\frac{\partial p}{\partial r}+\frac{1}{r}\frac{\partial}{\partial z}\left[r\mu\left(\frac{\partial v}{\partial z}+\frac{\partial u}{\partial r}\right)\right]+\frac{1}{r}\frac{\partial}{\partial r}\left[r\mu\left\{2\frac{\partial v}{\partial r}-\frac{2}{3}(\nabla\cdot\mathbf{u})\right\}\right]-\frac{2\mu v}{r^2}\\&+\frac{2}{3}\frac{\mu}{r}(\nabla\cdot\mathbf{u})+\mathbf{J}\times\mathbf{B}\big|_r\end{aligned} \tag{2-b}$$

where, $\nabla\cdot\mathbf{u}=\frac{\partial u}{\partial z}+\frac{1}{r}\frac{\partial}{\partial r}(rv)$.

Energy conservation:

$$\frac{\partial}{\partial t}\left[\rho\left(H-\frac{p}{\rho}+\frac{1}{2}|\mathbf{u}|^2\right)\right]+\frac{\partial}{\partial z}\left[u\rho\left(H+\frac{1}{2}|\mathbf{u}|^2\right)\right]+\frac{1}{r}\frac{\partial}{\partial r}\left[r\rho v\left(H+\frac{1}{2}|\mathbf{u}|^2\right)\right]=\frac{\partial}{\partial z}\left(\frac{\kappa}{C_p}\frac{\partial H}{\partial z}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left[\frac{\kappa}{C_p}\frac{\partial}{\partial}(rH)\right]+\phi$$
$$+\frac{5}{2}\frac{k}{e}\left(\frac{J_z}{C_p}\frac{\partial H}{\partial z}+\frac{J_r}{C_p}\frac{\partial H}{\partial r}\right)+\sigma E^2-R \qquad (3)$$

where, energy due to viscous dissipation is $\phi=\vec{\tau}\cdot\nabla\mathbf{u}=2\mu\left[\left(\frac{\partial u}{\partial z}\right)^2+\left\{\frac{1}{r}\frac{\partial}{\partial r}(rv)\right\}^2+\frac{1}{2}\left(\frac{\partial u}{\partial r}+\frac{\partial v}{\partial z}\right)^2\right]-\frac{2}{3}\mu\left[\frac{\partial u}{\partial z}+\frac{1}{r}\frac{\partial}{\partial r}(rv)\right]$.

Laplace equation:

$$\frac{\partial V}{\partial t}+\frac{\partial}{\partial z}(\sigma\frac{\partial V}{\partial z})+\frac{1}{r}\frac{\partial}{\partial r}(r\sigma\frac{\partial V}{\partial r})=0. \qquad (4)$$

Curl of Ampere's law:

$$\frac{\partial B_\theta}{\partial t}+\frac{\partial}{\partial z}(\frac{\partial B_\theta}{\partial z})+\frac{1}{r}\frac{\partial}{\partial r}(r\frac{\partial B_\theta}{\partial r})=\frac{B_\theta}{r^2}+\mu_0\frac{Jz}{\sigma}\frac{\partial\sigma}{\partial r}-\mu_0\frac{Jr}{\sigma}\frac{\partial\sigma}{\partial z}. \qquad (5)$$

Here, ρ is mass density; u and v are the axial (z-direction) and radial (r-direction) velocities; μ is the dynamic viscosity; σ and κ are electrical and thermal conductivities; C_p and H are specific heat at constant pressure and enthalpy; **u** is the velocity vector with u and v components; **J** is the current density vector with J_r and J_z components; **B** is the B_θ component of the magnetic field vector; p is the static pressure; V and E are electrostatic potential and electric field respectively; k is the Boltzmann constant; e is the electronic charge; R is the volumetric radiative loss; $\vec{\tau}$: is the stress tensor; and μ_0 is the free-space permeability.

The energy balance equation accounts for the pressure work and kinetic energy since these two effects can be significant in a compressible flow, especially when magnetic pumping is large. The model, however, does not include the gravitational effect. This effect would not play a role for a system with very high electromagnetic forces. For calculating the radiative energy, the P-1 radiation method [3] is employed. The radiation spectrum is divided into the following 5 bands between 2 and 20,000 nm: 2-13.365 nm, 13.365-13.635 nm, 13.635-100 nm, 100-400 nm, and 400-20000 nm. The radiation energy of band 2 (13.365-13.635 nm) is the in-band (2% centering 13.5 nm) EUV radiation energy that is useful for EUVL. The P-1 radiation method involves the solution of a Helmholtz-type equation of the following form for band i:

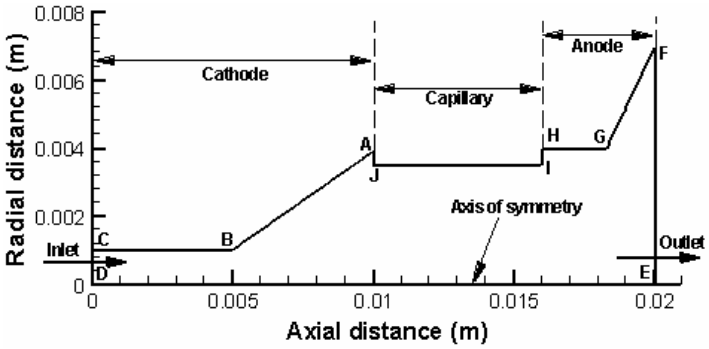

Figure 1 Schematic of the modeled discharge domain.

$$\frac{\partial G_i}{\partial t}+\frac{\partial}{\partial z}(\frac{1}{3\alpha_i}\frac{\partial G_i}{\partial z})+\frac{1}{r}\frac{\partial}{\partial r}(r\frac{1}{3\alpha_i}\frac{\partial G_i}{\partial r})=-\alpha_i(4\pi B_i-G_i) \qquad (7)$$

and the radiative energy R is calculated using the expression $R=\sum_i \alpha_i(4\pi B_i-G_i)$.

Here, G_i, B_i and α_i are the mean incident radiation, weighted Planck function and mean absorption coefficient of band *i* respectively.

3. Assumptions, boundary conditions, material and optical properties

The assumptions adopted for the model include: axisymmetric geometry with compressible flow and local thermodynamic equilibrium (LTE). The LTE assumption is likely critical for this discharge where temperature, density and pressure gradients are very high. However, information necessary for the very complicated non-LTE modeling of high-stage ionization species (viz. for Z between 4 and 10) is not available yet. The well-known numerical approach [2] is also based on the LTE assumption.

Figure 1 shows the schematic of the geometry used for the simulation. An arbitrary profile for the current density, at the cathode surface, with a known total current total has been chosen. The pulse current waveform and the assumed current density profile for peak current (23.7 kA at t = 137.5 ns) are shown in Figure 2. At the anode surface (HGF), a constant and reference potential of zero is specified. At the inlet and exit, current densities are set to zero. In an axisymmetric geometry, the azimuthal component of the magnetic field intensity is of interest and contributes to the Lorentz forces. Eqn. (5) is derived from Ampere's Law assuming an azimuthal magnetic field. In solving this equation, the following boundary conditions are used.

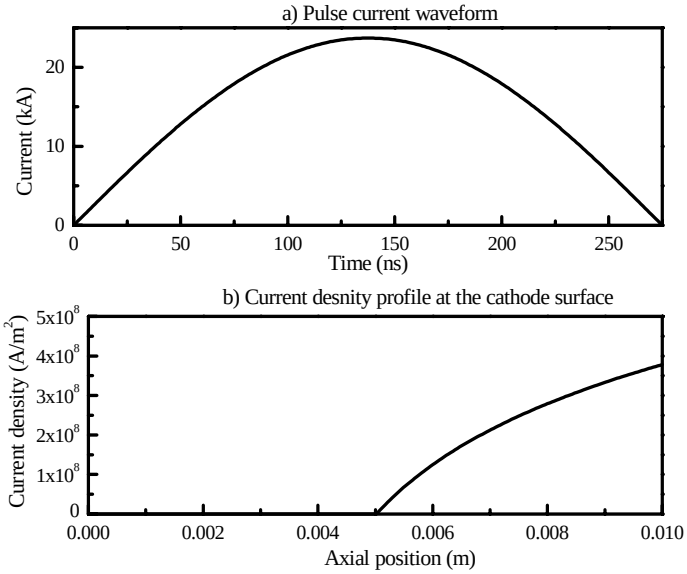

Figure 2 a) Waveform of the pulse current and b) the applied current density profile at the cathode surface

$$B_\theta\big|_w = \begin{cases} \sum_0^r \dfrac{\mu_0 I(r)}{2\pi r} & \text{on ABC} \\ \dfrac{\mu_0 I}{2\pi r} & \text{on AJIH and HGF} \end{cases} . \qquad (8)$$

Here subscript *w* is used to interpret the wall. At the inlet and outlet, B_θ is set to zero.

The following boundary conditions are used for the energy equation: 500 K at the inlet (CD), 1000 K at the outlet (EF), 3500 K at the cathode surface (ABC), 3000 K at the anode surface (HGF) and 1800 K at the capillary surface (AJIH). All of these conditions are chosen arbitrarily and are not likely to affect the plasma fields except energy conservation at the boundaries. For the P-1 radiation method, Marshak's boundary condition

in the following form is used to specify the boundary flux for the mean incident radiation of band *i*:

$$\Gamma_i \frac{\partial Gi}{\partial \vec{n}} = \frac{\varepsilon_{wi}}{2(2-\varepsilon_{wi})}(4\pi B_{wi} - G_{wi}). \tag{9}$$

Here, Γ_i and ε_{wi} are the diffusion coefficient and mean hemispherical emissivity of the boundary wall respectively for spectral band *i*. $\vec{n}$ is the outward normal vector to the boundary.

Other boundary conditions are: 1 Pa pressure at outlet, 40 or 100 sccm mass flow-rate at the inlet, no-slip at the walls (electrodes and capillary surface), and a zero axial gradient for all variables on the axis of symmetry (DE).

The calculation procedure for determining the material properties (σ, κ, μ, π and C_p) and optical properties (α_i) are the same as described in Ref. 4. Xenon species up to the 11th-stage ionization of xenon are considered; the spectroscopic data required for calculating the material and optical properties are taken from Ref. 5.

Calculations are performed by using a vendor-supplied software package, called Fluent, where most physical models are introduced through customized modules. The domain of Fig. 1 is divided into 23,000 quadrilateral meshes in order to calculate the dynamics of the discharge.

4. Results

Figure 3 shows the isotherms at two instants in time during the current pulse. Isocontours in the lower-half and upper half are for the time of 160 ns and 200 ns respectively. Although the peak current is at 137.5 ns, the plasma continues to be heated after that instant. In fact, the plasma temperature is found to be at its highest level just a few tens of nanoseconds prior to the current reaching zero. For instance, the maximum temperature of the discharge for a 100 sccm flow-rate is found to be 18 eV at 209 ns after the pulse has been initiated. Indeed, the spatial position of the highest-temperature changes with time. The plasma is mainly heated by extremely large magnetic compression. The distribution of magnetic field intensity and in-band mean incident radiation are presented in Figure 4. Although the P-1 radiation model can not give the directional radiation distribution, it helps in realizing the qualitative nature of radiation from a radiation source. Figure 5 illustrates the flow-rate effect on the plasma temperature. As was seen experimentally, the model also predicts an axial advancement of the hot-plasma or radiation core. The high flow-rate pushes the gas in the axial direction and the axial Lorentz force pushes the

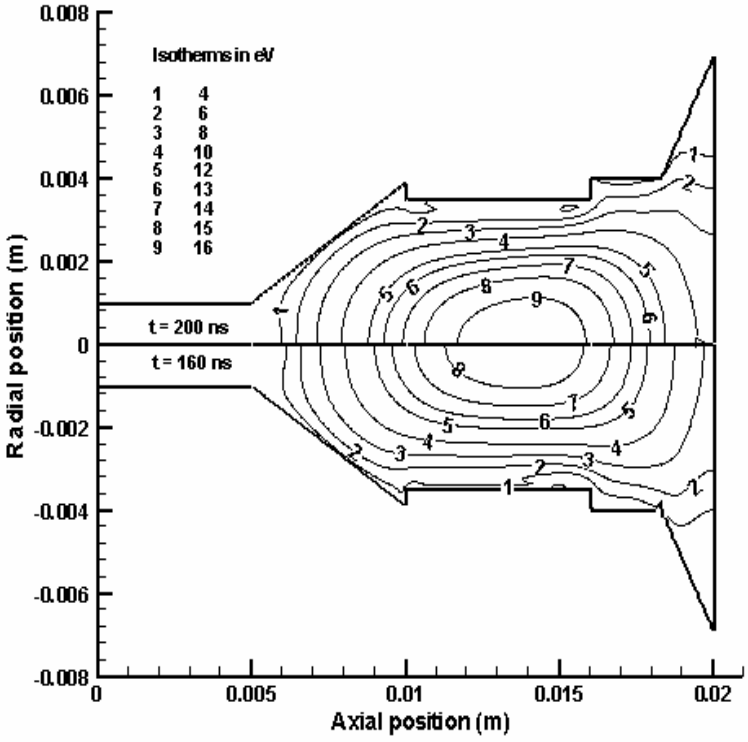

Figure 3 Temperature isocontours: upper-half is for t = 200 ns and lower-half for t = 160 ns

hot gas further in an axial direction.

5. Conclusions

In this paper, we have presented a time-dependent numerical model that solves the complete set of magnetohydrodynamics (MHD) assuming axisymmetry and compressibility. The model has been applied to calculate the dynamics of a capillary and Z-pinch discharge source. This source is expected to produce EUV radiation energy from a 2% spectral band, centering at 13.5 nm, for an EUVL application. The model predicts most physical phenomena and is helpful as a first principle design-approach.

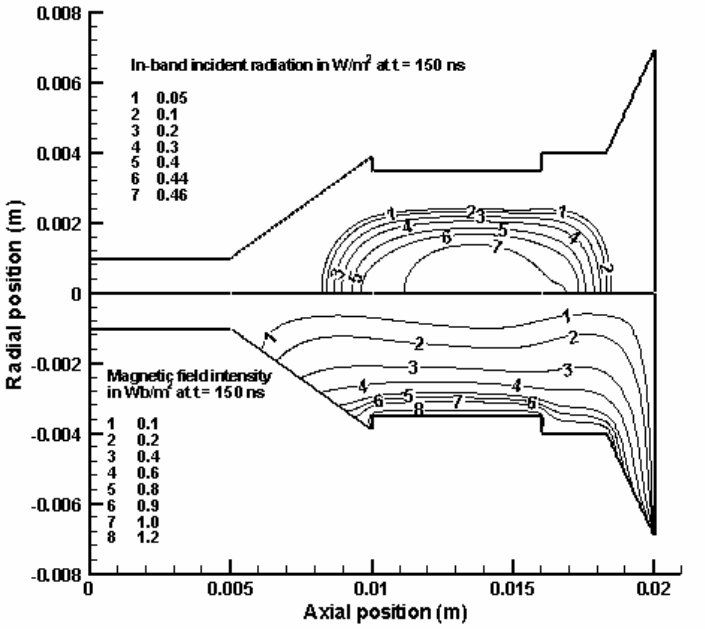

Figure 4 Isocontours of in-band radiation energy (upper-half) and magnetic field intensity (lower-half) at t = 150 ns

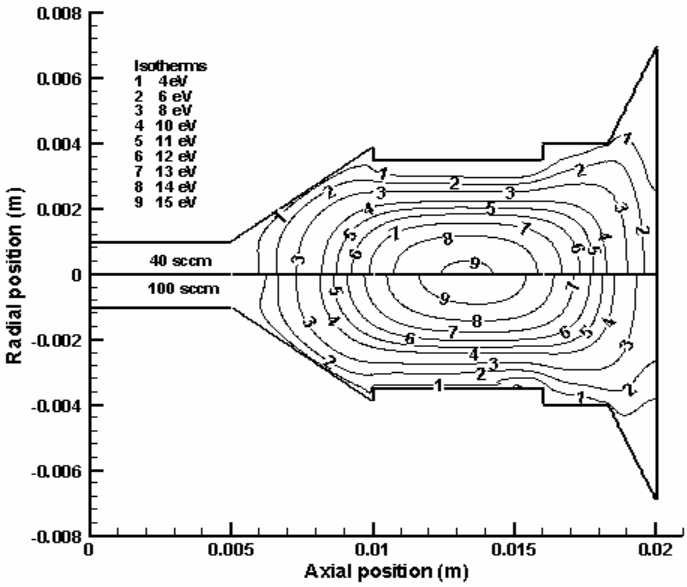

Figure 5 Isotherms for a flow-rate of 40 sccm (upper-half) and 100 sccm (lower-half) at t = 150 ns

Abstract

Polytetrafluoroethylene (PTFE) and poly(vinylidene fluoride) (PVDF) surfaces were treated by oxygen species generated either in a remote (filtered) RF plasma or in an ion gun. In the first case the majority of the species reaching the surface are neutral molecules, whereas in the second case, ions are the reactive agent. In this paper, we show that PTFE and PVDF exhibit a completely different behaviour versus oxygen species.

Keywords PTFE, PVDF, oxygen plasma, XPS, contact angle

Introduction

The modification of polymer surfaces is of enormous importance in today's chemical industry. Compared to traditional wet chemistry, plasma treatments are surface sensitive and environmental friendly. However due to the variety of species created in the plasma (ions, neutrals, electrons, UV), the understanding of the chemical mechanisms involved in the plasma treatment of polymer is not trivial.

This paper presents the result of a NSF-funded collaboration [1]. PTFE and PVDF samples were modified by the various constituents of a oxygen plasma: oxygen ions and a filtered plasma. The polymer was exposed to an ion gun or a modified RF plasma. In previous studies we've already shown the differences between the ionic and the plasma treatment of PE and PTFE with nitrogen [2,3]. The plasma was characterized by optical emission spectroscopy (OES). The samples were characterized by X—Ray photoelectron spectroscopy (XPS) and water contact angle (WCA).

Experimental

Sample preparation:
PTFE and PVDF samples were from Goodfellow. After having been cut to size, they were cleaned with methanol and then with pure isooctane. Once cleaned, they were introduced into the plasma chamber or into a UHV chamber equipped with an ion gun and a XPS analyser.

Plasma treatment:
The plasma chamber consisted of a stainless steel based vessel surmounted by a pyrex bell jar. Isolation was realised by a viton O-ring. The pumping system consisted in an Edwards primary pump (up to 1.33 Pa) and a turbomolecular pump (Balzers 230 l/s) coupled to a membrane pump. Pure oxygen from Alphagaz was used (Alphagaz 2). Before introduction of oxygen, the chamber was pumped down to a pressure of $2.67\ 10^{-4}$ Pa, and then backfilled to the working pressure. In order to avoid contamination, the chamber was continuously pumped during the experiments (dynamic regime). The RF plasma was initiated using a Huttinger PFG300RF generator,

coupled to a PFM 1500 A matchbox. The samples were positioned outside the plasma region, above the anode grid, which could be either grounded or biased. A schematic of the experimental setup has already been published [2]. As in a RF plasma the cations remain mostly close to the cathode and, as we put the sample out of the plasma (remote mode), and above the anode, we expect that the majority of the plasma – polymer interactions will be due to neutrals and electrons. This was already show in our previous studies dedicated to the N_2 plasma – PE, PTFE surface interaction [2,3].
The plasma chamber is also equipped with a multiple (up to 8) fiber optic probe in order to detect simultaneously the excited species generated into the plasma at different locations : close to the cathode, middle of the plasma, close to the anode and close to the sample. The plasma was characterized using a Acton SpectralPro 2500i (Acton Research) optical emission spectrometer (OES) capable of a resolution of 0.06 nm and operating in the 200 nm – 900 nm region. The detector consisted in a Princeton Instrument Digital Camera type EEV, 400x1340 pixels.
After treatment the chamber is backfilled to atmospheric pressure using liquid nitrogen, and the sample is transferred either to the XPS chamber or to the contact angle room.
XPS analysis was carried out in a UHV chamber (originally PHI AES 590 system) equipped with a VG clam II analyser. Spectra were acquired using the Mg anode (1253.6 eV), operating at 300 W. Wide surveys were acquired at 100 eV pass energy. Spectra of the C1s, O1s and F1s regions were acquired with a pass energy of 30 eV. The average surface concentrations were determined with the usual formula, with the following sensitivity coefficients: C = 0.296; F = 1; O = 0.711
Water contact angle (WCA) measurements were performed in the static mode, in a climatized room, with controlled humidity. Milli-Q water was used. 10 drops were deposited statistically on the modified surfaces, and the angle was measured on both sides of the drop. The results presented here are therefore an average of 20 measurements.

Ion treatment
PTFE or PVDF samples were introduced into a PHI 5400 UHV chamber equipped with a Physical Electronics (PHI) 04-303 ion gun, aligned at 45° with respect to the sample normal, a PHI 04-500 Dual anode X-ray Source (Mg Kα anode (1253.6 eV)) and a PHI 10-360 Semi-Hemispherical Analyzer. The typical base pressure of the system during analysis was 6.67 10^{-6} Pa. During O_2^+/O^+ ion beam treatment of the PTFE and PVDF surfaces, a typical chamber base pressure of 1.33^{-5} Pa was maintained, while a pressure of 1.5 10^{-2} Pa of oxygen was established in the ion gun. The emission current was set to 10 mA, while the accelerating voltage could be varied from 0.5 to 4 keV. As the only effect of the ion energy observed was on the duration of the experiment (faster at 4 keV), only the 4 keV results will be presented here. After exposure to the O_2^+/O^+ ion beam, PTFE and PVDF samples were analyzed in situ using XPS. All XPS spectra were acquired using 15 kV voltage and 300W power. Elemental scans employed a pass energy of 44.75 eV and 0.125 eV/step and the binding energy scale calibrated on the F1s peak of native PTFE (689.7 eV) and PVDF (688.2) [5].

Results

Ionic treatment:
The samples were exposed to oxygen ions for different times and then analyzed in-situ by XPS. The XPS results for PTFE shows that there is almost no oxygen (0.8%) grafted on the PTFE sample after 3 hours of treatment (Fig1a). There is a strong decrease of the fluorine content at the surface. This is probably due to a sputtering of the surface by the ions. Fig1b indicates that untreated PVDF contains already 3.5 at% of oxygen. This residual contamination could not be removed by the usual washing procedures. However this contamination decreases very rapidly (to 1.5 at%) during the first minute of the treatment probably because of the sputtering effect. The at% of oxygen increase then again to reach a final value of 3 at%.

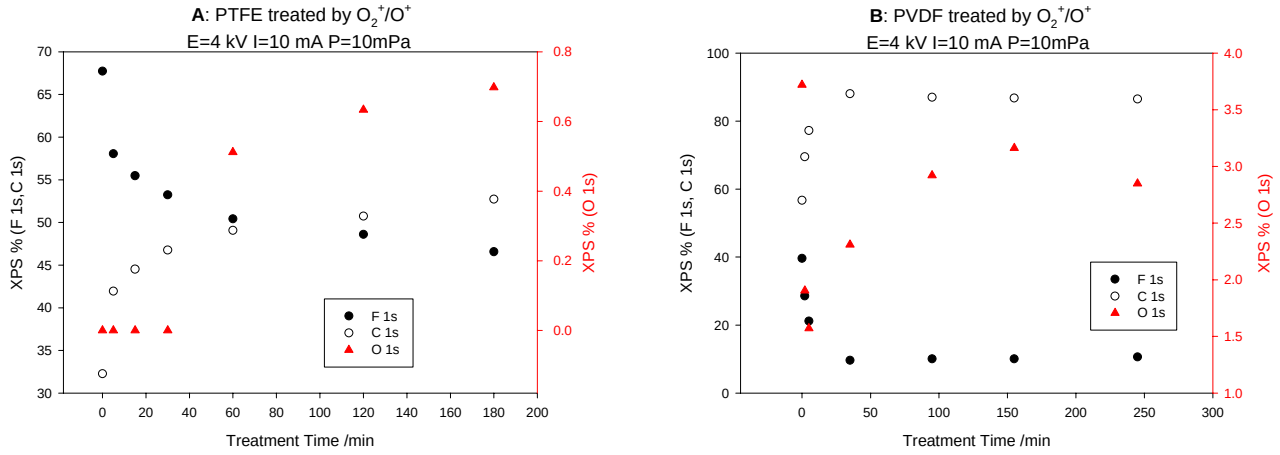

Fig1: XPS composition of PTFE (left) and PVDF (right) samples treated by oxygen ions.

Plasma treatment:

For PTFE, the ex-situ XPS results show that the oxygen content increases rapidly during the first 5 minutes and reaches a steady state value after 10 minutes at around 4.5% of oxygen on the surface (Fig2a). The same trend was observed for PVDF (Fig 2b) but with major differences in the time scale and in the amount grafted. Indeed, for PVDF, the oxygen content increases very rapidly during the first 2 minutes of treatment and the steady state value is around 25 at%.

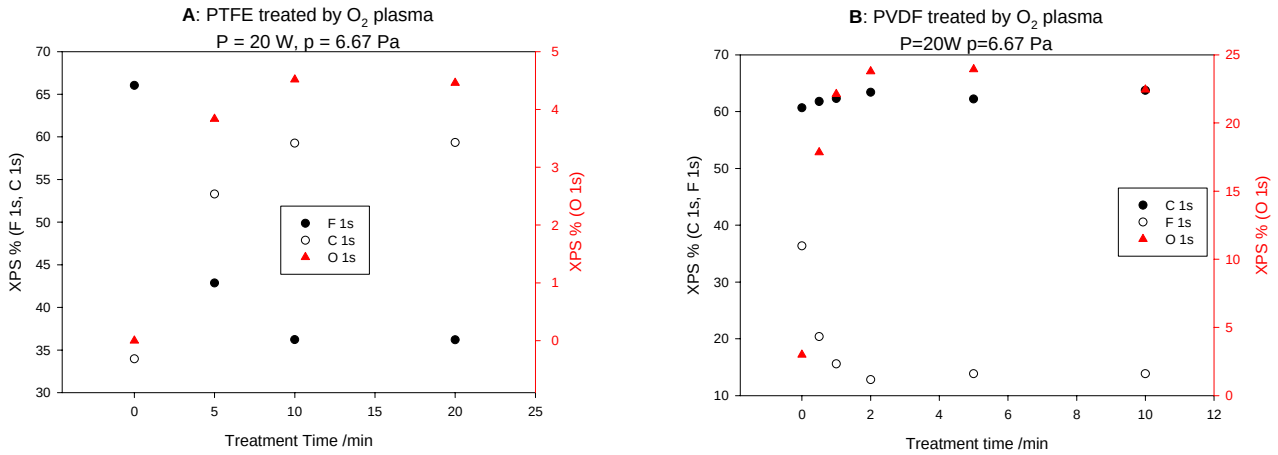

Fig2: XPS composition of PTFE (left) and PVDF (right) samples treated by oxygen plasma. Plasma power=20 W, O_2 pressure=6.67 Pa.

Water contact angle (WCA) measurements show that PTFE and PVDF exhibit a very different behavior upon the plasma treatment. PTFE becomes more hydrophobic (Fig3) but PVDF become very hydrophilic.

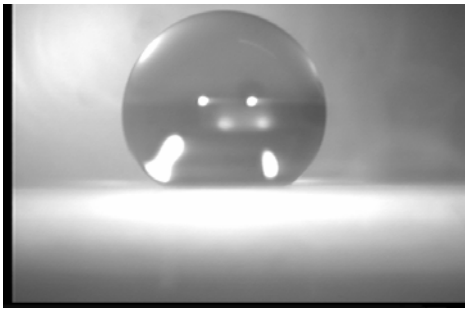

Fig3: Drop of milliQ water on a PTFE sample modified by an oxygen plasma.

For the PTFE no relation could be established between the surface composition and the surface free energy. As there is almost no oxygen grafted onto the sample and that the C1s peak shape doesn't change (Fig4). We suggest that the increase of WCA (i.e. decrease in surface energy) arise from an increase in the surface roughness due to a chemical etching (oxidation) of the polymer. The increase in roughness is therefore the only explanation left for the decrease in surface free energy. Figure 4 shows the evolution of the spectral envelope of the C1s peak for PTFE (A,C) and PVDF (B,D) during plasma treatment (A,B) and ion treatment (C,D). Whereas the ion treatment seems to suggest that there is mostly a defluorination of the surface leading as a final result to C-H type carbon (at 285 eV), the plasma treatment on PTFE shows no change of the C1s peak (indicating chemical etching) and shows that for PVDF, a lot of polar oxygenated functions are grafted (high energy components in the C1s peak). It seems that the presence of C-H bond in the PVDF allow to graft much more oxygen functionalities onto the samples surfaces. The formation of HF could be the driving force of the grafting reaction of oxygen functionalities onto PVDF surfaces.

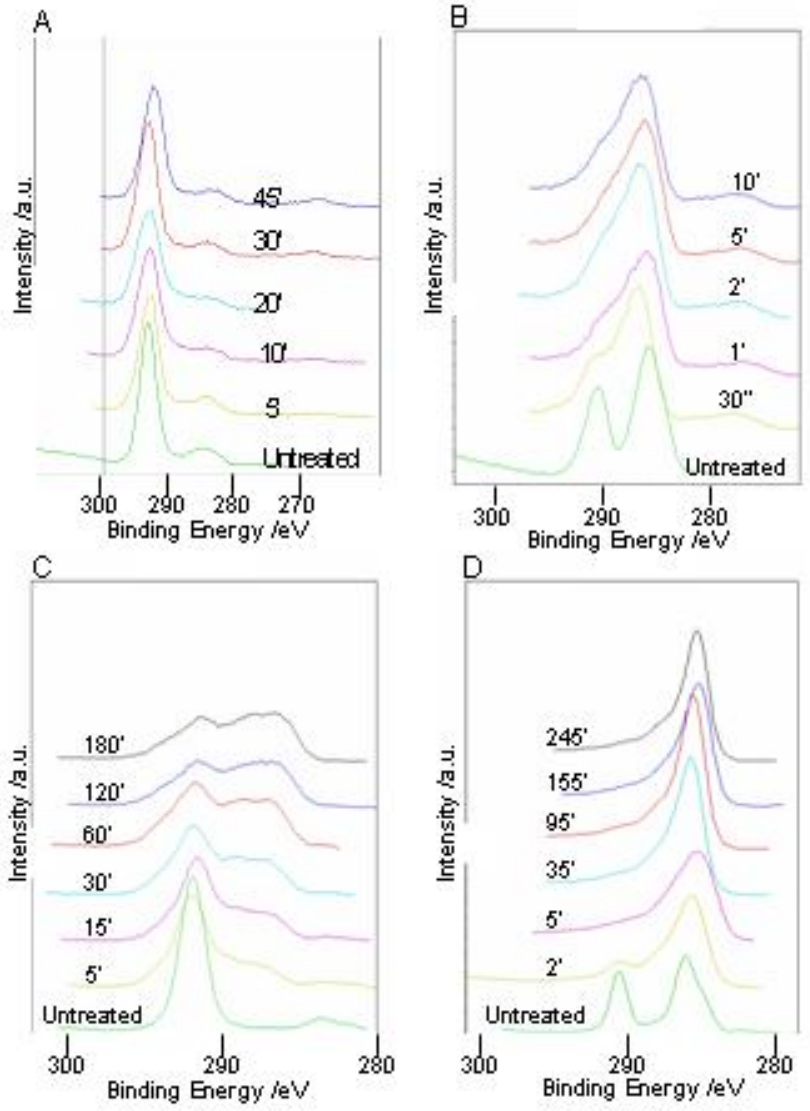

Fig4: C1s photoelectron peak of PTFE and PVDF exposed to an oxygen plasma or to an ion treatment.

A very clear relation between the amounts of these oxygenated polar groups grafted and the change in surface free energy is revealed in Figure 5.

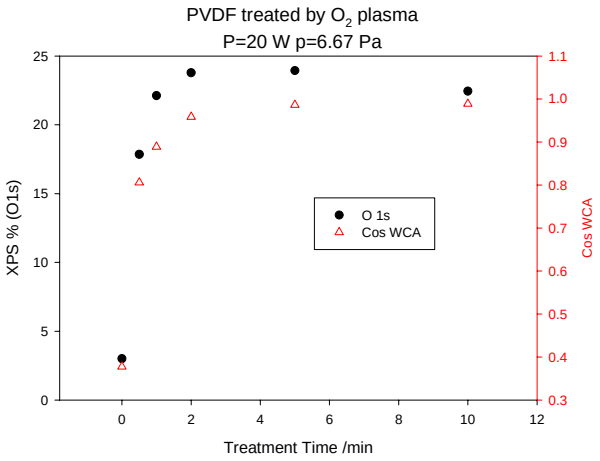

Fig5: Oxygen RF plasma treatment of PVDF surfaces, no bias was applied at the anode grid. The surface composition (at%) was determined by XPS. The working pressure is 6.67 Pa.

OES results show that during plasma treatment of PTFE, beside the O line at 777.39nm, F lines (685.63 nm and 703.84 nm), CO line (313.99 nm) and CO_2^+ line (289.83 nm) could also been observed. These results are in good agreement with the etching theory discussed above. This etching seems to be the only modification of the polymer as the C1s peak shape doesn't change.

Conclusions

Plasma treatment seems to be much more efficient than ionic treatment for the grafting of oxygen functionalities on the PVDF surfaces. For the PTFE there is a strong difference in the C1s peak shape between the ionic and the plasma treatment. The ionic treatment leads to a much wider peak than the plasma treatment in the case of PTFE. However in either case these treatments are not very efficient for grafting oxygen species onto PTFE surfaces. This is probably because oxygen treatments of PTFE lead mainly to an etching of the sample. This is confirmed in the case of the oxygen plasma by the contact angle measurement and the OES measurements. The contact angle increases after the plasma treatment. An increase in the surface roughness will increase the contact angle as stated by the Wenzel equation (1) were θ is the Young angle and r is the roughness:

$$\cos \theta^* = r \cos \theta \qquad (1)$$

For the PVDF the ionic treatment graft about 3 at% of oxygen functionalities on the surface but the plasma treatment are much more efficient. Indeed the oxygen content of the surface reached almost 25 at%. XPS results also shows that the fluorine content of the PVDF decreases very quickly with the treatment time for both ionic and plasma treatment. The contact angle of treated PVDF decreased dramatically after the plasma treatment, from 67° for an untreated sample to less than 10° after a 5 minutes plasma treatment at 20W.
For both PTFE and PVDF it seems that plasma treatment is more efficient for grafting oxygen functionalities. It also seems that the presence of C-H bond in the PVDF allow to graft much more oxygen functionalities onto the samples surfaces. The formation of HF could be the driving force of the grafting reaction of oxygen functionalities onto PVDF surfaces.

Abstract
Liquid hexachloropropene (HCP) was treated by a He/O_2 (5%) plasma and an O_2 plasma at, respectively, atmospheric and nearly atmospheric pressure. We show that the efficiency of the degradation depends on the number of electrons injected in the reaction, the oxygen pressure, and the presence of water in the plasma. After analysis of all the products obtained as a function of the experimental parameters, a tentative reaction path with as first step a successive dechlorination of HCP is proposed, followed by oxidation.

Keywords : hexachloropropene, organic pollutant remediation, dielectric barrier discharge, He/O_2 discharge, O_2 discharge

Introduction

Persistent organic pollutants such as polychlorinated molecules represent an environmental issue. Due to their hydrophobicity these molecules accumulate in fat tissues and some of them are suspected to be carcinogenic [1]. Such molecules were extensively used as pesticides and solvents during the past decades and consequently a large degree of contamination is observed in ground water, in soils and in the atmosphere.
Plasma techniques could represent a good alternative to incineration. Indeed, burning these molecules at high temperature requires a huge energy consumption, and undesired by-products such as dioxins can be formed. Since a few years, plasma techniques have been successfully used to degrade volatile organic compounds (VOC) in the gaseous phase [2], but few researches have been done regarding the destruction of halogenated molecules in the liquid or the solid phase. The purpose of this work is to study the degradation of hexachloropropene (HCP), which is liquid at room temperature, by means of a dielectric barrier discharge (DBD) at nearly or at atmospheric pressure. The expected overall degradation reaction can be summarized by:

$$C_3Cl_6 + a\ O_2 + b\ H_2O \rightarrow 3\ CO_2 + x\ HCl + y\ Cl_2 \qquad (1)$$

The left side of the expression contains all the oxygenated species which are brought into the plasma by O_2 (alone or mixed with He) and the liquid water (used in some experiments).

Experimental

Experiments were carried out in a home made steel – pyrex plasma chamber. A schematic of the experimental set up is presented in Fig. 1. More details can be found in the literature [3]. The plasma is initiated between two electrodes covered with alumina. The inter electrode spacing is set to 5 mm. The upper electrode is connected to the high voltage – low frequency generator (Solar Electronics, model 8850-1) which can deliver up to 4 kV at a frequency up to 100 kHz. The current delivered into the system is measured with a 23,5 Ω resistor. 200 or 2480 mg of HCP (Merck, 96%) and 2 ml of water, if needed, are placed on the alumina cover of the cold electrode, which is grounded. The gases used are O_2 (Air Liquide, N45), He (Air Liquide N45), CO_2 (Air Liquide N48). The gas mixture and the gas flow are realized using a mass flow controller (Brooks 5850s). Prior to any experiment, the chamber is isolated and pumped down to 50 mbar using a Edwards EDM2 rotary pump. For the He/O_2 set of experiments, a 150 ml/min gas flow at atmospheric pressure is applied during the plasma treatment, the gaseous products of the degradation being trapped in the liquid nitrogen trap. After the experiments, the flow is maintained during 1 hour to capture the residual products of the reaction.
For pure O_2 plasma experiments, the treatment is realized without flow, in static conditions. After the plasma, a He gas flow is introduced in the chamber to push products to the trap (cooled with liquid nitrogen).

After all the experiments, the trap is heated to temperatures higher than 373 K to release the gases and bring them under flow to the mass spectrometer.
An atmospheric pressure mass spectrometer (Pfeiffer Omnistar GSD 301, 0-300 amu) is used to analyze the gases released from the nitrogen cooling trap (see Fig. 1). The quantification of the degradation is realized on the CO_2^{2+} m/z signal at 22, therefore the spectrometer was calibrated using a CO_2 flow. The major gaseous by-products of the reaction were analysed using MS. The electrical characteristics of the discharge are recorded using a computer based oscilloscope (National Instruments, NI 5102).

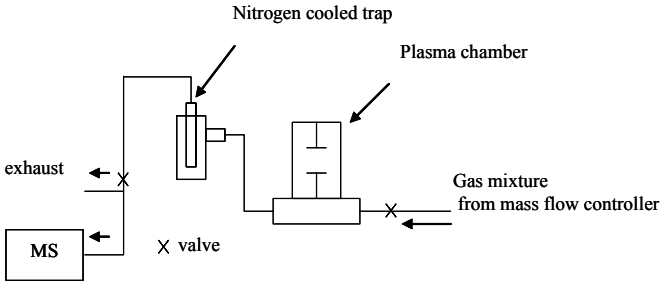

Fig. 1: Schematic of the plasma chamber used for the degradation of organohalides [3].

Two different sets of experiments were carried out : atmospheric pressure He-O_2 (5%) degradation of HCP, and pure oxygen plasma degradation of HCP at reduced pressure. The effect of the gas pressure, the plasma time, the water content and the discharge current were followed in this particular study. The other parameters (gas flow, He/O_2 composition, discharge voltage, frequency and inter electrode spacing) were optimized for the best degradation efficiency in a previous study [3]

Results and Discussion

Degradation by an He/O_2 plasma

A mixture of He/O_2 has been chosen to proceed with this set of experiments because the goal was to degrade HCP in a homogeneous way at atmospheric pressure (eventually under flow). Helium is known to stabilize glow discharges thanks to high a energy metastable state undergoes penning ionization without any influence of the electric field [4]. It also allows the initiation of an atmospheric pressure plasma at far lower voltages (around 1000 V) than other gases due to an favourable effective ionization coefficient [5].
The oxydation of the molecule is assumed to be performed by oxygen atoms and by all the others oxygenated species present in the plasma. The percentage of O_2 in the mixture is set to 5% (see Ref. 3).
In the results shown in Fig. 2, 200 mg of HCP, mixed with 2 ml of water (full circles), or alone (open circles) is treated by an He/O_2 (5%) plasma under atmospheric pressure and a 150 ml/min flow at a discharge current of 29 mA and reaction time from 1 to 40 min. In addition, to emphasize the importance of the electrical charge density applied, experiments at variable discharge current (20 and 25 mA) and constant reaction time of 10 min were performed. The charge density is obtained by integrating the discharge current over time and per unit area of the electrode, it can be expressed by the following equation:

$$\frac{Q}{A} = \frac{\int I_d dt}{A} \qquad (2)$$

Where Q/A is the electrical charge density (C/cm^2), I_d is the discharge current (mA) integrated over the reaction time t (s) and A is the electrode area (cm^2).
Figure 2 presents the evolution of the CO_2 amount produced at different discharge current and reaction time, with or without water. Increasing amount of CO_2 is released if the reaction time is increased, the dependence being quite linear. If the experiment is performed in anhydrous conditions the amount of CO_2 produced is between 30 and 50 % lower than the experiment with a mixture of 2 ml of water and HCP.

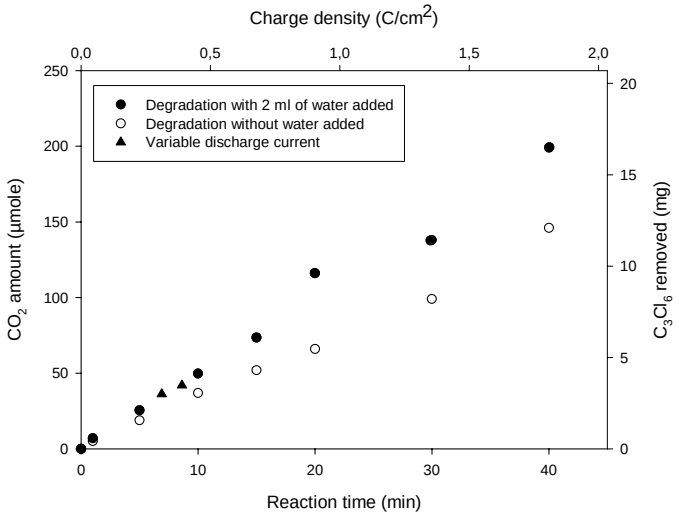

Fig. 2: Degradation of 200 mg HCP by an He/O_2 (5%) atmospheric pressure plasma (under a 150 ml/min flow). The discharge current is 29 mA and reaction time is going from 1 to 40 min. Full triangles represent experiments performed at other discharge currents (20 and 25 mA) for 10 min of reaction time.

Fig. 2 also shows that if the electrical charge density is kept constant by varying either the discharge current or the reaction time the CO_2 production will remain the same. Indeed, the triangles in fig. 2 are in good agreement with the linear dependence of the full circles, showing that the electrical charge is important for the degradation but not the way it is applied (in our experimental conditions.

The difference between the results obtained with and without water could be explained by the different active species present in each case. The creation processes of the main active species in the absence of water are:

$$He + e^- \rightarrow He^* + e^- \quad (3)$$

Where He^* is a metastable state with energy ranging from 18,8 to 20,6 eV,

$$O_2 + e^- \rightarrow 2\,O + e^- \quad (4)$$

$$He^* + O_2 \rightarrow 2\,O + He \quad (5)$$

The latest equations are the synthesis of complex processes involving inelastic collision and formation of ionic species which finally lead to O formation (O (^{3}P) or O (^{1}D)).

In absence of water the main active species, without taking into account the free electrons, is O (^{3}P)

When water is added, the following processes occur:

$$H_2O + e^- \rightarrow H + OH + e^- \quad (6)$$

$$He^* + H_2O \rightarrow H + OH + e^- \quad (7)$$

$$H_2O + O(^1D) \rightarrow 2\,OH \quad (8)$$

In presence of water, the reactive species are O and OH in addition to free electrons and a part of the O produced are used to dissociate water, therefore OH becomes the main actor in the formation of CO_2 process [6,7].

The analysis of the by-products obtained by MS shows that the main chlorinated products are HCl, $COCl_2$ and Cl_2. Traces of C_3H_5Cl have been detected and allow us to propose a reaction mechanism. Figure 3 represents the variation of the reduced area (RA) of the chlorinated by-products over the range of reaction time for the HCP + 2 ml of water degradation (same conditions as full circles on Fig. 2). The RA is the ratio between the MS signal area of the chlorinated product (HCl, $COCl_2$, Cl_2) and the MS signal area of CO_2, as shown in the following equation:

$$RA = \frac{\int MS\,signal\,X}{\int MS\,signal\,CO_2} \quad (9)$$

In this figure, the reduced area follows an exponential decay with time, suggesting that the first step of the degradation is the release of chlorinated molecules and then progressively production of CO_2.

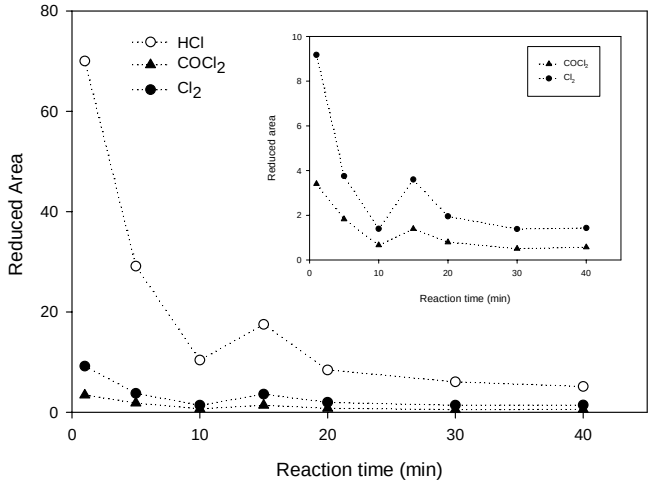

Fig. 3: Evolution of the relative amount of the main chlorinated by-products of the HCP degradation in an He/O_2 (5%) atmospheric pressure plasma (under a 150 ml/min flow). These results are extracted from the set of experiment in a aqueous medium (2 ml of water). The insert is a zoom on the regions of $COCl_2$ and Cl_2 contributions.

In absence of water, the exponential decay of the by-products formation is also observed. HCl seems to be the most abundant independently of the presence of water. HCl would normally not be produced in absence of water but it seems that the atmosphere contains small amount of water and this is enough to generate important amount (regarding the $COCl_2$ and Cl_2 quantities produced). The anhydrous set of degradation leads to the formation of twice more Cl_2 than in the aqueous set of degradation. This is normal if we consider that there is a lack of H atoms to form HCl and thus Cl atoms recombine to form preferentially Cl_2 in absence of water. Surprisingly the amount of $COCl_2$ produced seems to be identical in aqueous or anhydrous conditions. Although it is known that $COCl_2$ decompose in presence of water to give HCl and CO_2, as shown in Eqn. 10 [8]:

$$COCl_2 + H_2O \rightarrow CO_2 + 2\ HCl \qquad (10)$$

No clear explanation has been found yet. This kind of information in addition with the detection of C_3H_5Cl, which is the product of nearly complete dechlorination, allows us to suggest that this process is the starting point of the degradation.

A degradation experiment of 200 mg of HCP in anhydrous conditions by a pure He plasma at atmospheric pressure was done to confirm the dechlorination process as a possible step in the degradation mechanism (results on Table 1). He plasma interacts with the pollutant mainly by electronic collision and the result is the dissociation of HCP as shown in the Eqn. 11 :

$$R\text{-}Cl + e^- \rightarrow R + Cl^- \text{ or } R + Cl + e^- \qquad (11)$$

The formation of Cl^- instead of Cl depends on the electron energy. Table 1 shows the comparison between pure He degradation and He/O_2 degradation for 200 mg of HCP in anhydrous conditions. For both experiments, the plasma was at atmospheric pressure, the discharge current set at 29 mA and the reaction time at 10 min. In pure He plasma, no CO_2 (at m/z 22) was found but large quantities of chlorinated products were detected (HCl, $COCl_2$, Cl_2). There is more Cl_2 formed in respect with the He/O_2 experiment and a few $COCl_2$ is formed and his presence is due to a water contamination. Thus it seems that dechlorination by electronic collision is occurring.

Table 1 : Comparison between the products obtained for the degradation of HCP (200 mg) in a pure He plasma and a mix of He/O_2 (5%) both at atmospheric pressure. The discharge current is set at 29 mA and the reaction time at 10 min. No water was added is these experiments.

	MS normalized area			
	CO_2	HCl	$COCl_2$	Cl_2
He	NA	$1{,}11\ 10^{-9}$	$1{,}07\ 10^{-10}$	$2{,}15\ 10^{-10}$
He/O_2 (5%)	$1{,}46\ 10^{-10}$	$1{,}11\ 10^{-9}$	$9{,}45\ 10^{-10}$	$1{,}28\ 10^{-10}$

Degradation by an O_2 plasma

The degradation of HCP in a He/O_2 plasma has however some limitations. First, the O_2 percentage in the mixture is limited because large quantities of O_2 destabilize the discharge, which induces a decrease of the effeciency. The second issue is the expensive cost of He which is, thus, not suitable for industrial applications.

To get round of these problems a pure O_2 discharge seems to be the solution, but discharges in O_2 require very high voltages to be run at atmospheric pressure (10 000 V) and in our experimental conditions the maximum voltage allowed is 4 000 V. This set of experiment will be done at reduced total pressure (50 to 200 mbar O_2) to allow the initiation of the plasma.

As in the previous section we will work in aqueous (2 ml of water) or in anhydrous conditions. The degradation experiments are now conducted in static conditions (without flow) and for reaction time going from 5 to 15 min. We expect a greater efficiency in pure O_2 discharge because the amount available is larger. The results obtained for the degradation of HCP in an O_2 discharge (at various oxygen pressure, with and whitout water) are presented in the Fig. 4.

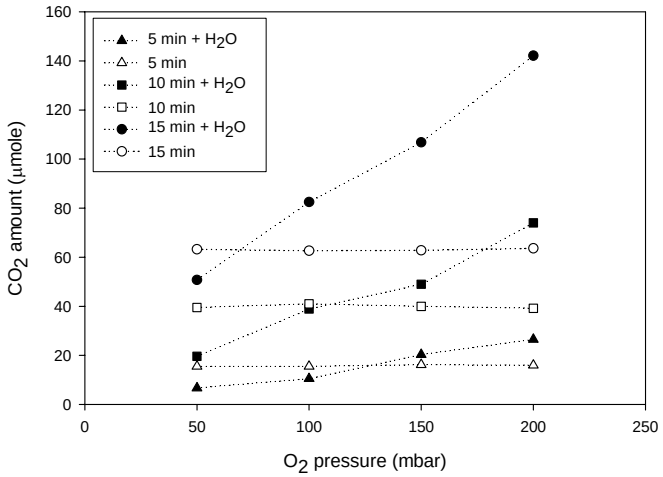

Fig. 4 : Degradation of HCP in an O_2 plasma at reduced pressure (50 to 200 mbar).For experiments at 5 and 10 min, 200 mg of HCP was used, and for experiments at 15 min, 2 480 mg of HCP was used.

In Fig. 4, the amount of CO_2 produced is constant over all the pressure range if the degradation is performed without water added (open circles). This means that the process is not dependent on the O_2 amount. However, as the quantity of CO_2 released is increasing with the charge density, in this case the number of electrons are the limiting reactant. If O (^{3}P or ^{1}D) is the active species for the degradation and is created by the processes described by the Eqn. 4, it is clear that the reaction will be limited by the amount of free electrons.

In presence of water, the CO_2 amount produced is dependent on the O_2 pressure and on the charge density applied. The lack of free electrons is no more restricting the reaction. If water is added to the medium, reactions 4, 6 and 8 will occur. Free electrons collide either with O_2 or H_2O to give O, OH and H (Eqn. 4 and 6) and subsequently O (^{1}D) can do inelastic collision with H_2O to produce more OH (Eqn. 8). This set of reactions can explain why the process is more efficient in the presence of water but not the O_2 dependence. The latter one can be explained by the following reactions:

$$H + O_2 \rightarrow HO_2 \quad (12)$$

$$H + HO_2 \rightarrow 2\ OH \quad (13)$$

H atoms coming from water dissociation react with O_2 to give the hydroperoxyl radical which in turn reacts again with an H to give two hydroxyl radicals. The first reaction is O_2 pressure dependent and the whole process explains the better results obtained with higher a O_2 pressure. The CO_2 amount depends also on the electrical charge density applied. For longer treatment times (thus higher charge density, see Eqn. 2) the CO_2 amount increases for all the pressures investigated (see Fig. 4) and the relation is always linear whether water is added or not. The chlorinated by-products obtained by the treatment of HCP in an O_2 discharge are the same as in a He/O_2 discharge, HCl, $COCl_2$, Cl_2 and C_3H_5Cl. Table 2 shows the reduced area of chlorinated products, the influence of

water and reaction time. For a short treatment time (1 min), mainly chlorinated products are detected (their reduced area is large). This supports our idea of a successive dechlorination mechanism prior to the oxidation of the carbon content. The presence of water increases the amount of HCl and C_3H_5Cl produced, while there is more Cl_2 when no water is present. The H atom is very important at this stage to control the recombination of Cl atoms.

Table 2: Chlorinated by-products obtained for the degradation of HCP in an O_2 plasma at 200 mbar and a discharge current of 27 mA. The experiment with 1 min of reaction time was performed with 200 mg of HCP, the other two with 2480 mg of HCP.

	Reduced Area		
	Reaction time : 15 min No water	Reaction time : 15 min 2 ml of water	Reaction time : 1 min 2 ml of water
HCl	30,8	173,6	1102
$COCl_2$	32,5	32,2	30,2
Cl_2	19,4	3,06	104,2
C_3H_5Cl	1,98	5,61	603

Conclusions

The tentative reaction mechanism for HCP degradation is presented in Fig 5. Based on the different chlorinated by-products found and their relative importance compared to CO_2 we attribute the first step of the degradation process to a successive dechlorination ending with the chloropropene. After this step the oxygenated species react with the molecules formed to lead to CO_2.

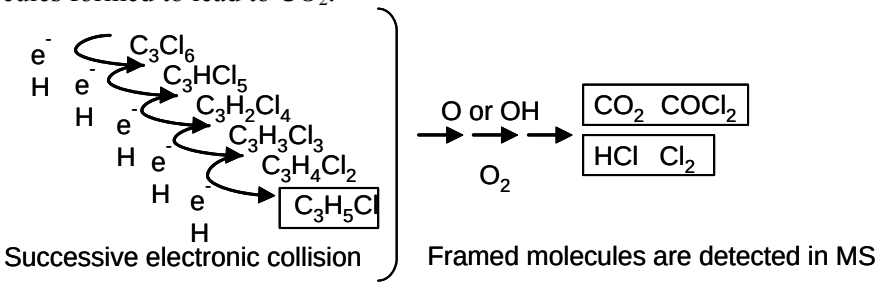

Fig 5: Reaction mechanism based on the experimental results obtained in He/O_2 and O_2 plasma degradation of HCP. Framed molecules have been detected in MS.

Abstract

An hydrogen DBD plasma was used to reduce surface oxides on steel substrates. We show that the reduction efficiency (analysed by XPS) increases with the discharge current, and decreases when the hydrogen pressure increases. The density of atomic hydrogen created in the discharge was studied by OES. We show that the reduction efficiency is directly correlated to the density of atomic hydrogen in the discharge.

Keywords: Hydrogen plasma; Discharge cleaning; Surface treatment; Steel products; Optical emission spectroscopy.

1. Introduction

The reduction of surface oxides on steel is of great importance in an industrial process, as they can influence the adhesion properties of the further coatings. Reduction of these oxides is often realized using wet chemistry (electrolysis in acid solution), but plasma techniques can lead to similar results, with a better respect for the environment. An hydrogen plasma is particularly suitable in this respect, as the active hydrogen atoms created in the discharge can react with surface oxide to produce water that desorbs and is pumped away. The overall reaction can be written as:

$$Fe_2O_3\ (s) + 6H \rightarrow 2Fe\ (s) + 3\ H_2O\ (g) \quad (1.1)$$

2. Experimental

Dielectric barrier discharges DBD are obtained between two parallel metallic electrodes, one of which being covered by a dielectric (Al_2O_3, thickness 1 mm). The second electrode on which the sample is located (steel substrate), is connected to the ground.
Steel plates either covered with their native oxide layer, or having been submitted to oxygen plasma, are introduced in a DBD plasma reactor. Hydrogen is injected in the chamber at a pressure varying from 2 to 200 mbar. In some experiments, helium was added. Typical plasma conditions were V = 1000 to 2000 V, frequency = 10 to 20 kHz.

2.1. Discharge characterisation

Figure 1 presents the oscillograms obtained in a hydrogen discharge. The applied voltage is measured with a high voltage probe (Lecroy, attenuation factor: 1000). The oscilloscope (Lecroy LT264) used for those experiments has a bandwidth of 350 MHz and its sampling rate is 1 GS/s. The total current delivered in the system was obtained by measuring the terminal voltage of the resistance.

To estimate the efficiency of the process from these data (applied voltage, current in the system), the discharge parameters (voltage and current) are calculated using an electrical model [1-3].

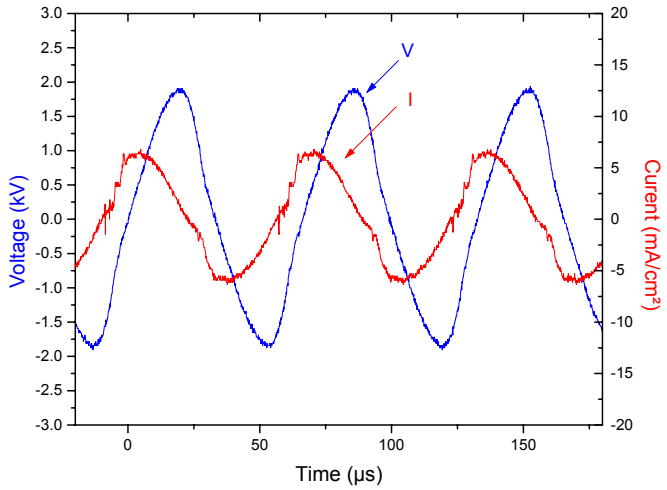

Fig 1 : Oscillograms obtained in a hydrogen discharge (5 mbar, V = 1700 V, 15 kHz).

The discharges are also characterized by OES (Optical Emission Spectroscopy, Digisem Sofie SCM 350 mm, 1800 g/mm, resolution of 0,14 nm) between 200 and 900 nm. Figure 2 presents an OES spectrum of hydrogen discharge. Molecular and atomic hydrogen emission lines are detected.

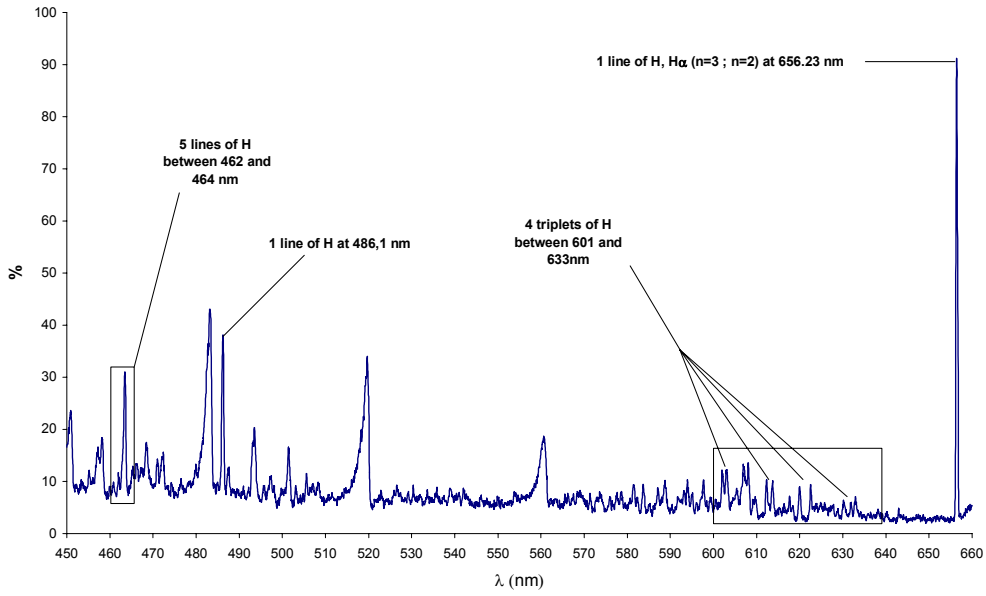

Fig 2: OES spectrum of a hydrogen discharge.

In this study, the intensity of the hydrogen line noted H_α (656,23 nm) was used as an indirect probe for the density of atomic hydrogen. The production and consumption of the excited atomic states are described by reactions 2.1 (electronic impact) and 2.2 (direct excitation).

$$H + e^- \rightarrow H^* + e^- \qquad (2.1)$$

$$H_2 + e^- \rightarrow H^* + H + e^- \qquad (2.2)$$

The processes of loss (de-excitation) can be radiative according to the reaction (2.3) and non radiative according to reactions (2.4) to (2.6). It should be noted that for a pressure higher than 5 mbar [4], the de-excitation by ionization is negligible.

$$H^* \rightarrow H + h\nu \qquad (2.3)$$

$$H^* + e^- \rightarrow H^+ + 2\,e^- \qquad (2.4)$$

$$H^* + H_2 \rightarrow H + H_2 \qquad (2.5)$$

$$H^* + H \rightarrow H + H \qquad (2.6)$$

According to Figure 3, the hydrogen signal increases with the discharge current (this can be realised either by increasing the frequency and/or by increasing the voltage). It should also be noted that the hydrogen signal is reversely proportional to the pressure.

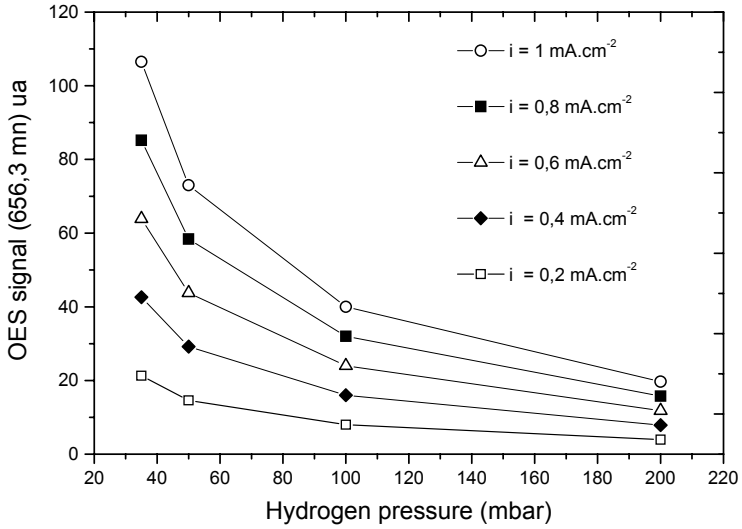

Figure 3: Evolution of hydrogen signal (656,23 nm) versus pressure, for different values of discharge current.

2.2. Surface analysis

The surface was analyzed by XPS in order to determine the oxidation and the contamination levels. We followed the O(1s)/Fe(2p3/2) and C(1s)/Fe(2p3/2) ratio respectively. The efficiency ε can be evaluated according to the equation (2.7):

$$\varepsilon = \frac{\dfrac{A_{XPS}^{Ref}O(1s)}{A_{XPS}^{Ref}Fe(2p3/2)} - \dfrac{A_{XPS}^{x}O(1s)}{A_{XPS}^{x}Fe(2p3/2)}}{\dfrac{A_{XPS}^{Ref}O(1s)}{A_{XPS}^{Ref}Fe(2p3/2)}} \qquad (2.7)$$

Where A is the peak area, *ref.* indicates the oxidized reference and X the sample treated by hydrogen plasma. This equation, which represents the reduced fraction, will be used to correlate the discharge parameters (current, pressure...) and the process efficiency.

Figure 4 presents the XPS spectrum of a steel plate surface. The binding energies are calculated using the carbon at 284,6 eV as a reference [5]. The iron oxide present at the surface is hematite (Fe_2O_3), as confirmed in the literature [6-8].

For steel plates covered with their native oxide layer, the O/Fe and C/Fe ratios are respectively equal at 2,1 ± 0,1 and 0,6 ± 0,1. For steel plates submitted to an oxygen plasma, the O/Fe and C/Fe ratios respectively worth 2,3 ± 0,1 and 0,3 ± 0,1.

To limit the oxidation after treatment, the DBD reactor is directly coupled to the XPS chamber. The residual pressure reached before the injection of hydrogen is about 10^{-6} mbar.

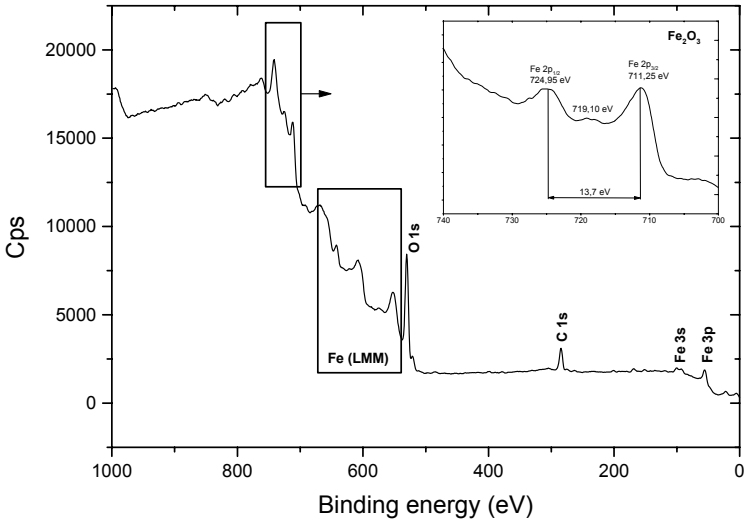

Fig 4: XPS spectrum of steel plate showing the presence of iron oxide.

3. Results and discussion

The effects of the hydrogen partial and total pressure and of the discharge current have been studied. Figure 5 presents the effect of the hydrogen pressure on the O/Fe ratio. By decreasing the hydrogen pressure, the $H \rightarrow H_2$ recombination reaction is disadvantaged and the reduction efficiency increases (the O/Fe ratio decreases). The number of active species (H) being more significant at low pressure (for an equal current), this result is in good agreement with the reaction (1.1).

On the other hand, an increase of the discharge current, leads to a better reduction efficiency, as shown in Figure 6. An increase in the discharge current leads to an increase of the hydrogen dissociation. Consequently, the number of active species is higher, as is the reduction efficiency (O/Fe decreases). This result is also in agreement with the reaction (1.1).

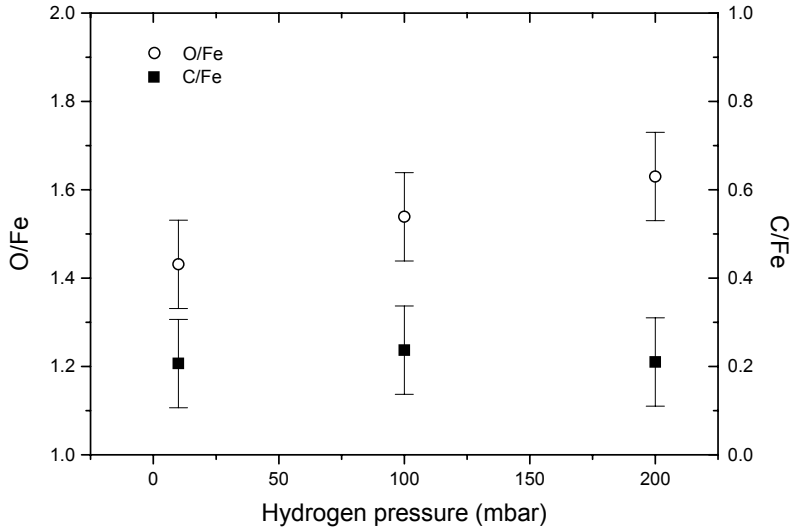

Fig 5: O(1s)/Fe(2p3/2) XPS ratio as a function of the total hydrogen pressure, the charge density is 0,8 mA/cm^2 and the treatment time is 3 min.

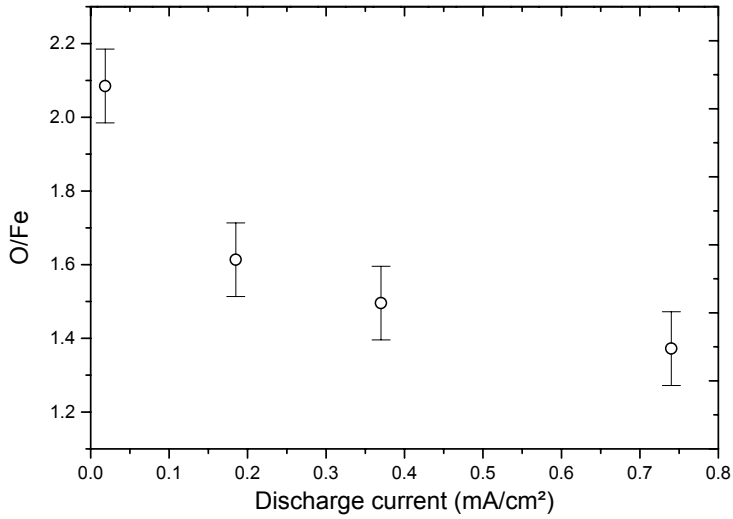

Fig 6: O(1s)/Fe(2p3/2) XPS ratio as a function of the discharge current for a fixed hydrogen pressure (35 mbar), and the treatment time is 10 min.

The reduction efficiency can be directly correlated to the intensity of the OES emission line of atomic hydrogen (Figure 7). This intensity decreases when the hydrogen pressure increases, indicating that recombination occurs in the gas phase. A complex kinetic process occurs in which atomic hydrogen is produced in the plasma by molecular hydrogen dissociation under the effect of electrons, and can either recombine in the gas phase, or react at the oxide surface to form OH or H_2O, both able to desorb and to be pumped away. The effective mean free path of hydrogen in the gas phase is the critical parameter. Helium was therefore introduced in the gas phase to raise the total pressure but, without being able to react with hydrogen, no decrease in the reduction efficiency was observed in such conditions.

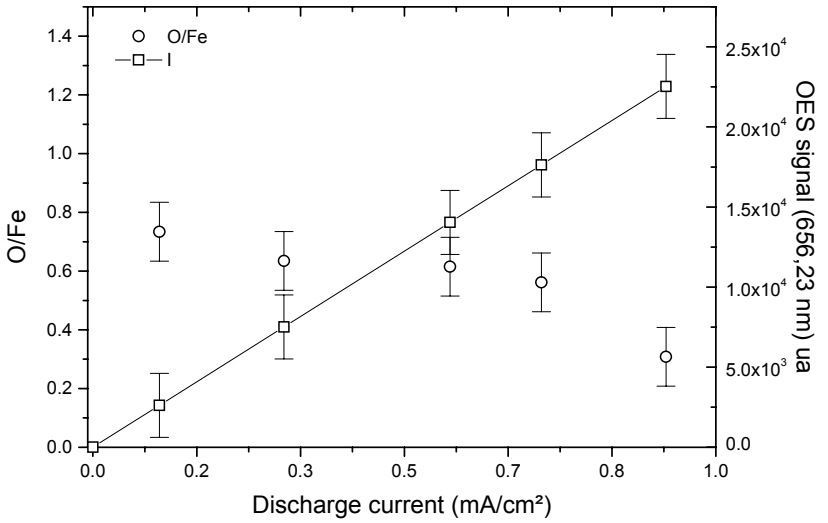

Fig 7: Correlation between the O(1s)/Fe(2p3/2) XPS ratio, the charge density, and the intensity of the H emission line at 656.23 nm (the H_2 pressure is 5 mbar, treatment time : 10 min).

4. Conclusions

A DBD H_2 plasma can successfully remove the surface oxide layer on steel substrates. The kinetics of reduction depends mostly on the amount of hydrogen atoms able to reach the surface.
The electrons of high energy (on average 10 eV) are able to dissociate molecular hydrogen by inelastic collisions. The oxide is reduced under the action of atomic hydrogen. The treatment time will depend on the H density. Consequently, for a greater efficiency, it is necessary to obtain a high dissociation degree. This can be reached by increasing the discharge current and/or by decreasing the total pressure.
In conclusion, this "dry" process respects the environment and gives good results for the reduction of metallic oxides. Under the best experimental conditions, approximately 90 % of the oxide initially present on the steel surface can be removed. It should be noted that the reduction efficiency by "wet" treatment tested in laboratory, reaches approximately 60 %.

Abstract

Silicon nitride thin films were deposited by DC magnetron sputtering. The sputtering was performed from a silicon target in a (Ar, H_2, N_2) atmosphere. Deposition rates of about 33.6 Å/s for pure Si and 13.5 Å/s for Si_3N_4 were obtained. The XPS spectra indicated that Si_3N_4 stoeichiometric was obtained for a molar fraction of nitrogen in the gas phase of 0.2 and above and also indicated that the sputtered silicon nitride films were uncontaminated. The process was stable and the structure of the films was amorphous.

Keywords

Silicon nitride; Magnetron sputtering.

Introduction

Silicon nitride thin films have numerous applications in the semiconductor industry. They are used in very large scale integrated circuits, thin film transistors, alkali-ion diffusion barrier, oxidation mask and solar cell applications. Silicon nitride can be prepared by various methods such as chemical vapour deposition (CVD), plasma-enhanced CVD, inductively coupled plasma (CVD) and sputtering. Among those methods, the sputtering technique is a low temperature method like plasma-enhanced CVD. Various sputtering techniques, including sputtering and reactive sputtering in different systems such as direct current (DC), radio frequency (RF), and S-gun, were used to prepare the silicon nitride. In this study we deposited SiN_x films using the plasma DC reactive magnetron technique.

Experimental

Silicon nitride thin films were deposited by DC magnetron sputtering on stainless steel substrates in a planar DC sputtering home apparatus. The sputtering was performed from a silicon target in a sputtering atmosphere of (Ar, H_2, N_2) mixture. The gas composition could be varied from 0 to 100% for Ar and N_2 and from 0 to 10% for H_2.

The deposition rate, the composition, structure and purity of the coatings have been investigated as a function of the process parameters, such as the composition of the sputtering atmosphere, the total pressure, and the plasma power. The plasma was characterized by the current – voltage curves. The deposited films were characterized by optical interferometry (thickness measurement) and XPS.

Results

Due to the high affinity of Si for oxygen, the deposition of silicon films is not trivial. Any trace of water vapour, or remaining oxygen contain molecule in the chamber usually induces the formation of a silicon oxide layer. Figure 1 shows that the use of pure Argon for sputtering leads to the formation of a SiO_2 film. In order to avoid this effect, we added hydrogen to the plasma. For our setup, pure silicon films can be obtained if the plasma gas contains at least 10% H_2. This gas mixture will therefore be the starting gas for the reactive sputter deposition of silicon nitride, through the addition of nitrogen.

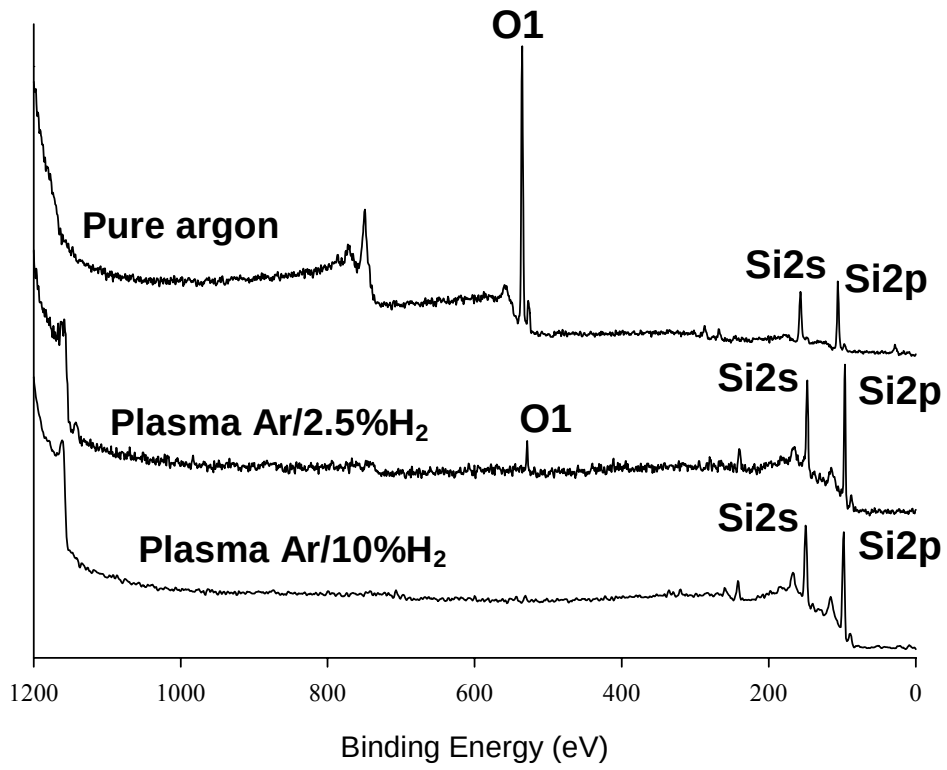

Figure 1: Effect of the hydrogen percentage in the sputtering gas on the purity of silicon films obtained.

When nitrogen is added to the plasma gas, pure silicon nitrides of various stoeichiometry (depending on the molar fraction of nitrogen in the plasma) are formed. Figure 2 shows a typical XPS survey of a Si_3N_4 film obtained with 50% nitrogen in the plasma. After a short cleaning of the film surface into the XPS chamber by Ar^+ bombardment, no contaminations (C, O) are detected.

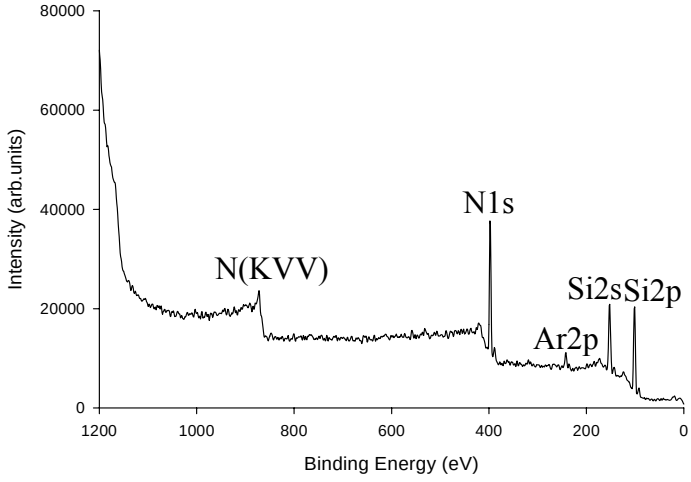

Figure 2: XPS survey spectra of a Si_3N_4 film obtained using a $((Ar/10\%H_2)/50\%N_2)$ plasma.

The XPS spectra indicated that Si_3N_4 stoeichiometric was obtained for a molar fraction of nitrogen in the plasma of 0.2 and above and also indicated that the sputtered silicon nitride films were uncontaminated with oxygen and carbon. Figure 3 illustrates the evolution of the Si XPS peak as a function of the nitrogen concentration. X-ray diffraction analysis indicates that the structure of all the films was amorphous.

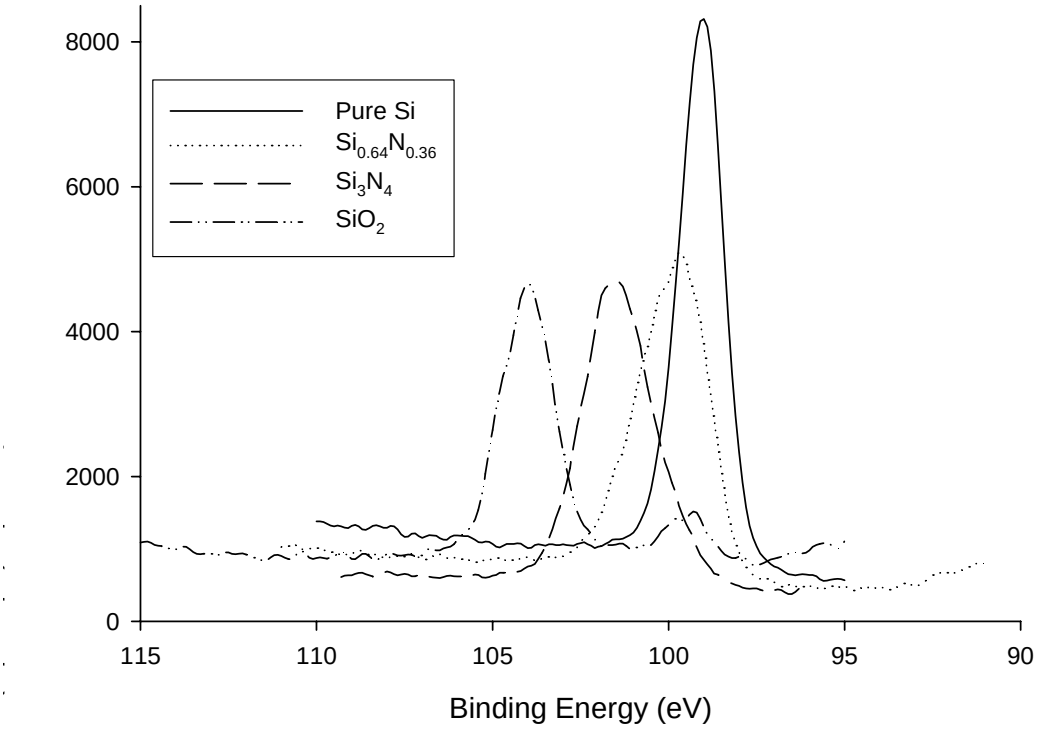

Figure 3: XPS Si 2p peak for pure silicon, silicon nitride under-stoichiometric, Si_3N_4 and SiO_2.

Study of the deposition rate

Figure 4 shows the average deposition rate as a function of the nitrogen mole fraction in the plasma gas for a fixed total pressure. Deposition rates of 33.6 Å/s for pure Si using a $Ar/10\%H_2$ are obtained. The deposition rate decreases rapidly when nitrogen replaces argon, due mainly to a strong difference in the sputtering yield of the two gases.

The behavior is different if nitrogen is added to a fixed Ar/H_2 pressure in the plasma gas. Figure 5 shows that the deposition rate decreases also, but with a different slope. This decrease is not due in this case to a decrease of the Argon amount available, but to a pressure effect. When the total pressure increases, the mean free path in the gas phase decreases, lowering therefore the deposition rate. Similarly, a pressure increase leads to a decrease of the target voltage (at same current). This induces lower energies for the sputtering ions, and consequently a smaller sputtering yield, and a lower deposition rate. A deposition rate of 13.5 Å/s for pure Si_3N_4 could be reached (see Fig.5)

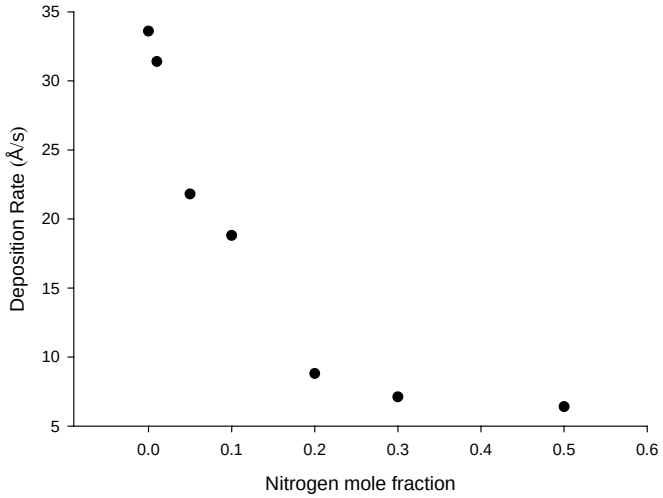

Figure 4. Deposition rate vs nitrogen mole fraction (sputtering current and total pressure are 0.35A and 10^{-2}Torr respectively)

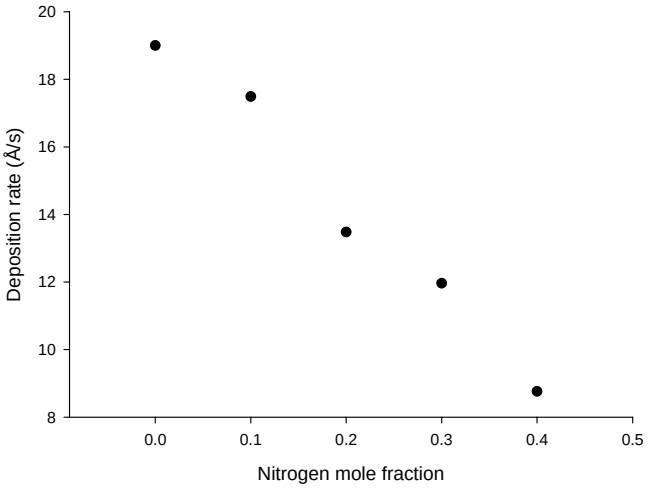

Figure 5. Deposition rate vs nitrogen mole fraction (sputtering current: 0.3 A and ($Ar/10\%H_2$) partial pressure: 910^{-3}Torr)

Stability of the plasma process

The influence of the nitrogen addition to the ($Ar/10\%H_2$) gas on the stability of the plasma process is shown in Figure 6. The mole fraction of nitrogen was increased stepwise with 2 min between two consequent additions. After reaching a nitrogen mole fraction of 0.8, the nitrogen flow was reduced stepwise with again 2 min between two points. The increase of the nitrogen mole fraction leads to a decrease of the target voltage. This

well-known effect can be attributed to more volume ionisation resulting in a current increase and, at constant power, a target voltage decrease. Switching off the nitrogen flow resulted in a reverse behaviour with a small increase in the target voltage compared to the one obtained in the forward process. This increase is due to the implantation of reactive ions in the target surface [1-4]. No hysteresis effect was observed.

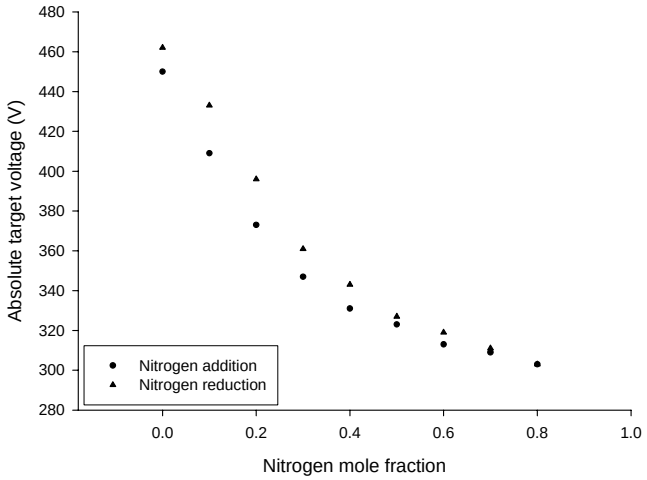

Figure 6. Target voltage vs the nitrogen mole fraction (Ar/10%H_2 partial pressure: 9 10^{-3} Torr; time between points: 120s; pumping speed of 230 l/s).

The addition of nitrogen to the plasma gas was repeated at a lower pumping speed (23 L/s instead of 230 L/s). As shown in Figure 7, the transition from the metallic state to the 'poisoned' state occurs at a critical nitrogen mole fraction of x = 0.5, where a sudden change of the target voltage behaviour as a function of the nitrogen content is observed. This indicates a change in the surface state of the target. This instability is due to an insufficient pumping speed of the reactive gas. We also noted, for nitrogen mole fractions larger than 0.3, a small decrease in the target voltage when we diminished the nitrogen flow. This decrease of the target voltage is probably due to the formation of silicon nitride layer, which is characterized by a high secondary electron emission coefficient compared to the metal and leads to a decrease in the target voltage.

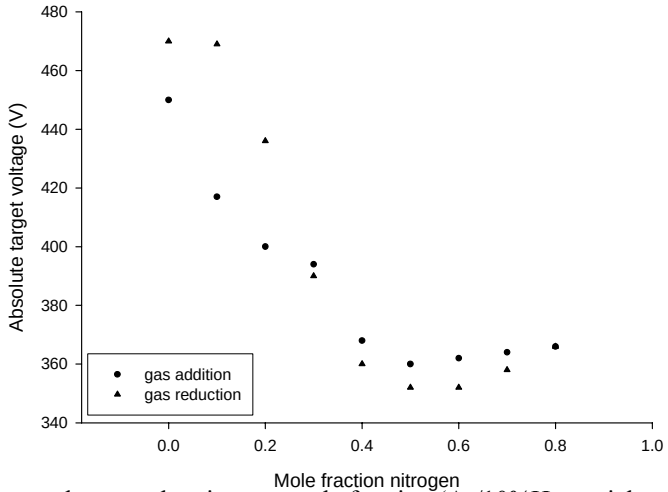

Figure 7. Target voltage vs the nitrogen mole fraction (Ar/10%H_2 partial pressure: 9 10^{-3} Torr; time between points: 120s; pumping speed of 23 l/s).

For pumping speeds of 230 L/s, Figure 8 reveals that no hysteresis effect is detected in the current-voltage curves indicating that the reactive sputtering proceeds in the metallic mode and the process is stable.

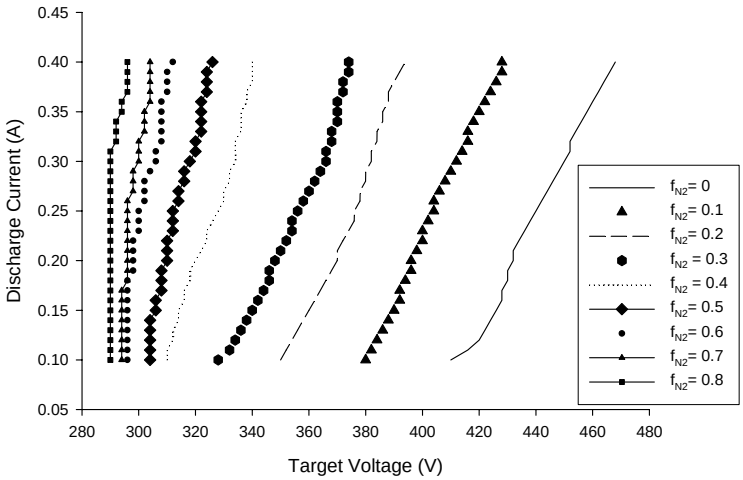

Figure 8: I-U characteristics of the discharge vs nitrogen mole fraction (Ar/10%H_2 partial pressure fixed: 9 10^{-3} Torr, variable total pressure).

Conclusions

High purity SiN_x films could be deposited at a high speed by DC planar magnetron sputtering. The sputtering is operating in the metallic mode, and no hysteresis effect is observed in our deposition conditions. A high pumping speed is needed to avoid a contamination of the target. The deposition rate decreases when the fraction of nitrogen in the plasma gas increases. The reasons identified are synergetic: lowering in the sputtering yield, lowering of the target voltage, decrease of the mean free path. Therefore, a compromise has to be found between high speed and efficient nitridation.

Abstract
Carbon nanowalls, two-dimensional carbon nanostructures, were fabricated using fluorocarbon plasma-enhanced chemical vapor deposition assisted by H radical injection. The correlation between carbon nanowall growth and the fabrication conditions was investigated. The morphologies and growth rate of carbon nanowalls were dependent on the types of carbon source gases and the amount of H radicals injected. In addition, straight, aligned carbon nanowalls with regular spacing were fabricated by controlling the radical flow configuration.
Keywords: Carbon nanowalls, PECVD, Field emission

1. Introduction

Self-assembled carbon nanostructures such as carbon nanotubes have attracted much attention for several applications, including field emitter arrays, gas storage, and membranes for electrochemical energy storage [1-4]. Recently, two-dimensional carbon nanostructures have also been grown. Shang *et al*. [5] prepared carbon nanoflake films using hot filament chemical vapor deposition (CVD). Wu *et al*. [6] reported the fabrication of two-dimensional carbon nanostructures (carbon nanowalls) standing vertically on a catalyzed substrate using microwave plasma-enhanced chemical vapor deposition (CVD). Very recently, the authors have fabricated carbon nanowalls without catalysts, using radio-frequency (rf) plasma-enhanced CVD (PECVD), assisted by a hydrogen (H) radical injection [7,8]. Carbon nanowalls, two-dimensional carbon nanostructures consisting of plane graphene layers standing on the substrate, have been grown recently. The large surface area of carbon nanowalls may provide opportunities for various applications. In view of their practical application, further investigations should be performed in order to enable control over the structure and electronic properties and understand their growth mechanism.

In this work, carbon nanowalls were fabricated on a Si substrate without catalysts, using rf-PECVD assisted by H radical injection. The correlation between carbon nanowall growth and the fabrication conditions, such as the carbon source gases used, was investigated. As one of applications of carbon nanowalls, field electron emission characteristics were investigated for the carbon nanowall film.

2. Experiments

The experimental setup used in this study is shown in Figs. 1(a) and 1(b). Figure 1(a) shows a schematic of the rf-PECVD assisted by a remote radical source, which consists of a parallel-plate rf (13.56 MHz) capacitively coupled plasma (CCP) region and a remote radical source which uses an inductively coupled H_2 plasma (H_2 ICP). The main reaction chamber was equipped with circular parallel-plate electrodes separated by 5 cm. Carbon source gas (C_2F_6, CH_4, CF_4, CHF_3 and C_4F_8) was introduced into the rf-CCP region. H_2 was fed through a quartz tube of 26 mm inner diameter and 20 cm in length. A five-turn rf coil was mounted on the quartz tube. The rf coil was connected to the rf power generator operating at 13.56 MHz. The flow rates of carbon source gas and H_2 were kept at 15 and 30 sccm, respectively, and the total gas pressure was 100 mTorr. Typical rf powers of CCP and ICP were 100 W and 400 W, respectively, and the substrate temperature was 500 °C, which was the maximum temperature in the present system.

Figure 1(b) shows a schematic of the experimental arrangement for measuring the absolute H radical density by the VUVAS system employing a microdischarge hollow-cathode lamp (MHCL). The VUVAS technique has been described in detail elsewhere [9,10]. The MHCL was used as a vacuum ultraviolet (VUV)

light source for absorption spectroscopy. The absorption path length was restricted to be 15 cm by using two stainless steel pipes and the capillary plates in order to prevent the saturation of absorption. The VUV light passed once through the chamber at 2 cm above the substrate, and was focused on the slit of a VUV monochromator (Acton Research Corp., ARC VM-520) by MgF_2 lens and detected by a photomultipliar tube (PMT). The transition line used for the absorption measurement was Lyman alpha at 121.6 nm for the H radical density.

Scanning electron microscopy (SEM) was used to evaluate the surface morphology of the deposits grown under various conditions. In addition, the field electron emission characteristics of the carbon nanowall films were measured with a spherical stainless steel anode of 2-mm diameter in a vacuum of 10^{-6} Torr. The distance between anode and cathode (carbon nanowall film) was kept at 80 μm.

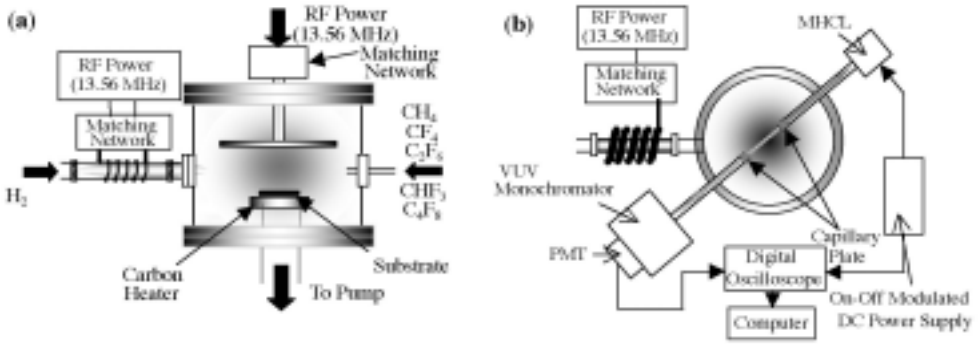

Fig. 1. (a) Schematic of the rf-PECVD assisted by a remote H radical source used for the growth of carbon nanowalls. (b) Schematic diagram of the experimental arrangement for measuring absolute H radical density using VUVAS technique.

3. Results and discussion

Typical SEM image of the carbon nanowalls grown on Si substrate using a C_2F_6/H_2 system for 8 hours are shown in Figs. 2(a) and 2(b). These pictures show that two-dimensional carbon sheets were grown vertically on the substrate, forming a unique nanostructure like a maze. The thickness of carbon nanowalls was 40-60 nm, and their height was about 1.5 μm. Figure 2(c) shows a SEM image of 8-hour-grown carbon nanowall mat scratched out from substrate, which implies that free-standing aligned carbon nanowall filter will be fabricated using the present system.

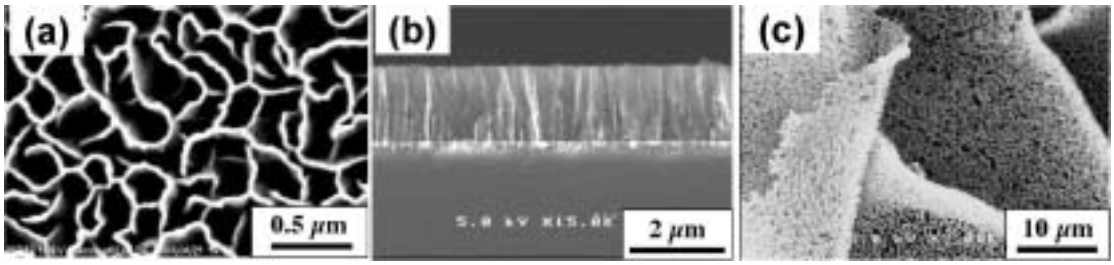

Fig. 2. SEM images of carbon nanowalls using C_2F_6/H_2 system for 8 hours; (a) top view, (b) cross-sectional view, and (c) carbon nanowall filter which was scratched out from Si substrate.

Figures 3(a) - 3(c) show SEM images of carbon nanowalls grown for 15 min, 30 min, and 1 hour, respectively. As shown in Fig. 3(a), at the nucleation stage of growth, nano-islands with size of 3-10 nm were formed on the substrate, followed by the formation of disordered carbon nanoflakes of smaller sizes (Fig. 3(b)) and subsequent growth of isolated nanowalls with semicircular shape standing vertically on the substrate in the next stage of growth as shown in Fig. 3(c).

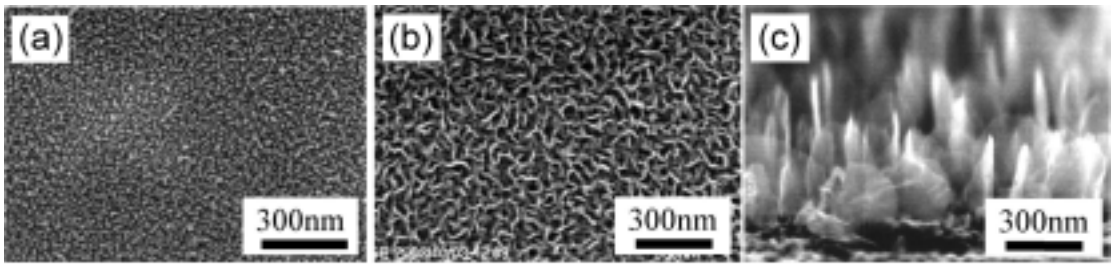

Fig. 3. SEM images of carbon naowalls grown for (a) 15 min, (b) 30 min, and (c) 1 hour.

The mechanism responsible for the nanowall growth was speculated as follows. At the nucleation stage, carbon species would condense to form nano-islands with dangling bonds as shown in Fig. 3(a). At these dangling bonds, disordered carbon nanoflakes of smaller sizes would be nucleated, followed by the two-dimensional growth and subsequent formation of graphene sheets. Among nucleated graphene sheets with random orientations, those standing almost vertically on the substrate continued preferably to grow up faster to aligned nanowalls, as shown in Fig. 3(c), due to the difference of the growth rates in the direction of parallel and perpendicular to the graphene layer. Here, parallel growth indicates that reactive carbon species arrive at the edge of graphene layer and this plane graphene layer expands, while perpendicular growth indicates that reactive carbon species arriving at the surface of graphene layer form another layer on the surface. On the other hand, low-lying inclined graphene sheets were shadowed by the high-grown vertical graphene sheets. As a result, amounts of reactive carbon species arriving at the low-lying inclined graphene sheets decreased, resulting in the termination of growth for the inclined smaller nanowalls. Sifting vertical nanowalls from nucleated graphene sheets with random orientations at the early stage of growth would occur, resulting in the increase of spacing between nanowalls. As the growth time increased, spread vertical nanowalls met with one another, eventually resulting in the formation of linked nanowalls like a maze. With the further increase of growth time, it became more difficult for the reactive carbon species to reach the sidewall, resulting in the saturation of increase in the wall thickness.

Growth experiments were carried out using CH_4, CF_4, CHF_3 or C_4F_8 as a carbon source gas under similar conditions as those for the case using the C_2F_6/H_2 system. Carbon nanowalls were successfully fabricated using CH_4/H_2, CF_4/H_2 and CHF_3/H_2 systems. The morphology of the carbon nanowalls grown using CF_4/H_2 and CHF_3/H_2 systems was similar to that using the C_2F_6/H_2 system shown in Fig. 2(a), except that the spacing between nanowalls was a little larger than that of nanowalls grown using C_2F_6/H_2 system. Carbon nanowalls grown using CH_4 were rather wavy and very thin, and their thickness was less than 10 nm. When using C_4F_8/H_2 system, on the other hand, definite nanowalls were not grown.

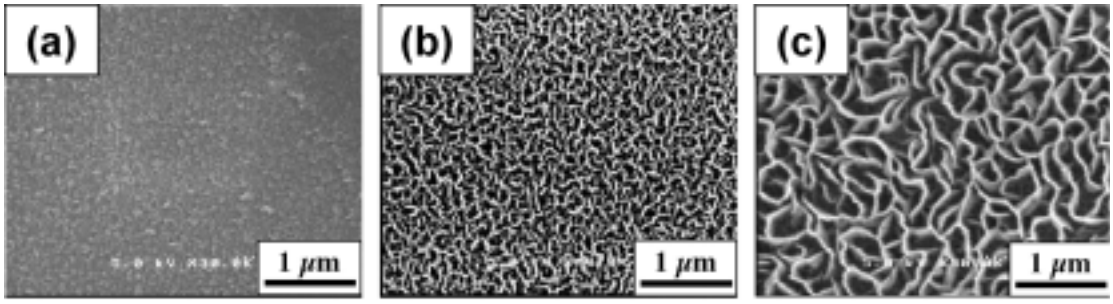

Fig. 4. SEM images of carbon nanowalls grown at the rf power of remote H_2 ICP of (a) 0 W, (b) 100 W and (c) 400 W.

The effect of H atom injection into the CCP region on the morphology of deposits was investigated by changing the rf power of the H_2 ICP. It was observed that the morphologies were dependent on the rf power of the remote H_2 ICP. Figs. 4(a) - 4(c) show SEM images of deposits grown using the C_2F_6/H_2 system for 3 hours at

various rf powers of the H_2 ICP. In the case of deposition without the H_2 ICP, where a C_2F_6/H_2 mixture was excited only by the rf-CCP, carbon nanowalls were not fabricated, but fluorocarbon polymers with a cauliflower shape were deposited, as shown in Fig. 4(a). At a low power of 100 W, however, carbon nanowalls were grown as shown in Fig. 4(b), although the carbon nanowalls grown at the ICP power of 100 W were not so clear, as compared with the carbon nanowalls grown at 400 W, as shown in Fig. 4(c).

We have measured H radical density in the plasma by the VUVAS technique. Absorption measurements were carried out with varying the rf power of the H_2 ICP. Figure 5 shows the H radical density in the CCP region as a function of rf power of remote H_2 ICP. The H radical density in the CCP region without H radical injection, where C_2F_6/H_2 mixture was excited by rf-CCP only, was $1.7x10^{11}$ cm^{-3}. As the rf power of remote H_2 ICP increased, the amount of H radicals produced in the ICP increased, resulting in the increase of the H radical density in the CCP region. The H radical density was $3.1x10^{11}$ cm^{-3} at the rf ICP power of 400 W, where definite typical carbon nanowalls were fabricated as shown in Fig. 2. The H radical density in the CCP region increased by about two times as a result of the H radical injection under the typical growth condition for the carbon nanowalls.

The morphologies and growth rate of carbon nanowalls were found to depend on the type of carbon source gas. Of the variety of fluorocarbon gases investigated in this study, C_2F_6 is expected to yield CF_3 radicals most effectively. CF_3 radicals could also be generated in the CF_4 or CHF_3 plasma to some extent. Meanwhile, the CF_3 radical density in the C_4F_8 plasma is considered to be low, although large amounts of CF_2 radicals would be generated in the C_4F_8 plasma, due to the cyclic structure of C_4F_8. Therefore, it is suggested that the CF_3 radicals are important species responsible for the formation of carbon nanowalls from fluorocarbon/hydrogen systems.

Injected H atoms would react effectively with fluorocarbon radicals in the gas phase as well as at the surface by the reaction of F abstraction. At a substrate temperature of 500 °C, H atoms play an important role for producing sp^2-bonded carbons at the surface to form a continuous sp^2 network, eventually resulting in the formation of carbon nanowalls. However, the H atom density in the CCP region measured using vacuum ultraviolet absorption spectroscopy (VUVAS) increased by two times at most, as a result of H atom injection using the remote H_2 ICP, in spite of the fact that the surface morphology of the carbon films was drastically influenced by the H radical injection. It is possible that the ratio of CF_x (x=1-3) radicals to H atoms could be an important factor in the formation of carbon nanowalls. Measurement of the CF_x radical density in the plasma is currently being performed using appearance mass spectrometry.

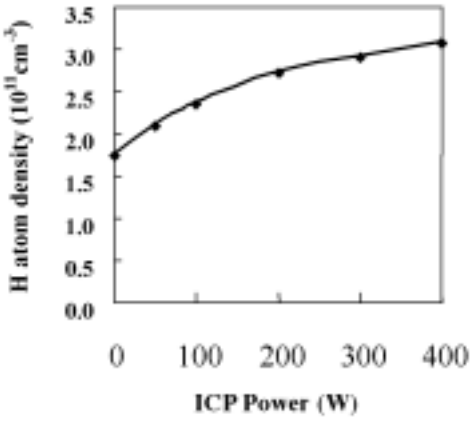

Fig. 5. H atom density of in the CCP region measured using VUVAS technique as a function of rf power of remote H_2 ICP.

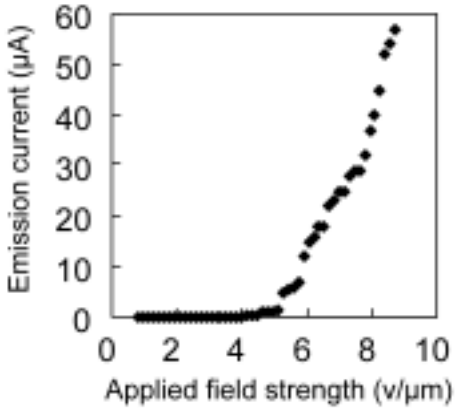

Fig. 6. Field emission characteristic of the vertically aligned carbon nanowall film.

As one of applications of carbon nanowalls, field electron emission characteristics were investigated for the carbon nanowall film. Figure 6 shows the characteristic curve of the electron emission current as a function of the field strength for the carbon nanowall film. The onset electric field for the electron field emission was 5

V/μm.

The aggregation of carbon nanowalls would be useful as templates for the fabrication of other types of nanostructured materials, supporting materials for nano-particles of catalysts, and would certainly find application in gas sensors, bio-sensors, energy storage devices and electrodes for fuel cells, due to their large surface areas.

4. Conclusions

We have presented a fabrication of vertically aligned carbon nanowalls using capacitively coupled, rf-PECVD assisted by H radical injection. The morphologies and growth rate of carbon nanowalls were dependent on the kinds of carbon source gases and the rf power of remote H_2 ICP. Without H radical injection, carbon nanowalls were not fabricated. H radicals were found to play an important role for forming nanowalls. In addition, H radical density in the plasma was measured using a VUVAS. The H radical density in the CCP region increased by about two times as a result of H radical injection using remote H_2 ICP. Furthermore, The field electron emission from carbon nanowalls was clearly observed.

Abstract
Carbon nanotube (CNT) films were grown using microwave plasma-enhanced chemical vapor deposition. Catalytic Co nanoparticles were prepared on a Si substrate using the pulsed arc deposition. Titanium nitride (TiN) thin film was used as a buffer layer in order to prevent the formation of Co silicide. Dense, vertically aligned, CNT film was grown rapidly on the Co-catalyzed Si substrate. The CNTs grew at an extremely high rate of 600 nm/s during the first 10 min. Dense films with thickness over 500 μm could be obtained in 20 min.
Keywords: carbon nanotube, microwave plasma-enhanced chemical vapor deposition, Co catalyst

1. Introduction

Carbon nanotubes (CNTs) have attracted much attention for several applications, such as electron field emitter arrays and multi-level interconnection of ultra-large scale next generation integrated circuits [1,2]. Many of the proposed applications for CNTs require aligned nanotubes grown on a substrate. Of the variety of methods used for growing CNTs, plasma-enhanced chemical vapor deposition (PCVD) has gained considerable importance for industrial application compared to other methods, due to its feasibility and potential for large-area production with reasonable growth rates at relatively low temperatures.

When using PCVD to synthesize CNTs on a substrate with a catalytic metal thin film, the substrate is preheated. This is done in order to form catalytic nano-islands in the range of 10-100 nm, prior to the CNT growth. The size of the catalyst islands depends on the initial thickness of the catalytic metal thin film. In other words, thicker catalyst films yield larger catalyst islands, whereas thinner films result in the formation of smaller catalyst islands. When using a Si substrate, the formation of metal-silicide, as a result of the heat pre-treatment, will complicate the synthesis process. At present, it is difficult to simultaneously control both the size of the catalyst particles and their density on the substrate surface. Considering the practical applications of CNTs, further investigations should be performed in order to enable control over the structure and electronic properties, and to understand the growth mechanism. In particular, the control over the preparation of catalytic metal nanoparticles on the substrate would be essential to realize the potential of CNTs. In this work, CNTs were synthesized on a Si substrate using microwave plasma-enhanced CVD (MWPCVD). Co nanoparticles were prepared on the substrate using the pulsed arc plasma deposition. Titanium nitride (TiN) thin film was used as a buffer layer in order to prevent the formation of Co silicide. A film of dense, aligned CNTs was grown on the Co-catalyzed Si substrate.

2. Experiments

CNT films were grown by conventional MWPCVD with a 2.45 GHz, 1.5 kW microwave generator [3-5], as shown in Fig. 1. The reactor consists of a cylindrical-stainless steel chamber of 11 cm inner diameter and a molybdenum substrate stage with a graphite heater that allows control of the substrate temperature independent of the input microwave power. This MWPCVD system is usually used to grow diamond films [3]. A mixture of CH_4 and H_2 was used as a source gas. The flow rates of CH_4 and H_2 were 50 and 70 sccm, respectively. The microwave power and total pressure were 900 W and 70 Torr, respectively. The growth experiments were carried out for 0.5-20 min at a substrate temperature ranging from 600 to 800˚C, which was measured using an optical pyrometer. The substrate used for the growth experiments was Si (100).

Substrate treatment was performed as follows. Firstly, a thin TiN layer, with thickness of 20 nm, was prepared on the Si substrate. The TiN thin layer has an important role as a buffer layer, in order to prevent the

formation of Co silicide during the increase of substrate temperature, just before introducing CH_4 gas into the reaction chamber. Secondly, Co particles were deposited on the TiN buffer layer using pulsed arc plasma deposition (Arc plasma gun, ULVAC, Inc.) in vacuum, at a pressure of 10^{-4} Torr at room temperature. The Arc plasma gun was operated intermittently (pulse operation). No heat pre-treatment was performed for the catalyst prior to the CNT growth process. We have found that the pulsed arc evaporation using the Arc plasma gun yielded Co nanoparticles of about 4 nm in size, according to the preliminary experiment. However, Co nanoparticles deposited on the TiN buffer layer have not been recognized yet, although we tried to observe using scanning electron microscopy (SEM) and atomic force microscopy (AFM). The density of Co nanoparticles on the substrate was controlled by varying the number of pulses in the range from 50 to 250 shots.

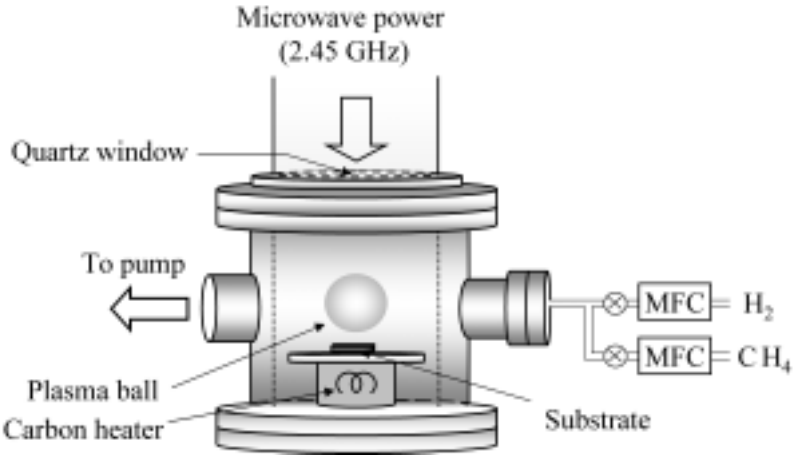

Fig. 1. Schematic of microwave plasma-enhanced CVD reactor used for formation of carbon nanotube films.

3. Results and discussion

CNTs were grown on the Co-catalyzed Si substrates at a substrate temperature of 700 °C. Figures 2(a) and 2(b) show typical SEM images of CNT films. Dense CNTs were grown on the Co-catalyzed substrate with a TiN buffer layer. From consideration of the morphology observed in Fig. 2(b), it was found that individual CNTs were not straight, but grown almost vertically, via a self-support mechanism, due to the extremely high density of the CNTs. It was noted that there was a tangled appearance of some CNT bundles, as seen in the cross-sectional SEM image of Fig. 2(b), and this was presumed to have originated from the cleaving of the substrate.

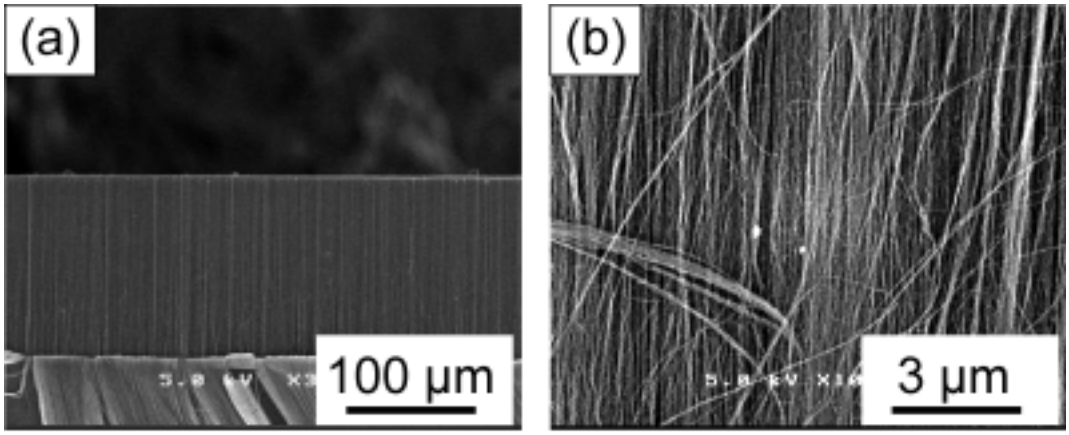

Fig. 2. SEM images of CNT films grown on a Co-catalyzed Si substrate with TiN buffer layer. Co particles were prepared using pulsed arc plasma deposition by 250 pulses. (a) Cross-sectional SEM image of dense CNT film. (b) Close-up image of cleaved CNT film showing aligned growth of nanotubes.

A growth rate curve for the CNT film was obtained by measuring the thickness of the CNT films at different growth times. CNT films were grown from Co nanoparticles deposited by 250 shots using pulsed arc plasma, which were nearly optimum conditions for the extremely dense nucleation of CNTs. The thickness of the CNT

film increased linearly up to 10 min of growth. The CNTs grew at an extremely high rate of 600 nm/s during the first 10 min. Dense CNT films with thickness over 500 μm could be obtained in 20 min.

Figure 3(a) shows a low-magnification transmission electron microscopy (TEM) image of typical CNTs grown under the same condition as that in Figs. 1(a) and 1(b). TEM specimen shown in Fig. 3(a) was scraped away from the substrate. CNTs are hollow and have small average diameter of approximately 4.5 nm. Note that no Co particles were observed at the nanotube tips with TEM. Figure 3(b) shows a typical magnified TEM image of the same CNTs, revealing that most of CNTs have the double-walled structure, which contains a clear inner channel with an inner diameter of about 4 nm. Single-walled nanotubes were also found in the CNTs grown, as shown in Fig. 3(c). It is noted that no Co particles were observed at the nanotube tips in the TEM images. The fact that no Co particles were observed at the nanotube tips, suggests that our process could be explained by the base-growth mechanism.

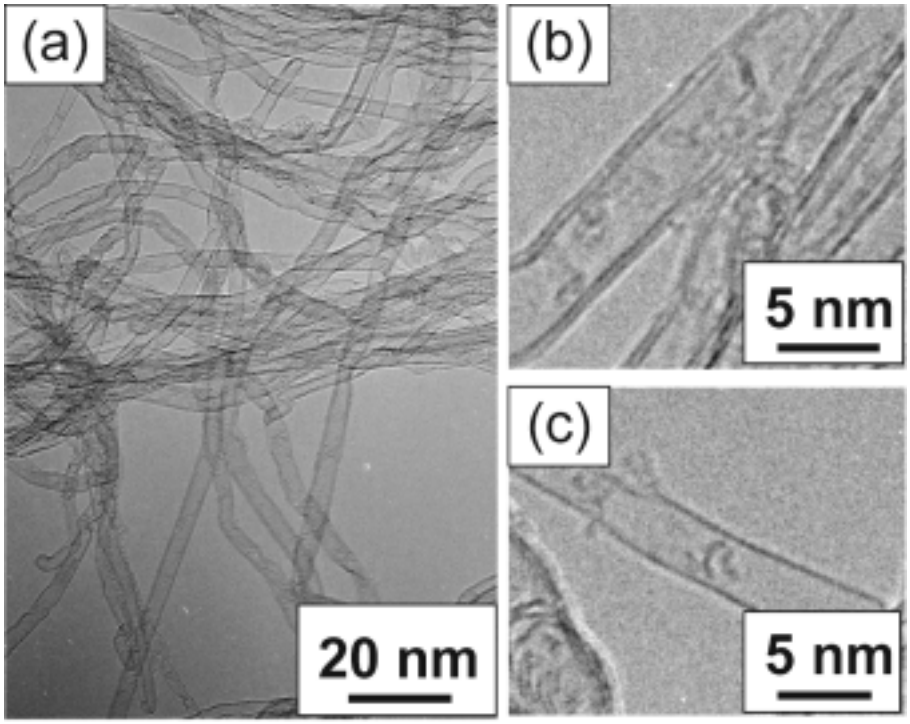

Fig. 3 TEM images of CNTs scraped from the substrate. CNTs were grown on the Co-catalyzed Si substrates at a substrate temperature of 700 °C. (a) A low-magnification TEM image of CNTs. (b)(c) Magnified images of the CNTs shown in (a).

The most significant difference from previous reports is that the catalyst was prepared originally in the form of nanoparticles in our case. It was reported that the nanotube growth rate was inversely proportional to the nanotube diameter [6]. Namely, the smaller diameter nanotubes would grow at a faster rate in their height. In our case, the size of Co particles formed by pulsed arc deposition was relatively small. The density of isolated Co nanoparticles on the Si substrate was found to be of the order of 10^{13} cm^{-2} after 50 shots of pulsed arc deposition at room temperature. In our system, it takes about 10 minutes to increase the substrate temperature from room temperature to 700 ˚C. Many of nanoparticles would remain nearly unchanged in increasing substrate temperature just before CNT growth, due to the existence of TiN buffer layer prepared to prevent the formation of Co silicide, although the overlapped or closely adjacent particles would join together during the increase of substrate temperature up to 700 ˚C in the case of high density of Co particles after 250 shots of pulsed arc deposition. Deposited Co nanoparticles would play an important role as a template for the CNT growth, resulting in the determination of nanotube diameters as small as 4.5 nm and consequently, a fast rate of growth could be attained for the CNTs.

Unlike the PCVD-grown, well-aligned, isolated CNTs reported by Bower *et al.* [6,7] and Hirata *et al.* [8], individual nanotubes in our case were not so isolated, and aligned nanotube forests were composed of nanotube bundles supporting one another. Bower *et al.* have explained that the alignment was induced by the electrical self-bias field imposed on the substrate surface from the plasma environment. On the other hand, in our case, the substrate was not exposed to a plasma ball, and the contribution of the self-bias to the alignment was low. The 'remote' plasma mainly produces important radicals for the CNT growth and heats the substrate to some extent in our case. In the case of CNT growth without the electrical field, CNTs would grow in a curly fashion. If the density of catalytic particles with small size on the substrate is low, CNTs would grow in random orientation or in less aligned manner, resulting in the low growth rate of CNT film. The density of Co nanoparticles on the substrate was changed by varying the shot numbers of pulsed arc discharges in the range from 50 to 250. Figure 4(a) shows a cross-sectional SEM image of CNT film grown from Co nanoparticles deposited by 250 shots using pulsed arc plasma, which were nearly optimum conditions for the extremely dense nucleation of CNTs. As shown in Fig. 4(a), nanotube bundles grew almost straight due to the high density of CNTs, corresponding to the high growth rate of 600 nm/s for the growth of 5 minutes. On the other hand, in the case of the growth using a substrate with low-density Co nanoparticles, the growth rate of CNT film decreased. Figure 4(b) shows a cross-sectional SEM image of CNT film grown from Co nanoparticles deposited by 50 shots using pulsed arc plasma. As shown in Fig. 4(b), the CNTs grew in a curly fashion because individual nanotubes had more space to grow, resulting in the decrease of CNT film growth rate (150 nm/s for the growth of 5 minutes).

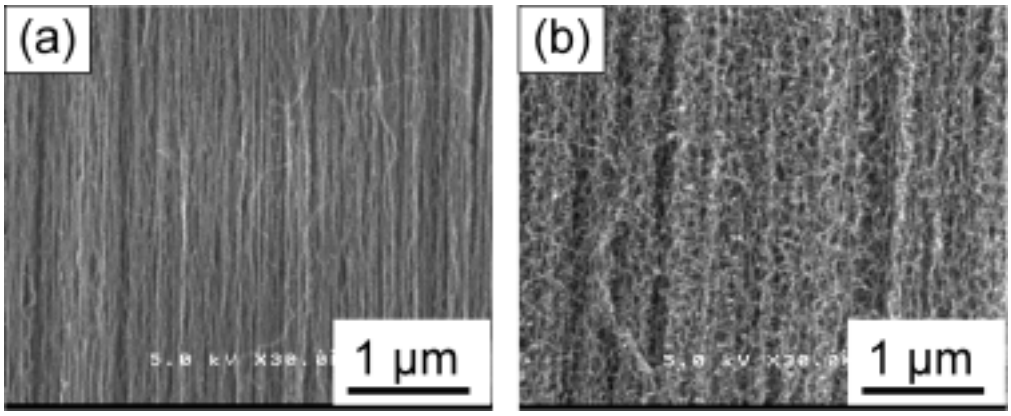

Fig. 4. Cross-sectional SEM images of CNT films grown from Co nanoparticles prepared using pulsed arc plasma by (a) 250 shots and (b) 50 shots.

In summary, we have presented a fabrication of dense, vertically aligned, double-walled carbon nanotube films at an extremely high rate. The film growth rate of 600 nm/s was attained by controlling the size and density of catalytic nanoparticles on the substrate.

Abstract
Effective generation of chemical reactive species in thermal plasmas has been required in the field of material processing and waste treatment. The effect of oxygen injection into argon induction plasmas was investigated by numerical analysis without chemical equilibrium assumptions for the dissociation and ionization. Oxygen dissociation and heat flux to torch wall can be controlled by oxygen injection location. Therefore, suitable oxygen injection needs to be chosen according to the application requirement.

1. Introduction

Thermal plasmas have been used for a number of applications of material processing and waste treatment. In these applications, effective generation of chemical reactive species is required. The modeling of induction thermal plasmas with several injection methods of nitrogen or hydrogen was performed previously [1]. The purpose of this work is to investigate the effect of oxygen injection into argon induction plasmas on chemically non-equilibrium (CNE) conditions by numerical analysis. Reaction kinetics rates of the dissociation and recombination of oxygen as well as the ionization were taken into account in this modeling. The transport properties were estimated using higher-order approximation of Chapman-Enskog method [2].

2. Numerical formulation

2-1 Thermodynamic and transport properties

Higher-order approximation of the Chapman-Enskog method is used according to the required accuracy for transport properties. Modeling of induction thermal plasmas has been performed with the first-order approximation because higher-order of Sonine polynomial expansion requires many kinds of collision integrals resulting in the complex formula. The first-order approximation may cause errors especially for electrical conductivity and thermal conductivity of electron translational contribution over 10000 K [3]. The collision integrals were taken from Ref. [4-11] which provide intermolecular potential and fitting data. Detailed descriptions of the calculation method of viscosity, thermal conductivity and electrical conductivity are given by Watanabe and Sugimoto [3]. In CNE model, the transport and thermodynamic properties are related to the temperature and the composition of plasmas. Therefore, the transport and thermodynamic properties should be estimated considering the diffusion of species in plasmas at each calculation step until the convergence.

The thermodynamic properties, enthalpy and specific heat at constant pressure, were obtained from the equilibrium properties. This would be oversimplification, however, the exact estimation of the non-equilibrium thermodynamics properties is very complex to satisfy the self-consistent conditions. The radiative intensity of argon and oxygen was taken from Ref. [12-13].

2-2 Kinetic rate constants

The equilibrium composition was estimated by FACT (Center for Research in Computational Thermochemistry), considering six species of Ar, Ar^+, O_2, O, O^+, and e^-. Table 1 summarizes the reactions of Ar-O_2 mixture considered in this study. Twelve reactions comprising 6 forward reactions in Table 1 and their backward reactions were taken into account. The reaction rates for forward direction are given by Arrhenius equation.

Table 1 Chemical reactions in argon-oxygen mixtures.

Reaction	a_l	b_l	c_l
$O_2 + O_2 \rightarrow O + O + O_2$	2.0×10^{21}	-1.5	59500
$O_2 + O \rightarrow O + O + O$	1.0×10^{22}	-1.5	59500
$O_2 + Ar \rightarrow O + O + Ar$	1.0×10^{22}	-1.5	59500
$O_2 + e^- \rightarrow O + O + e^-$	9.68×10^{22}	-2.0	59500
$O + e^- \rightarrow O^+ + e^- + e^-$	3.91×10^{33}	-3.78	158500
$Ar + e^- \rightarrow Ar^+ + e^- + e^-$	k_l^f was calculated by Eq. (2)		

$$k_l^f = a_l T^{b_l} \exp(-c_l / T) \qquad (1)$$

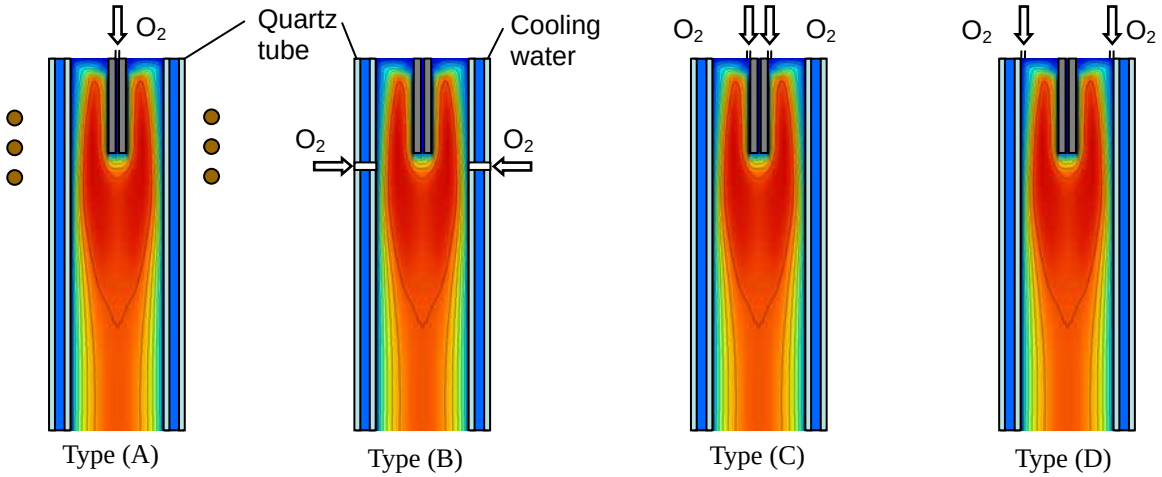

Fig. 1 Schematic diagram of oxygen injection location types.

For Ar ionization reaction, the reaction rate can be calculated by Eq. (2) [14].

$$k_l^f = 1.68\times10^{-20}T^{1.5}(135300/T+2)\exp(-135300/T) \quad (2)$$

2-4 Calculation model

Four injection locations of oxygen were considered in the modeling as illustrated in Fig. 1; (A) center injection; (B) radial injection at the center of the coil; (C) inner injection from the top; (D) sheath gas injection.

The geometry of calculation domain of induction plasma torch is shown in Fig. 2 and the operating conditions are summarized in Table 2. Gas flow rate of each oxygen injection type was shown in Table 3. The plasma torch consists of a water-cooled quartz tube, and is surrounded by a water-cooled induction coil. The coil consists of three turns and applies the induction frequency at 4 MHz to the plasma. The actual power level was assumed to be 5 kW.

The calculation are based on the following assumptions to derive the governing equations: (a) steady-state laminar flow; (b) axial symmetry; (c) optically thin; (d) negligible viscous dissipation in energy equation; (e) negligible displacement current in comparison with the conductive current; (f) negligible flow-induced electric field; (g) same temperature of heavy particles and electrons.

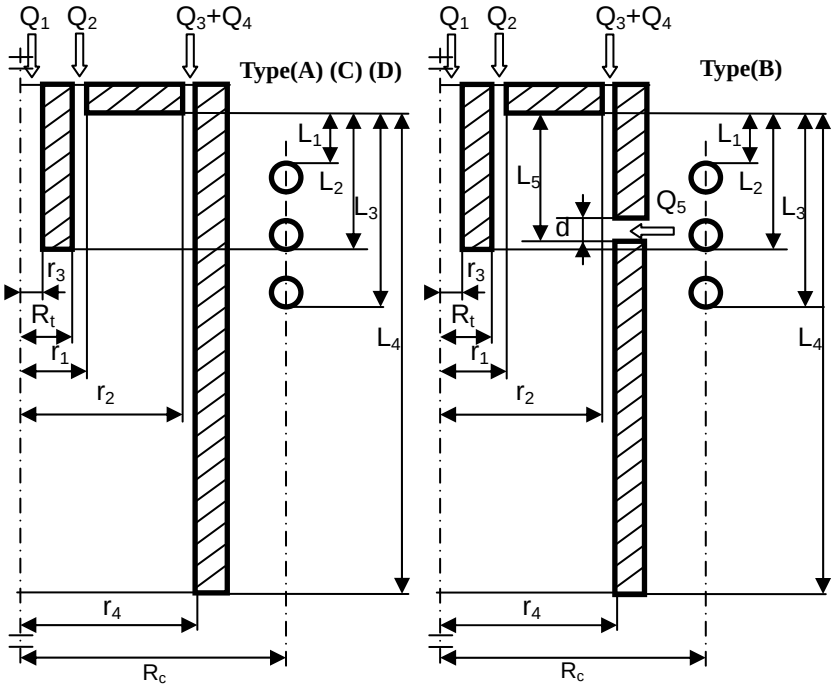

Fig. 2 Geometry of calculation domain of induction plasma torch.

Table 2 Torch characteristic dimensions and operational condition.

Torch Power	5 kW
Work Frequency	4 MHz
Reactor Pressure	101.3 kPa
Coil Radius	32 mm
Coil turn number	3
Wall thickness	1.5 mm
L_1	19 mm
L_2	45 mm
L_3	65 mm
L_4	190 mm
L_5	40 mm
r_1	6.5mm
r_2	21 mm
r_3	1 mm
r_4	22.5 mm
R_t	4.5 mm
d	0.1 mm

The effect of turbulence has been reported by Chen and Boulos [15]. They reported that most of the flow field in induction plasmas was laminar at the Reynolds number 625 at the gas inlet, while the turbulence effect is large at the Reynolds number 3125. The flow field of the present induction plasmas can be considered as laminar, because the inlet Reynolds number is 350 in this study.

Table 3 Flow rate of each injection type.

(L/min)	Type (A)	Type (B)	Type (C)	Type (D)
Q1	**O_2: 0.1**	0	0	0
Q2	3	3	3 (**O_2: 0.1**)	3
Q3 + Q4	26.9	24	27	27(**O_2: 1**)
Q5	-	**O_2: 3**	-	-
Total	30	30	30	30

2-5 Governing equations and boundary conditions

The field of flow, temperature and concentration in induction thermal plasmas were calculated by solving the two-dimensional continuity, momentum, energy, and species conservation equations coupled with the Maxwell's equations. Reactions of the dissociation and recombination as well as the ionization were taken into account in this modeling.

Continuity:

$$\nabla \cdot (\rho \mathbf{u}) = 0 \tag{3}$$

Momentum:

$$\rho \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + \nabla \tau + \mathbf{J} \times \mathbf{B} \tag{4}$$

Energy:

$$\rho \mathbf{u} \cdot \nabla h = \nabla \cdot \left(\frac{\lambda}{C_p} \nabla h \right) + \mathbf{J} \cdot \mathbf{E} - q_r \tag{5}$$

Species:

$$\rho \mathbf{u} \cdot \nabla Y_i = \nabla \cdot (\rho D \nabla Y_i) + R_{ri} \tag{7}$$

Electromagnetic:

$$\nabla^2 \mathbf{E} - \xi \sigma \frac{\partial \mathbf{E}}{\partial t} = 0 \tag{8}$$

The boundary conditions along the centerline were set to insure axial symmetry. At the wall of the plasma torch, no slip conditions are maintained for the velocity, and the concentrations have zero gradient. The temperature at the inside wall of the plasma torch was calculated assuming that the outside wall was maintained at 300 K by water cooling. The injection tube was assumed to be at 500 K. The outflow boundary conditions at the torch were assumed that the gradient of the variables are zero. The sheath gas has swirl velocity component. Each gas stream has constant axial velocity with zero radial velocity having temperature at 300 K.

2-5 Calculation procedure

The governing conservation equations were solved using SIMPLER (Semi-Implicit Method for Pressure Linked Equation Revised) algorithm [16]. The governing equations and the electric field intensity equation with the associated boundary conditions were discretized into finite difference from using control-volume technique. In oxygen injection types (A), (C), and (D), non-uniform grid points 30 by 30 were used for radial and axial directions, respectively. In oxygen injection type (B), non-uniform grid points 30 by 54 were used for radial and axial directions, respectively. Grids are made finer close to the center and the coil region. Thermodynamic and transport properties were calculated from the temperature and compositions at each position in the calculation domain at each iteration step.

3. Result and discussion

The effect of oxygen injection of type (A: center injection) on plasma characteristics is presented in Fig. 3. At the oxygen injection region, the temperature decreases due to oxygen dissociation as shown in Fig. 3 (a). Higher heat capacity including oxygen dissociation approximately 4000 K leads to a decrease in the plasma temperature. The flow field in Fig. 3 (b) exhibits the characteristic recirculation caused by the radial Lorentz force above the coil region. The corresponding concentration profiles of oxygen atoms and molecules are illustrated in Fig. 3 (c) and (d), respectively. Injected oxygen molecules are dissociated quickly because oxygen is injected directly into the high-temperature region. Therefore, dissociated oxygen

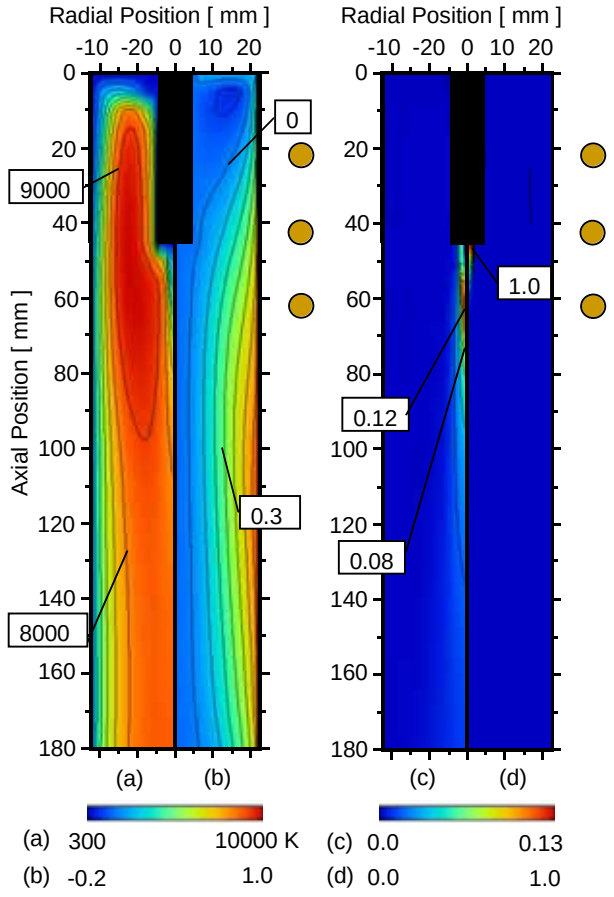

Fig. 3 (a) Isotherms, (b) streamlines, (c) O atom concentration, and (d) O_2 concentration distributions in an Ar-O_2 plasma; Type (A): center injection at 0.1 L/min.

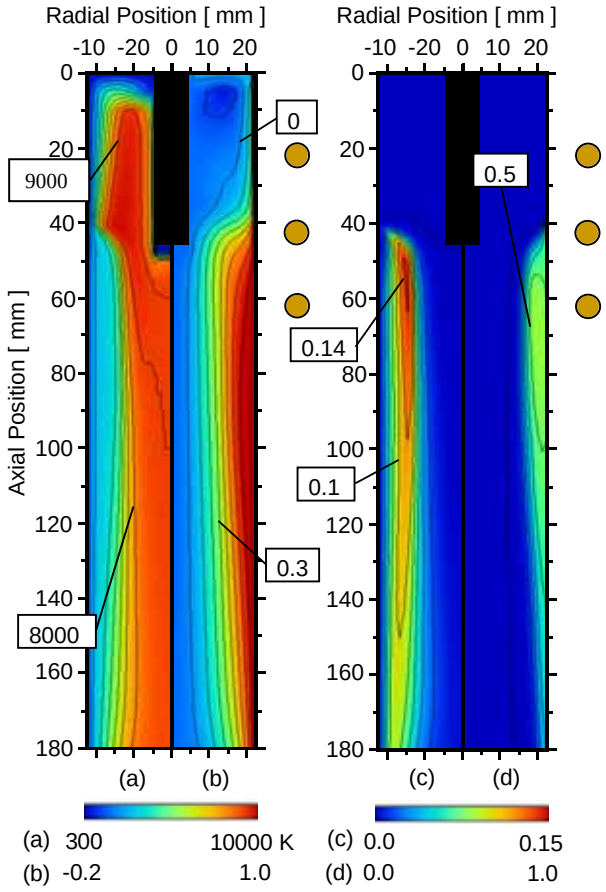

Fig. 4 (a) Isotherms, (b) streamlines, (c) O atom concentration, and (d) O_2 concentration distributions in an Ar-O_2 plasma; Type (B): radial injection at 3 L/min.

atoms can be found near the center of the torch.

Numerical results of oxygen injection type (B: radial injection) is shown in Fig. 4. The calculated temperature field in Fig. 4 (a) shows the severe decrease in temperature at the oxygen injection region along the torch wall due to oxygen dissociation. The streamlines shown in Fig. 4 (b) demonstrate the modified flow field from other injection types in the coil region because of the radial injection toward the high-temperature region. The concentration profiles of oxygen atoms and molecules are presented in Fig. 4 (c) and (d), respectively. Oxygen molecules and dissociated oxygen atoms exist locally near the torch wall owing to the negligible diffusion of dissociated oxygen atoms toward the torch center.

The temperature field in Fig. 5 (a) and the flow field in Fig. 5 (b) in the case of oxygen injection type (C: inner injection) are comparable to types (A) and (D). Thus, the effect of inner injection from the top is weak on the plasma characteristics. The corresponding concentration profiles of oxygen atoms in Fig. 5 (c) and molecules in Fig. 5 (d) indicate that injected oxygen molecules are dissociated quickly above the coil region. Dissociated oxygen atoms exist broadly except the low-temperature region near the torch wall. The widespread mixing of oxygen is due to the recirculation caused by the Lorentz force in the coil region.

The effect of oxygen injection type (D: sheath gas injection) is presented in Fig. 6. High-temperature region above 8000 K is almost the same with an argon plasma, while the temperature decreases slightly near the torch wall region as shown in Fig. 6 (a). The concentration profiles of oxygen atoms and molecules are shown in Fig. 6 (c) and (d), respectively. Injected oxygen molecules exist near the torch wall through the downstream region. The dissociated oxygen atoms exist broadly to the torch center owing to the recirculation. Oxygen injection from the top of the torch results in the broad distribution of dissociated oxygen atoms.

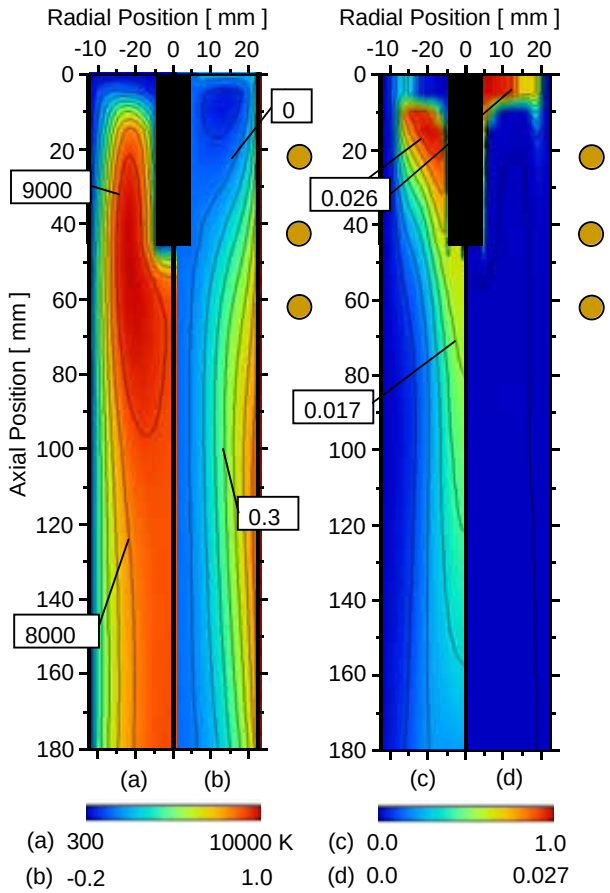

Fig. 5 (a) Isotherms, (b) streamlines, (c) O atom concentration, and (d) O_2 concentration distributions in an Ar-O_2 plasma; Type (C): inner injection at 0.1 L/min.

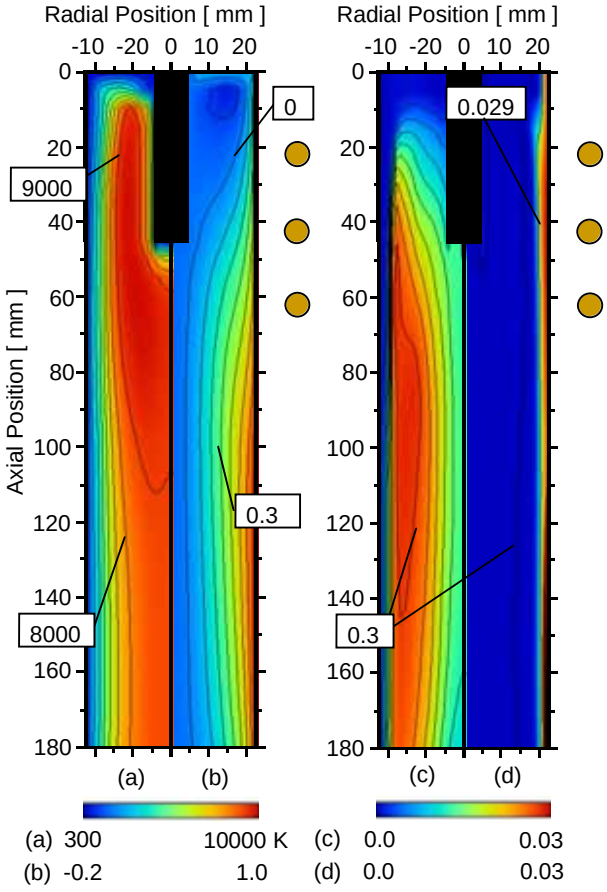

Fig. 6 (a) Isotherms, (b) streamlines, (c) O atom concentration, and (d) O_2 concentration distributions in an Ar-O_2 plasma; Type (D): sheath gas injection at 1 L/min.

Degree of CNE, δ, was introduced to evaluate chemical non-equilibrium of plasmas.

$$\text{Degree of CNE for dissociation: } \delta^{d}_{O_2} = \frac{[O]^2}{[O_2]K_d} \tag{9}$$

$$\text{Degree of CNE for ionization: } \delta^{i}_{O} = \frac{[O^+][e^-]}{[O]K_i} \tag{10}$$

In these definitions, value of $\delta = 1$ represents complete equilibrium. In non-equilibrium, $\delta > 1$ represents overpopulation of products and underpopulation of reactants for $\delta < 1$.

Fig. 7 presents the radial profiles of the degree of CNE due to dissociation of injected oxygen with type (B) at the center of the coil. The degree of CNE deviates strongly from the equilibrium value at the oxygen injection region. This indicates that the chemical non-equilibrium occurs at the injection region due to the effect of diffusion and finite reaction rate. In the downstream region, the chemical non-equilibrium occurs near the torch wall. In all injection types, the strong chemical non-equilibrium was found at the oxygen injection region and near the torch wall where the concentration gradient is high.

Fig. 8 shows the effect of oxygen injection on axial profiles of the degree of dissociation. High degree of dissociation is obtained by oxygen injection types (A) and (C). The high degree of dissociation in types (A) and (C) is attributed to the direct oxygen injection into the high-temperature region of plasmas. While, the degree of dissociation is low in the case of types (B) and (D), because oxygen molecules exist locally near the torch wall. Oxygen injection type (B) which is direct radial injection from the torch wall provides the lowest degree of dissociation. The lowest degree of dissociation results from the insufficient penetration of

injected oxygen into the high-temperature region of plasmas, therefore higher injection velocity is required to obtain higher degree of dissociation of oxygen.

Fig. 9 presents the effect of oxygen injection on axial profiles of heat flux to the torch wall. The low heat flux in the coil region in type (B) and (D) is due to the large amount oxygen flow along the torch wall, resulting in the severe decrease in the temperature. In contrast, the heat flux to the torch wall in type (A) and (C) is high. The contribution of the center or inner oxygen injection is small for lowering the heat flux to the torch wall by the oxygen injection.

Non-equilibrium modeling with finite reaction rates for various oxygen injection locations demonstrates the following results; chemical non-equilibrium exists at the region of high-concentration gradient such as oxygen injection region and near the torch wall. The degree of dissociation of oxygen and the heat flux to torch wall can be controlled by oxygen injection location. Therefore, suitable oxygen injection location needs to be chosen according to the application requirements. The present modeling would give the guidance for the rational design of new material processing with effective reactive gas injection into plasmas.

Effect of Metal-Wire Catalyst on Non-Thermal Plasma NO Decomposition

Nobuyuki Kikukawa, Yoshiaki Kintaichi, and Hideaki Hamada

National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba 305-8569, Japan

Abstract

We investigated NO decomposition reactions over metal-wire (Pd, Fe, Ni, SUS) catalysts in a DBD plasma. The catalysts were found to improve remarkably the NO*x* decomposition rate. The metal-wire was concluded to play a role of not redox reagent but catalyst. The catalytic active points were found to consist in the both end of metal-wire. The metal-wire catalyst also promoted N_2O formation rate depending on metal materials.

Moreover, the present work clearly indicates the importance of the catalytic effects of the electrode metals.

Keywords *nitrogen oxides, atmospheric pressure low temperature plasma, metal wire catalyst, DBD*

1. Introduction

Air pollution caused by nitrogen oxides (NO*x*) emitted from combustors and automotive engines is a serious environmental problem. Although catalytic NO reduction processes have already been put to practical use such as in three-way catalysts for gasolinefueled vehicles and in the ammonia SCR process for large-scale boilers, the development of effective abatement technique for such as diesel exhaust is still a subject to be solved.

There have been many attempts applying non-thermal plasmas (NTP) for de-NO*x* reaction [1]. But a few works have considered the catalytic effects of electrode metal [2-4]. *Takaki et al.* have examined NO*x* decomposition using several types of multipoint-to-plane geometry and found that this geometry effectively lowered the operation voltage. However, they used brass as an electrode material only and did not consider the effects of materials. *Hayashi et al.* developed a plasma chemical reactor using plasma-assisted catalytic technology (PACT) [3]. Using this concept, *Suib et al.* compared the de-NO*x* reactions using metal (Rh or Fe)-electrode reactors with that using all-glass reactors, and they observed much higher initial NO conversion and gradual deactivation with both metal electrodes [4], which clearly indicates the influence of the existence of metal substances in the plasma zone.

We have investigated plasma-assisted catalytic decomposition of NO using a dielectric barrier discharge (DBD) plasma reactor. In this presentation, we report the results of NO decomposition over metal-wire catalysts settled in the plasma zone.

2. Experimental

The DBD reactor used was parallel plane type, and was originally designed by Kodama and Sekiguchi [5]. The schematic of experimental setup was shown in Fig. 1. Both electrodes (80ϕ alunimum discs) were covered with quartz plates (1 mm thick). The chamber wall was made of polymethylmethacrylate (PMMA). Therefore, the

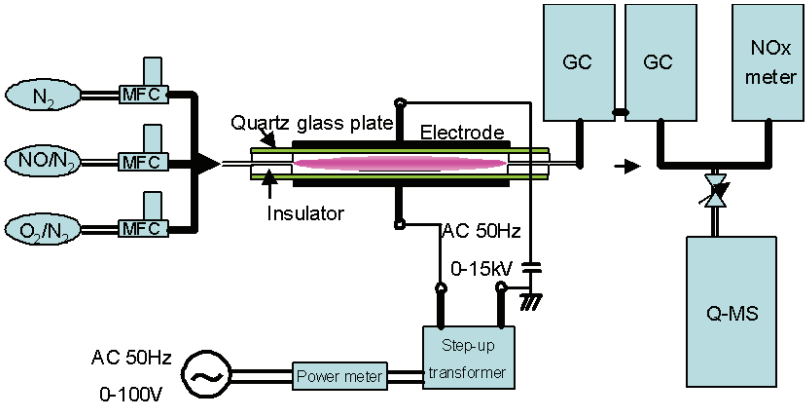

Fig.1 Schematic of experimental setup.

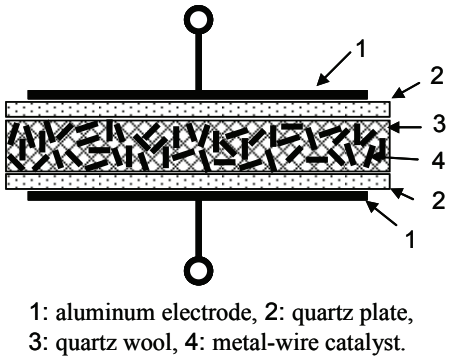

Fig.2 Schematic of plasma chamber.

generated plasma does not contact with any metal parts. The gap between electrodes was 10 mm.

The metal-wire catalysts used were Pd, Fe, Ni, SUS. Each wire or mesh was cut into short chips (2-3 mm). For comparison, a commercial Pd/Al_2O_3 powder catalyst (Pd: 5%, Wako Pure Chemical Ind., Ltd.) was also used. These catalysts were dispersed in quartz wool and put into the plasma chamber, as shown schematically in Fig. 2.

The reaction gas containing 1000 ppm NO, 0-10% O_2, and N_2 as the balance, was fed. The total flow rate was 20 ml/min. Some experiments were carried out with He as the balance gas. The effluent gas was monitored by a quadrapole mass spectrometer and was analyzed using a chemiluminescent-type NO*x* analyzer (Shimadzu MOA-305A) and two gas chromatographs with a Molecular Sieve 5A column (for the analysis of O_2, N_2, CO and NO) and a Porapak Q column (for that of N_2O and CO_2).

High voltage was supplied through a step-up transformer and the frequency was 50 Hz. The power was measured in two ways. One is input power to step-up transformer measured by a power meter (Hioki 3332)("gross power"). The other is power consumed in plasma which was calculated from *V-Q* Lissajous figure ("net power").

3. Results and Discussion

3.1 NO decomposition with/without metal-wire catalyst and with powder catalyst

Figure 3 shows the results of NO*x* decomposition rate, deduced from NO*x* analyser, in the presence of stainless steel (SUS) mesh chip catalyst compared with that in the absence of any catalyst. From the figure, it is clearly seen that the SUS catalyst improved the NO decomposition reaction. All metal-wire catalysts examined showed improving effects and lowered the minimum operating voltage.

Figure 4 shows the dependency of the NO*x* decomposition rate on O_2 concentration in reactant. The catalysts used were Pd wire chips (0.05ϕ, total length of 2 m, 0.045g) and Pd/Al_2O_3 (Pd: 5%, 0.94 g). Although the Pd weights of both Pd catalysts were almost same, powder-shaped Pd did not improve the NO*x* decomposition. This result implies that the catalytic effect should be attributed to the shape of the catalyst.

These metal-wire catalysts did not show any deactivation after long time experiments, indicated in Fig. 5. Moreover, according to a gas chromatogram shown in Fig. 6, the ratio of the amounts of product oxygen and nitrogen was nearly 1:1. From these results we can conclude that metal-wire plays a role of not redox reagent but catalyst.

Next, we examined the effect of the number of chips, that is, we cut a piece of Pd wire of 2 m long into 8, 32, and about 600 chips, and then we investigated the NO*x* decomposition. The result is shown in Fig.7, which clearly shows that the active points exist in both end of each Pd segment.

The fact that these metal-wires showed catalytic behaviours even in the case of oxygen-sensitive Fe implies that the "self-cleaning mechanism" found in vacuum arcs [6] might occur at the both end of metal catalyst chips. The detailed mechanism will be the subject to be solved.

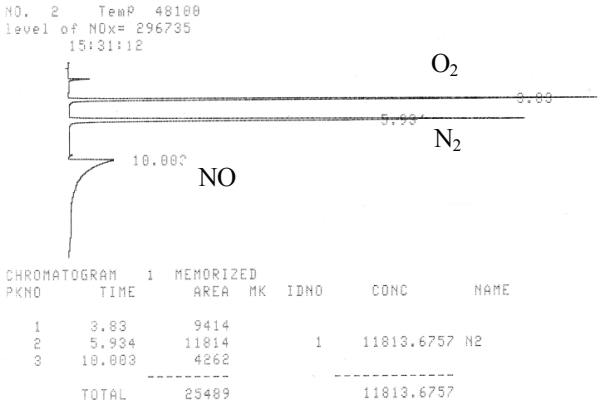

Fig.6 Example of gas chromatogram.
NO: 1060ppm, base He 60 ml/min, 10kVpk, Pd catalyst.

3.2 Effect of metal materials on product gas composition

In N_2-O_2-NO system, we also found that these metal-wire catalysts promoted a side reaction, N_2O formation. Figure 8 shows the N_2O concentrations in the presence of various metal-wire catalysts as a function of oxygen concentration in the reactant. The amounts of the catalysts were chosen so that the improvement of NO*x* decomposition was almost the same. From the figure, there are some differences of N_2O formation rates between metal materials. From the experiments of He-O_2-NO system, we found that the amount of the decomposed NO was equal to the amount of the generated N_2 and that negligible amount of N_2O was formed. Therefore, N_2O might be formed through the catalytic reaction of N_2 and O_2.

This effects is clearly shown in the experiments of N_2- O_2 system without NO (Fig. 9). Fe wire catalyst much more promoted the formation of NO and NO_2 as well as N_2O. Although the comparison among various metal materials is still inadequate, these results at least indicate that metal parts in plasma zone may substantially affect NO decomposition reaction.

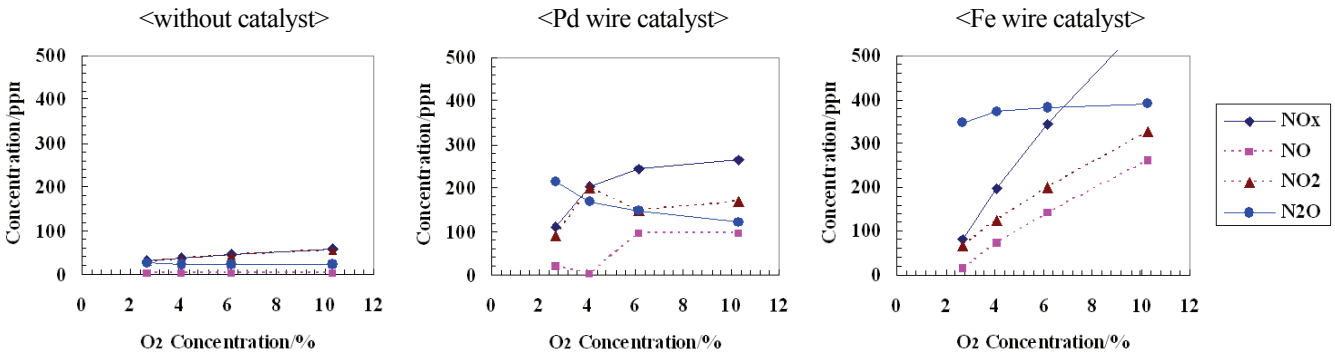

Fig.9 Product gas concentrations as a function of O_2 concentration in reactant gas.
[NOx]=[NO]+[NO_2], Initial NO : 0ppm, base : N_2 20ml/min, 22-24 kVpk.

3.3 Comparison of "gross power" and "net power"

Figure 10 shows the relationships between gross power and applied voltage (Fig.10a) and between net power and applied voltage (Fig.10b) in the N_2-O_2-NO system with several catalysts. From the figure, one can see the net power depends on the amount of metal-wire catalysts, while gross power is a simple function of applied voltage. The power dependency of NO decomposition with/without Pd-wire catalysts as functions of gross power (a) and net power (b) are shown in Fig. 11. From Fig.11b, the amount of Pd does not affect the NO decomposition rate. Therefore, the amount of Pd-wire catalyst affects the energy efficiency that means how much energy was absorbed in plasma from input energy. Since the gross power directly affects electric energy consumption, this improving effect of metal-wire would lead to a new energy saving plasma reactor. Moreover in Fig.11b, the difference of NO decomposition rates between with Pd-wire catalyst and without catalyst should be regarded as the net catalytic effect.

4. Conclusion

Through the experiments on the plasma-assisted catalytic NO decomposition in DBD reactor, we found that the NO*x* decomposition rate remarkably increased in the presence of metal-wire catalysts and that N_2O formation rate also increased. The metal-wire was found to play a role of not redox reagent but catalyst. The catalytic active points are concluded to consist in the both end of metal-wire.

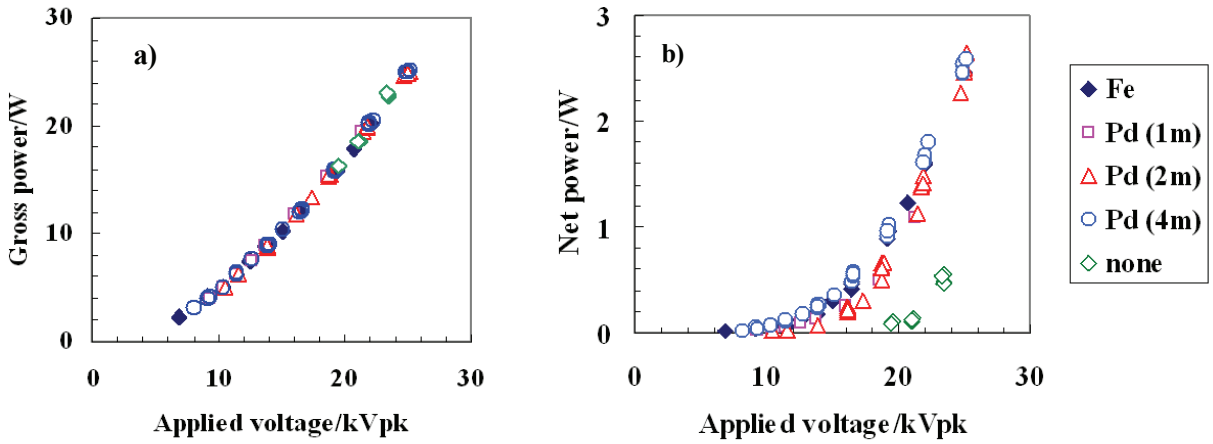

Fig.10 Relationships between applied voltage and gross power (a) net power (b) in N_2-(O_2) plasma with/without several metal-wire catalyst.
Pd (1m), Pd (2m), Pd (4m) : total Pd wire length were 1m, 2m, 4m, respectively.

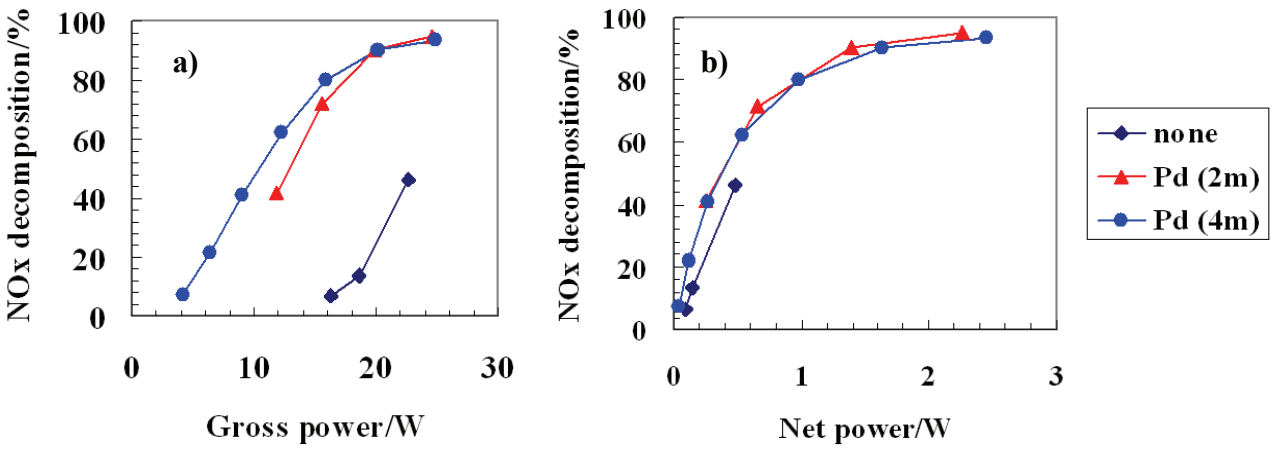

Fig.11 NOx decomposition rate with Pd-wire catalysts as functions of gross power (a) and net power(b).
NO : 1000ppm, O_2 : 2.7%, base : N_2 20 ml/min.

Finally, the primary effect of metal-wire catalyst probably consists in improving the energy efficiency, and depending on the metal materials, there appear somewhat the differences of product gas composition as the secondary effect.

Moreover, the present work clearly indicates the importance of the catalytic effects of the electrode metals.

Abstract

The densities of metastable He*(2^3S_1) atoms and electrons were measured in two-types of DBD plasma sources operated at atmospheric pressure in He containing a small amount of impurities, depending on the gas flow. It was found that the Penning ionization of He*(2^3S_1) atoms with impurities contributes considerably to the production of electrons. Both densities are larger in a mesh-type system than in a conventional parallel-plate system by about five to ten times in accordance with the input power densities.

1. Introduction

Dielectric barrier discharge (DBD) has been enthusiastically investigated for the generation of glow discharge at atmospheric pressure range (APGD) [1]. Specific conditions for realizing APGD have been found, which depend on the electrode structure, gas species, flow rate and power-source in each experimental situation. In order to find out generalized conditions based on physical parameters, plasma diagnostics in DBDs must be performed systematically. In the first step towards the purpose, we have performed the measurement of metastable He*(2^3S_1) atoms with diode laser absorption spectroscopy as well as the measurement of electron density with mm-wave transmission experiment in two different types of DBDs as described below. The obtained results in those two types of plasma sources are compared with each other and argued on the production and loss processes of metastable atoms and electrons.

2. Experimental

We have been using two types of electrode structures with the DBD scheme. One is a conventional parallel plate system with electrodes of 60 mm diameter covered by ceramic (Al_2O_3) insulating plates of 1 mm thickness at a gas gap of 3 mm [2]. A unique pulsed power supply was used, in which the primary square-wave bipolar-pulse train was amplified by a high-voltage transformer, so that the output waveform had a high-voltage impulse followed with a ringing tail as shown below. The other is an integrated type of coaxial-hollow microdischarges with metal mesh electrodes covered by thick Al_2O_3 films [3]. The latter structure is shown in **Fig. 1** together with the driving pulse waveform and the discharge image in N_2. The firing voltage with this structure is as low as 500 V in He gas and 1.2 kV in pure N_2 gas at atmospheric pressure.

We measured the absolute density of He metastable atoms in the 2^3S_1 state by a laser absorption spectroscopy (LAS) technique using a tunable diode laser operated at around 1083 nm. The absolute density of He*(2^3S_1) atoms was derived from the integrated area of the absorption line profile [4]. The plasma density in these DBDs was estimated from the transmission of mm-waves in the frequency

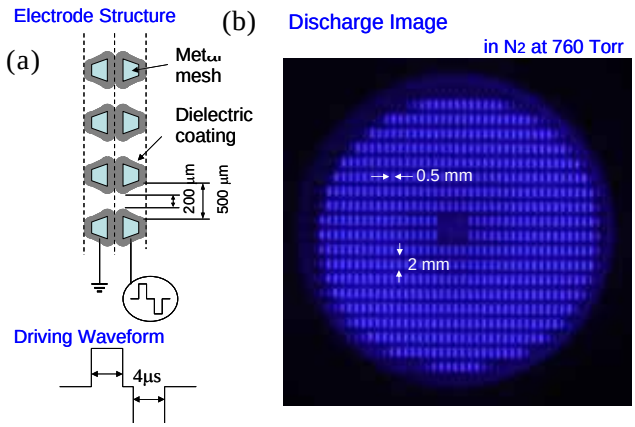

Fig. 1 (a) Structure of mesh-type system and driving waveform, and (b) discharge image in N_2.

range from 50 to 75 GHz.

3. Results and Discussion

3. 1. Discharge characteristics

The driving waveform in the parallel plate system is shown in **Fig. 2 (a)** and the operating regimes are classified in **Fig.2 (b)** by eye observation in the parameter ranges characterizing the waveform. To investigate the underlying physics, we analyzed the transferred charge to each electrode by the conduction current as shown in **Fig. 3**. From the result it is seen that the glow-like (uniformly looking) discharge is realized when the accumulated charge by the impulse current is almost erased by the following ringing current. This suggests that even if a non-uniform charge distribution is formed at first, the following current sweep out the source of the positive feedback which leads to the filamentation of the discharge. In the microdischarge integrated type (mesh-type) system, there observed is no current constriction in each cell and the discharge looks glow-like. Uniformity was also good over the whole electrode area of 50 mm diameter.

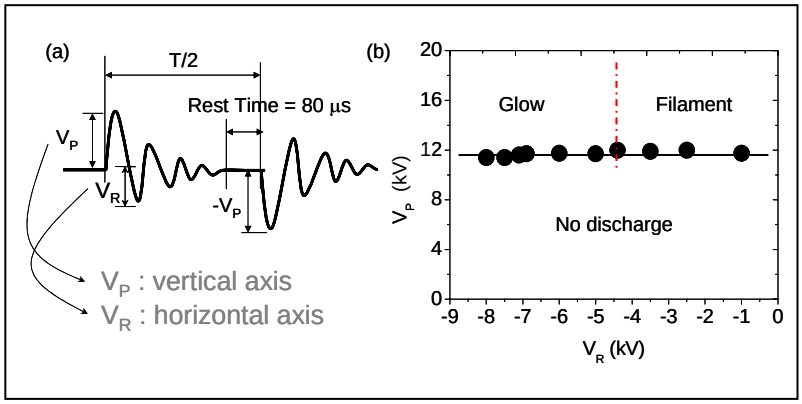

Fig. 2 (a) Driving waveform of parallel plate system and (b) operating regimes in the parameter plane of waveform characteristics.

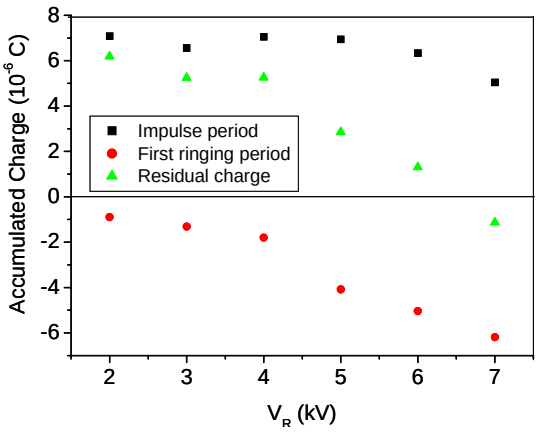

Fig.3 Accumulated charge in the first and second periods and the residual charge.

3. 2. Measurement of metastable atom density

The results on the density of metastable He*(2^3S_1) atoms N_m measured by the LAS method in the two configurations are shown in **Fig. 4**. It is seen that the density in the parallel plate system is smaller by about an order of magnitude than the mesh-type system in the active plasma region. The reason will be attributed to the difference in the electron density as argued below. The density of He*(2^3S_1) atoms depends strongly on the gas flow rate. It suggests that the impurity concentration decreases as the gas flow rate increases.

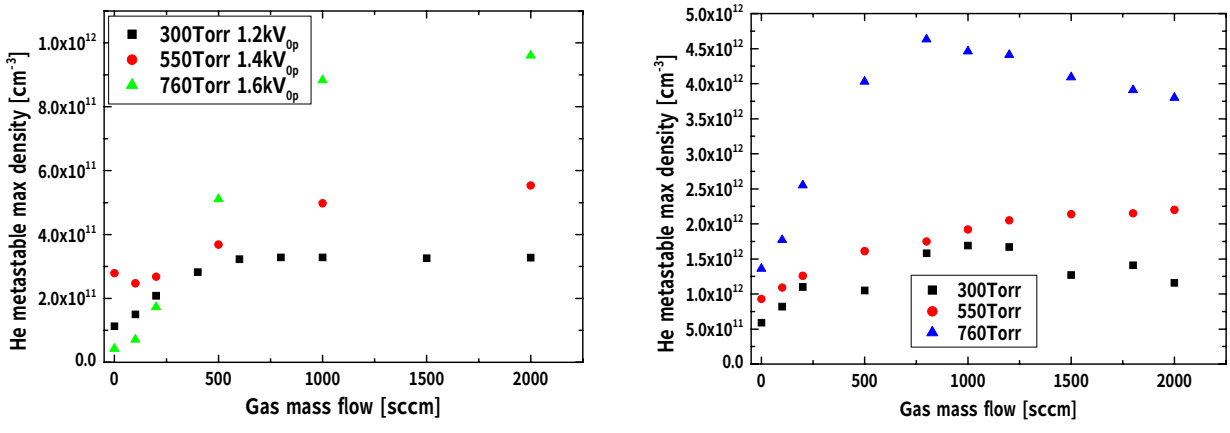

Fig. 4 Density of He* metastable atoms measured in (a) parallel plate system and (b) mesh-type system at several pressures as a function of the gas flow rate.

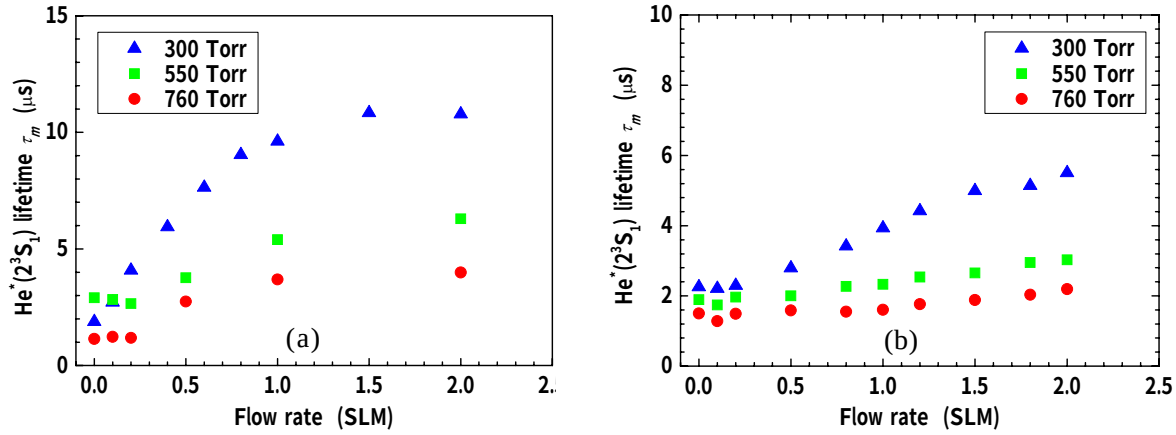

Fig. 5 Lifetime of He*(2^3S_1) atoms measured in (a) parallel plate system and (b) mesh-type system under situations corresponding to those given in Fig. 4

Figure 5 shows the lifetime of He*(2^3S_1) atoms τ_m measured under the same experimental conditions as in those given in Fig. 4. From the comparison of Fig. 4(a) and Fig. 5(a), it is seen that both the He*(2^3S_1) atom density and the lifetime behave similarly in the parallel-plate system. It suggests that the impurity level is decreasing with the gas flow rate. However, the absolute values of the lifetime are still smaller than those estimated from the rate constant of the three-body collisional process; He*(2^3S_1) + 2He → He_2 + He. If the difference is attributed to quenching by the Penning ionization with N_2, the major impurity species, the impurity concentration is estimated to be about 100 ppm at the flow rate more than 1 SLM. On the other hand, in the mesh-type system the measured lifetime keeps increasing gradually with the flow rate, but the absolute values are smaller than those in the parallel plate system. It is due to the smaller dimension of the mesh-type system with larger surface losses. The saturating tendency of the He*(2^3S_1) atom density observed in this system at the higher flow rate may be attributed to the effect of blowing-out loss of plasma species which leads to the decrease of plasma density.

3. 3. Measurement of electron density

The temporal transmittance characteristics of mm-waves were analyzed for the derivation of electron density [5]. The results are shown in Figs. 6(a) and 6(b) for the absolute density of electrons n_e and the corresponding lifetime τ_e measured in the parallel plate system. For the data at 1 atm, both n_e and τ_e behave

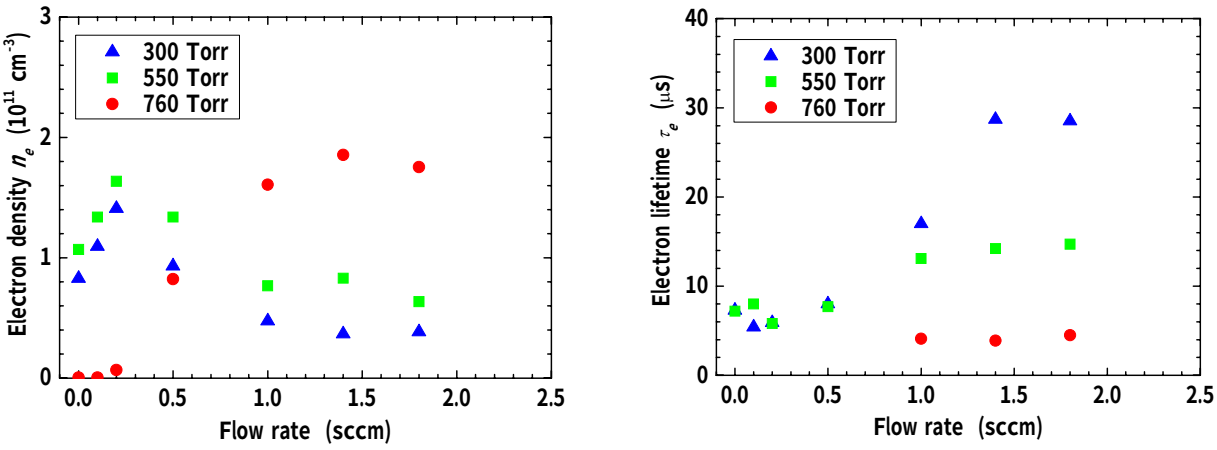

Fig. 6 (a) Electron density and (b) the lifetime measured in parallel-plate system as a function of the gas flow rate

similarly to the pressures probably due to the change in the contribution of the Penning ionization process to the production metastable atom density N_m and the lifetime τ_m, respectively. Noticeable differences are seen at lower of electrons, depending on the impurity level. However, the fairly large values of lifetime at those low pressure cases remain unexplained at the moment. At the atmospheric pressure, a comparison of waveforms of the mm-transmission and the laser absorption signal suggests that in the early period of rising current the direct ionization process is predominant, but in the afterglow period the contribution of the Penning ionization becomes important for the production of electrons.

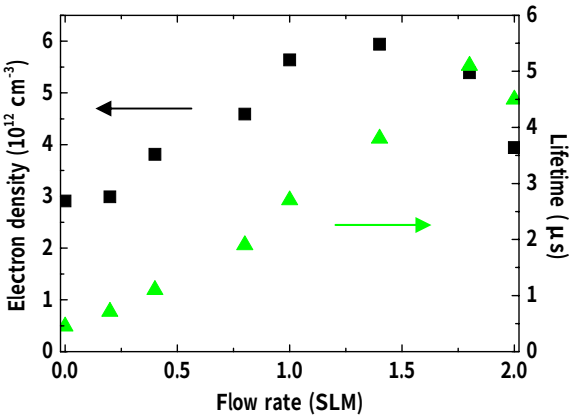

Fig. 7 Electron density and the lifetime measured in mesh-type system as a function of the flow rate.

The results of n_e and τ_e measured in the mesh-type system at 1 atm are shown in **Fig. 7**. It is seen that n_e increases with the gas flow rate and then saturates similarly to the density of He*(2^3S_1) atoms. However, the behavior of τ_e is somewhat different, showing a larger increasing tendency at higher flow rates. The reason for this discrepancy should also be answered later. We are now working on the measurement in the mixture of He with N_2 by varying the mixing ratio up to 100%. As a preliminary result, the measured values of n_e take a peak at a N_2 concentration of 1%, showing the maximum contribution of the Penning effects to the production of electrons. The full results will be shown at the time of the symposium.

4. Concluding Remarks

The density of He*(2^3S_1) atoms in the metastable state was successfully measured in two different types of DBD systems in pure He gas containing a trace of impurities. The densities measured in the mesh-type system were larger than those in the parallel plate system by five to ten times. The electron density estimated by the mm-wave attenuation in the mesh-type ranged on the order of 10^{12} cm^{-3}, which was also larger than the values obtained in the parallel plate system. However, by considering the difference in the active volume of those systems, the production efficiency of the metastable atoms and electrons per input electric power is equivalent in both systems. Experiments in N_2 are going on, in which the density of N_2^+ ions is also going to be measured by a laser induced fluorescence (LIF) technique as well as the mm-wave transmission technique.

Abstract
We pick up two typical plasma reactions, which we have tried recently, and discuss about the effectiveness of micro channel for plasma reaction. One is the plasma CVD in the inner surface of micro channel and another is the plasma decomposition reaction of CO_2 in a micro channel. From these demonstration, we can conclude that the plasma reaction in a micro channel can be achieved with high effectiveness and efficiency, if the reaction is selected properly, considering the reaction time and the diffusion time which characterize the phenomena in the plasma in a micro channel.
Keywords: micro plasma, micro channel, plasma CVD, CO_2 decomposition**.**

1. Introduction

Various micro plasmas have been developed and many basic and application studies have been done since the concept of micro plasmas was proposed[1-5]. In particular, application studies of micro plasmas in the fields of micro total analysis system (μ-TAS) and micro electro mechanical system (MEMS) have been developed extensively.

Generally, the advantage of plasma chemistry is to promote selective reactions effectively among active species generated by electron impacts in the plasma. A micro channel reactor has enough wide area to deactivate the active species and it is not suitable to the plasma chemistry, in this point of view. A micro plasma reactor can be useful sometimes, however, if the inner surface area is utilized positively.

In the past studies, for example, it has been recognized that, in the steady-state of electrical discharge of CO_2, a significant amount of CO_2 equilibrates with CO even if the input energy and gas residence time are increased and it is difficult to decompose CO_2 completely into CO and O_2 by the conventional plasma reactors[6]. As shown in this paper, the micro channel reaction has a potential to complete such a decomposition reaction.

In the heterogeneous reaction such a micro channel reaction with having wide surface area, we can determine whether the dominant reaction takes place in bulk or at surface by comparing characteristic diffusion time (τ_d) and characteristic gas phase reaction time (τ_r). For example, we consider the following dissociation reaction of molecule (*AB*) in plasma phase.

$$e + AB \rightarrow A + B + e$$

In the heterogeneous system, which contains the surface, usually it works as a catalytic wall and reactive species, either *A* or *B*, which diffuses to surface is lost at surface immediately. In this situation characteristic diffusion time (τ_d) is expressed, for example, such as b/V by using diffusion velocity V of species and micro channel gap b. And also V is evaluated such as D/b by diffusion coefficient. On the other hand characteristic gas phase reaction time (τ_r) can be expressed such as $1/kC_i$ by using species concentration C_i and recombination reaction rate k. By using these parameters we can select the effective plasma reaction in the micro channel reactor configuration.

In this paper, We pick up two typical plasma reactions, which we have tried recently, and discuss about the effectiveness of micro channel for plasma reaction. One is the plasma CVD in the inner surface of micro channel and another is the plasma decomposition reaction of CO_2 in a micro channel.

2. Plasma CVD Reaction on Inner Surface of Micro Channel.

Plasma CVD reaction on inner surface of micro channel is effective. Especially, it is effective when using unstable chemical compound as a precursor. We tried uniform plasma chemical vapor deposition (P-CVD)

process on inner surface of a micro capillary and a micro channel generating plasma inside a micro channel[2]. This process has an advantage to be able to coat the inner surface of a micro channel after graving a micro channel on a glass plate and fabricating glass plates by fusing, instead of using lithography technique.

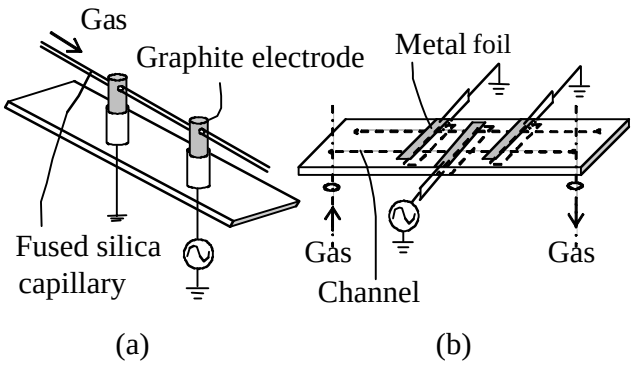

Fig.1 Electrode arrangements for palasma CVD in microchannel.

2.1 Micro channel plasma CVD method[7].

We tried uniform plasma chemical vapor deposition (P-CVD) process on inner surface of a micro capillary and a micro channel generating plasma inside a micro channel[2]. Figure 1 shows schematics of the electrode layouts of the micro capillary plasma and of the micro channel plasma in a Pyrex chip. The micro capillary plasma was generated by dielectric barrier discharge between cylindrical graphite electrodes (ϕ4mm) pierced by a capillary as shown in Fig. 1(a). The distance between the centers of the electrodes was defined as the electrode gap (20mm). A fused silica capillary of 450 m o.d., 320 m i.d., and 150mm length (Shimadzu) was used. For the micro channel (100 m×40 m×60mm) fabricated in a Pyrex chip (Institute of Micro chemical Technology), micro channel plasma was generated by the discharge between metal foil electrodes attached to the outer surface of the Pyrex chip as shown in Fig. 1(b). We chose the platinum film for CVD demonstration, which is used widely as catalyst, electrode, sensor, etc. For this purpose, we used platinum (II) bisacetylacetonate ($Pt(C_5H_7O_2)_2$) as a precursor, which was diluted by Ar, He, or O_2. Micro plasmas can be generated in a micro capillary (450μm o.d., 320μm i.d.), and a micro channel (100μm) fabricated in a chip by applying a few kilo volts by using outer electrodes at a few Torr. After P-CVD processing, the capillary with deposited film is cut in some parts and dissolved into hydrogen fluoride acid to measure the platinum quantity in each part by inductively coupled plasma mass spectrometry (ICP-MS). Also, effects of changing plasma power on distribution of platinum quantity deposited on inner surface of the micro capillary are investigated. Also the cross sectional view of deposited samples was observed with a scanning electron microscope.

Table 1 Experimental conditions of plasma CVD in micro channel.

No.	Run 1	Run 2	Run 3	Run 4	Run 5	Run 6
Frequency (kHz)	2	5	10	5	5	5
Current density (mA/cm2)	21	65	150	59	69	69
Power(mW)	25	59	130	53	63	63
Deposition time (sec)	30 Completion	150 Completion	375 Completion	50	120	160 Completion
Tt (℃)	170					
Tf (℃)	200					
Flow rate (sccm)	0.06					
Pressure (kPa)	1.0					
Peak voltage (kV)	2.6					

2.3 Characteristics of microchannel CVD

In our demonstration, if the voltage is properly controlled, for example at 2.6 kV as is indicated in Table 1, the film is almost evenly deposited between the electrodes. During the deposition of electrically conductive materials such as platinum, the plasma discharge has a peculiar behavior. When film deposition between electrodes is completed, the plasma in the capillary is extinguished. Deposition time for runs 1-3 and run 6 in Table 1 is the time in which film deposition is completed. After complete film deposition, surface discharge takes place at the outer capillary surface around the electrodes. This change of discharge is attributed to the electrical conductivity of the deposited film. Hence there is a fair possibility that the deposited film mostly consists in metal platinum.

Figure. 2 shows the profiles of the platinum amount deposited on inner surface of a fused silica capillary in runs 1-3. These results were obtained by varying the frequency. An increase in frequency corresponds to an increase in input power. The upstream and downstream electrode positions are located between –12~–8 mm and 8~12 mm, respectively. The results indicate that as input power is increased, the time required for film deposition completion is longer, and the amount deposited is larger. Although it is assumed that these results have a strong connection with the concentration gradient of a precursor generated at upstream range in the plasma, an accurate explanation to this phenomenon has not yet been found. Figure. 3 shows the profiles of the platinum amount deposited on inner surface of a fused silica capillary in runs 4-6. These three runs indicate the progression of the deposition profile in time for similar experimental conditions. The figure shows that little platinum is deposited around the point of the downstream electrode in runs 2 and 3. In these conditions, the decomposition of the precursor and film deposition mostly takes place at the upstream range in the plasma and the precursor is no longer transported to the range around the downstream electrode. In addition, judging from little deposition in the range of –20~–4 mm after 50 sec, it is clear that the plasma discharge region is shortened as film deposition proceeds. Therefore, it seems reasonable to conclude that film deposition starts locally at the inner surface attached with an upstream electrode, and is completed at a downstream electrode. Also SEM micrographs showed that the average deposition rate between electrodes is evaluated roughly at 16-22 nm/min, based on the film thickness of approximately 110-150 nm measured with some SEM micrographs.

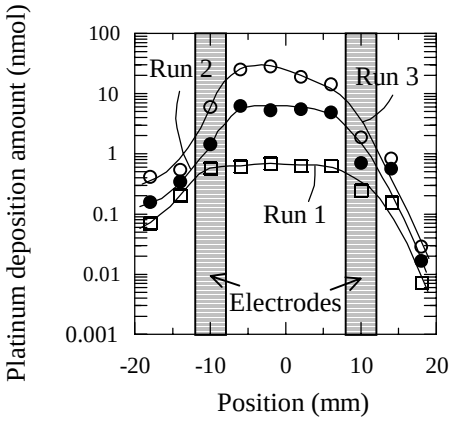

Fig. 2 Experimental results of plasma CVD for experiments for run 1 ~ run3

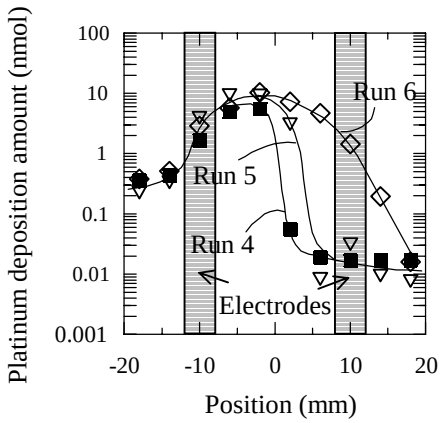

Fig. 3 Experimental results of plasma CVD for experiments for run 5 ~ run6

3. Dissociation Reaction of Carbon Dioxide[8].

We tried to carry out plasma decomposition experiments of carbon dioxide in a micro channel. This reaction is the typical one, whose heterogeneous effect is required very much. Because the recombination reaction takes place in the gas phase and the dissociation reaction of carbon dioxide can not completed only in gas phase plasma reaction.

3.1 Experimental Setup

The micro plasma reactor is a Pyrex glass tube of 48-mm length, 6-mm outer diameter, and 500, 1000, 1500-μm inner diameter, which is connected to the gas inlet and outlet line by 1/4" stainless steel union tee. In order to create the uniform glow discharge plasma in the capillary tube, the stainless steel union tees are used as hollow electrodes and a 50 Hz AC voltage (Max. 15kV) is applied between those two electrodes. Helium gas is used as carrier gas to stabilize the micro plasma. The conditions for discharge were as follows: discharge pressure was about 10–300 Torr, discharge voltage was 3.7 to 12.3 kV, discharge current was 0.8 to 19.8 mA, the mole ratio of helium to CO_2 was 1 to 4, and total gas flow rate was 6.8 to 60.8 cm^3/min (at 101.3 kPa, 293.15K). Composition of decomposed gas was measured by gas chromatography.

3.2 Numerical Simulation

The CO_2 decomposition in a micro plasma reactor have been studied experimentally and decomposition degree over 90% of initial CO_2 have been obtained without scavenger species that avoid recombination of O and CO. Similar studies, not in microscale reactors, are reported and low CO_2 decomposition degree are obtained in a case without scavenger species [1]. Therefore, downscaling effect in a plasma rector is conceivable. Since reactions of the CO_2 decomposition is very fast and flow rate through a reactor decreases as reactor size decreases, it is very hard to investigate precisely in experiments. In this study, we developed a model for describing the kinetics of the CO_2 decomposition in a micro plasma rector and carried out simulations to obtain characteristics of the CO_2 decomposition.

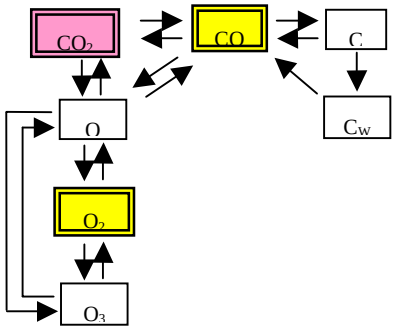

Fig. 4 Dominant channels of the CO_2 decomposition reaction in a micro plasma reactor.

Three types of reactions are considered: i) plasma reaction, ii) homogeneous reaction, and iii) heterogeneous reaction. Dominant reaction channels are shown in Fig. 1. Data of reactions and their rate coefficients are obtained from reports of CO_2 laser, O_2 glow discharge, and ozone generator, mainly. Heterogeneous reactions at a reactor wall is one of the most important process in effect of downscaling, and rate coefficients for those reactions are represented by $k=\gamma u/d$, where γ is the recombination probability, u is the mean molecular velocity, and d is the reactor diameter. The reactor in this study is a simple tube type reactor (Fig. 2). We carried out computer simulations for reactions about the CO_2 decomposition in a micro plasma rector and time evolutions of number density of each species were obtained. Conditions used in simulations are listed in Table 1 and simulated results are shown in Fig. 3.

3.3 Results

In these experiments we measured decomposition degree of CO_2 in each size of micro channel changing input energy, flow rate and pressure. The smaller size of reactor and the higher input power give the higher decomposition degree as we expected. Figures 4 show that the decomposition degree of CO_2 increases and saturates as current density increases. In these figures, all of data obtained in the channel diameter, 0.5mm and 3mm are plotted simultaneously. And it can be seen that their data have the same tendency and they can be fit on one curve line. This is the reason why each experiment for different diameter was carried out under the same residence time by changing each flow rate properly. Of course these results show that the data in the lower pressure saturate in the earlier period and gives the higher decomposed degree of CO_2 decomposition up to over 95%. Although it is not impossible to make the difference of the saturated values among micro channel diameters clear, because of difficulty of plasma experiments under the same flow rate, simulation results, whose data are virtual ones, can make them clear as shown in Figures 5. These figures include the numerical results calculated for large diameter, 10mm and infinity adding to the same channel diameter, 0.5mm 1mm and 3mm as experiments. Although the decomposition degree looks like being saturated, the decomposition reaction may be completed at last at infinity current density, which is not realistic..

4. Discussion

In these typical reactions, the surface, which is the most important characteristic in a micro channel, works effectively.

In plasma CVD experiments, it can be reasonable to conclude that film deposition starts locally at the inner surface attached with an upstream electrode, and is completed at a downstream electrode. Hence, we can suggest the model picture as following. When the plasma discharge in a capillary is maintained between a downstream electrode and the end of a deposited film instead of an upstream electrode, it is reduced in length as film deposition proceeds. After completion of film deposition, surface discharge at the outer surface around electrodes takes place and the inside discharge quits no longer and film deposition completed automatically. Fujiyama [9] reported such a behavior of discharge as “the extended anode effect” in plasma sputtering. This phenomenon works effectively to create uniform films in the P-CVD process even if the concentration gradient of the precursor in the micro channel is steep. In the usual plasma CVD reaction, it is very scarce that all of reactants dissociate and all of dissociated species deposit on the surface wall. This means that the micro plasma CVD complete with high efficiency, utilizing the characteristics of micro channel.

Also in the dissociation of CO_2, we can see that the heterogeneous reaction works effectively in such a

reaction as CO_2 dissociation. Plasma decomposition of CO_2 in gas phase has been tried by other researchers and they reported[6] that the decomposition degree could be improved up to 75% by using the reaction quenching technique. This means the upper limit of CO_2 decomposition in gas phase reaction. Although high temperature plasma can decompose CO_2 to CO and O very much, recombination reaction occurs simultaneously and consequently it gives low decomposition degree. In heterogeneous micro channel reaction, however, the micro channel wall works to promote consumption of O by O-O reaction and it can give such a high decomposition degree. We demonstrated the decomposition reaction to show the effectiveness of heterogeneous plasma reaction in a micro channel. In this point of view, the demonstration is successful, but the example is not proper as an application because of low pressure operation. It is very important to search more effective reactions to be applied, judging from the reaction time and the diffusion time, which we mentioned in above introduction of this paper.

These two examples which are the typical heterogeneous reaction suggest us how to use a micro reactor. We can conclude that the micro channel plasma reactor can be useful, if the suitable chemical reaction is selected.

5. Conclusion.

We mentioned two typical plasma reactions, which we have tried recently. One is the plasma CVD in the inner surface of micro channel and another is the plasma decomposition reaction of CO_2 in a micro channel. From these demonstrations, we can conclude that the plasma reaction in a micro channel can be achieved with high effectiveness and efficiency, if the reaction is selected properly, considering the reaction time and the diffusion time which characterize the phenomena in the plasma in a micro channel. We can also conclude that excellent ideas can lead the fruitful applications for the micro plasma reactor.

Abstract

Authors have developed a barrier discharge/catalyst hybrid reactor for the reforming of low-calorie fuels such as biogas (main component is methane) at low temperature (300°C~600°C). This technique allows utilizing low temperature thermal energy wasted from various industries, which eventually provides variety of energy utility options. The idea behind the project is that radicals produced by non-thermal plasma can be decomposed at much lower temperature than normal reforming condition. However, situation becomes even more complicated since barrier discharge enhances chemical reaction in many different ways: (1) Excited species, radicals, and ions decompose on catalyst at lower temperature than stable molecule. Life time of radical species has remarkable effect on synergistic effects. (2) Secondary products such as acetylene and ethane decompose at lower temperature than methane. Life time of those products is long enough so that they reach catalyst surface to decompose. (3) Heat generated by barrier discharge also enhances regular catalytic reforming. Relationship between discharge energy (J) and endothermic enthalpy (J) has remarkable effect on the increase in reaction temperature. In order to distinguish each contribution, steam reforming in regular catalytic reactor, barrier discharge reactor, and combination of these two has been demonstrated in detail. In addition, infrared camera was used to measure temperature distribution of catalyst bed for the best understanding of given hybrid system.

1. Introduction

Renewable energy from bio-resources such as organic wastes, landfill gas, and agricultural residues is attracting considerable attention with growing concern of energy saving and environmental protection. Since bio-resource is carbon neutral and potentially minimizes both consumption of fossil fuel and CO_2 emission. However, efficient use of bio-resource has major challenges. First of all, heating value of bio-resource is generally 20% to 80% of natural gas and many of them are flame-resistant. Diversity of composition and both moisture an energy content of bio-resource makes the situation even more difficult. Those “poor” resources are primarily upgraded for desired purpose; however, reforming reaction generally requires high temperature heat source (~800°C) where large part of initial fuel must be burned out, losing initial enthalpy of the fuel or resulting in much lower calorie fuel than it is before. Even though conventional catalytic reforming is a promising option, further development of existing process is being claimed with increasing demand of bio-resources.

More recently, atmospheric pressure non-thermal plasmas such as Plasmatron [1-2] and Glidarc [3-5] are recognized as economically competitive plasma fuel converters. Electrical energy consumption of those plasma reactors is normally less than 10% of heating value of the initial fuel when combined with partial oxidation. Because driving force of reforming reaction essentially depends on heat released by partial oxidation, while the plasma preliminary enhances the combustion process of low-calorie poor fuels. Unfortunately, heating value of resulting upgraded fuel is inherently low because air is used as oxidant that introduce large amount of nitrogen into the fuel.

From these aspects, authors have proposed combustion-free, low-temperature (300°C~600°C) steam reforming of low-calorie fuels using DBD/catalyst hybrid reactor [4-5]. The idea behind the project is that radicals produced by non-thermal plasma can be decomposed at much lower temperature than normal reforming conditions, and thus low temperature wasted thermal energy could be utilized in the process: reforming reaction is completely free from combustion of initial fuel. It does not necessarily mean that initial fuel is fully reformed since partially hydrogen enriched fuel remarkably improves combustibility and enables to drive an internal combustion engine. On the contrary, polymer electrolyte fuel cells, for instance, might not be an economically

compatible partner since the temperature of exhaust is too much low to drive hybrid reactor. Not only plasma reactor, but also appropriate energy utility system must be well considered so that a small amount of electrical energy input improves the entire energy system. Otherwise, consumption of electricity may become large and proposed plasma process will not be economically competitive. Up to now, authors have demonstrated that existence of non-thermal plasma in catalyst bed reactor enhances the hydrogen production rate. Radical injection due to non-thermal plasma is essential in order to derive synergistic effect between catalyst and plasma; however, situation becomes even more complicated in hybrid reactor since barrier discharge enhances chemical reaction in many different ways:

(1) Excited species, radicals, and ions are decomposed on catalyst at lower temperature than ground state molecules. Lifetime of radical species has remarkable effect on lowering reaction temperature.
(2) Secondary products such as acetylene and ethane also decompose at lower temperature than methane. Lifetime of secondary products is long enough so that they reach catalyst surface to decompose.
(3) Heat generated by barrier discharge also enhances regular catalytic reaction. Relationship between discharge energy (J) and endothermic enthalpy (J) has remarkable effect on the increase in reaction temperature.

In order to distinguish each contribution, steam reforming in regular catalytic reactor, non-thermal plasma reactor, and combination of those two has been investigated in detail. In addition, infrared camera was used to measure temperature distribution of catalyst bed for the best understanding of given hybrid system.

2. Experimental system

Figure 1 schematically shows experimental setup and Fig. 2 illustrates the configuration of barrier discharge/catalyst hybrid reactor. The rod-to-tube (ϕ_r 3 mm × ϕ_i 20 mm) reactor was located in a constant temperature bath where ambient temperature was 150°C to avoid liquid condensation. Catalyst pellets of 12wt%/γ-Al_2O_3 (3 mm) was packed in the volume of ϕ_i 20 mm × 50 mm. Bipolar pulsed voltage (+/- 20 kV at 1-5 kpps) was applied between center and external electrode. The discharge is ignited at pellet contacts, and then propagates covering pellet surface. We used simulated biogas which includes 60% methane and 40% nitrogen (CH_4:N_2 = 6:4). Steam and methane ratio (S/C) was set to one (S/C = H_2O/CH_4 = 1). S/C is normally set to between 2 and 3 in order to prevent carbon precipitation. We do not have to supply excess amount of water vapor since our purpose is partial steam reforming of initial methane, that is,

Initial composition: CH_4: N_2: H_2O = 6: 4: 6 ; where S/C = 1.
Steam reforming: $CH_4 + 2H_2O = CO_2 + 4H_2$; low temperature reforming does not yield CO.
Gas composition after 20% of methane converted (dry base) ; CH_4: N_2: CO_2: H_2 = 4.8: 4: 1.2: 4.8.

When methane conversion is 20%, hydrogen in the resulting gas is enriched by 32vol%. Initial S/C ratio (= 1) is large enough for converted methane to prevent carbon precipitation. Total gas flow (including CH_4, H_2O, and N_2) was selected so that space velocity (SV) becomes 10000 hr^{-1}. The reaction temperature increased up to 600°C with external electric heater, and discharge power was carefully selected so as not to exceed endothermic

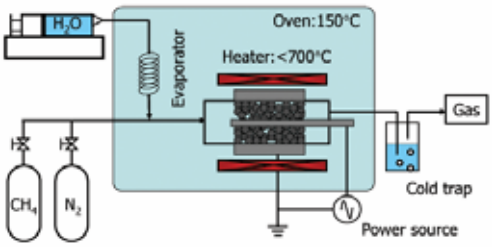

Fig. 1 Experimental setup of reactor.

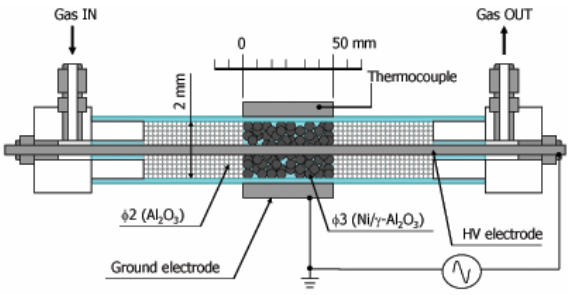

Fig. 2 Plasma/catalyst hybrid reactor.

enthalpy due to steam reforming of methane. Part of reaction gas was sampled after cold trap. H_2 and N_2 were analyzed by gas chromatograph equipped with TCD detector. Methane, CO, and CO_2 were measured by GC (FID) after methanation.

3. Enhancement of methane conversion in plasma/catalyst hybrid reactor

Figure 3 shows methane conversion with respect to electrode temperature in both hybrid and normal catalyst reactor. It is no doubt that methane conversion in hybrid reactor is larger than those in regular catalyst reactor. It is interesting why such high rate could be resulted from combined reactor. This question has not been understood well, and it is important to investigate reaction mechanisms for further improvement of given hybrid reactor. From next section, we will investigate the reaction mechanism in plasma/catalyst hybrid reactor. First of all, we will measure catalyst bed temperature distribution during reaction and see how electrode temperature could be different from catalyst bed temperature that directly influences reforming reaction.

4. Catalyst bed temperature measurement

We used infrared camera to measure catalyst bed temperature. Figure 4 shows temperature measurement setup. The external electrode has a square window that allows infrared signal coming out of the bed medium. The reactor is made of sapphire in this measurement so that infrared signal transmits the reactor wall. The infrared camera made a focus to 10 mm × 50 mm square window and detected signals. The camera was calibrated in advance. The advantage of

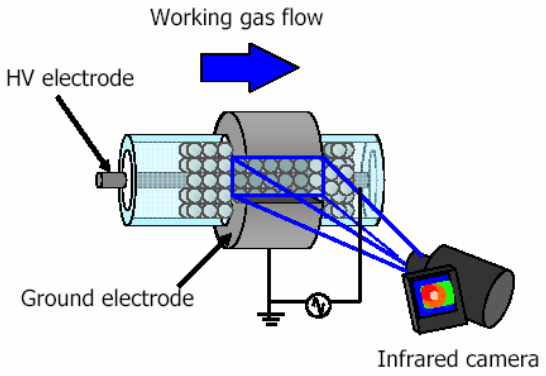

Fig. 4 Temperature measurement setup.

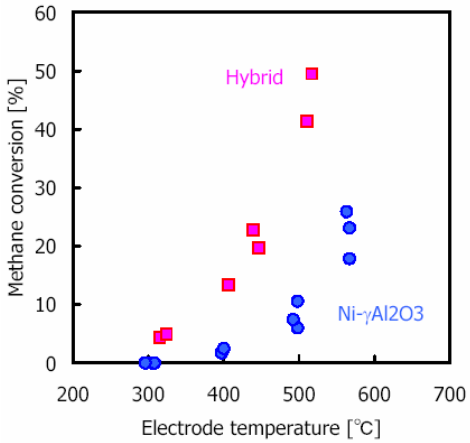

Fig. 3 Methane conversion vs. electrode temperature. SV = 10000 hr^{-1}, $CH_4/N_2/H_2O$ = 1100/733/1100 sccm (S/C = 1). Discharge power = 25-220 $kJ/mol_{\_CH4}$

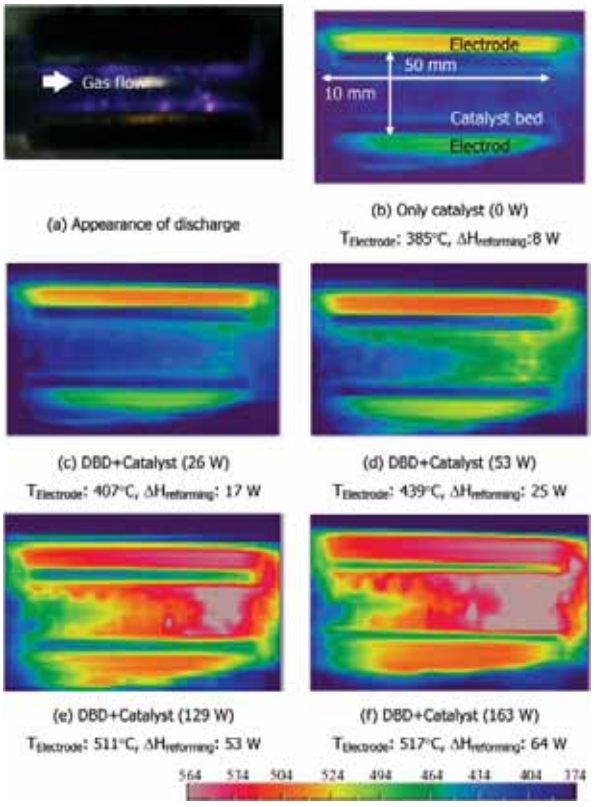

Fig. 5 Temperature distribution of catalyst bed. P: Discharge power, Q: Endothermic enthalpy, SV = 10000hr^{-1}, $CH_4/N_2/H_2O$ = 1100/733/1100 sccm (S/C = 1).

using infrared camera is that temperature distribution in bed medium is obtained by in situ and results are not disturbed by either electrical noise or visible light emission from plasma.

Figure 5 (a) shows actual picture of reactor during plasma operation. Figure 5 (b) shows an infrared image of catalyst bed without plasma, and (c) through (f) corresponds to the bed temperature with plasma. A caption of each image shows discharge power, endothermic enthalpy of steam reforming, and temperature of ground electrode which was measured by thermocouple. In the case of (b), temperature of the bed is almost uniform. In the case of (c) where discharge power (P) and endothermic enthalpy of methane steam reforming (Q) is the same level, temperature distribution is still uniform. And these temperatures were almost same level as electrode temperature. However, in the case of P > Q, i.e. from (d) to (f), we observed that bed temperature in downstream was 200°C higher than inlet. It suggests that both feed gas and catalyst bed were heated by plasma, and bed temperature is not uniform and increases much higher than electrode temperature. Reaction mechanisms must be analyzed on the basis of catalyst bed temperature.

5. Contribution of secondary products to the synergistic effect

Three different conditions were investigated in the hybrid reactor shown in Fig. 2: (1) Ni/γ-Al_2O_3 (without plasma), (2) hybrid (plasma and Ni/γ-Al_2O_3), and (3) plasma with α-Al_2O_3 (without catalyst). Figure 6 compares methane conversion obtained by three different conditions. The results clearly show that methane is hardly decomposed by barrier discharge since discharge power was limited in order to avoid excess gas heating, i.e. input power was carefully adjusted so as not to exceed endothermic enthalpy. Input power density with respect to methane flow rate was smaller than 120 kJ/mol$_{_CH4}$. According to Fig. 6, Ni/γ-Al_2O_3 catalyst is more effective than barrier discharge, but result does not reach equilibrium because the space velocity is high (SV = 10000 hr^{-1}). On the other hand, combined result reached equilibrium all the way through the temperature tested. Plasma produces secondary products such as acetylene and ethane. Those products also contribute to low temperature catalysis of methane since they decompose at lower temperature; however, yield of secondary products is obviously negligible small. Thus contribution of those products to the synergistic effect can be reasonably neglected.

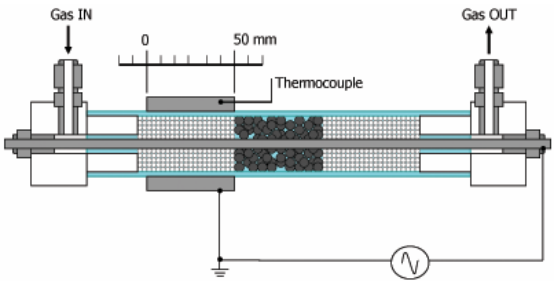

Fig. 7 Plasma pre-processing reactor.

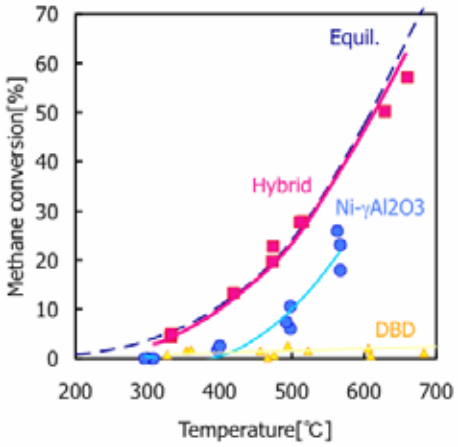

Fig. 6 Methane conversion between DBD and Ni-γAl_2O_3 catalyst. SV = 10000hr^{-1}, $CH_4/N_2/H_2O$ = 1100/733/2200 sccm (S/C = 1). Power = 25-120 kJ/mol$_{_CH4}$.

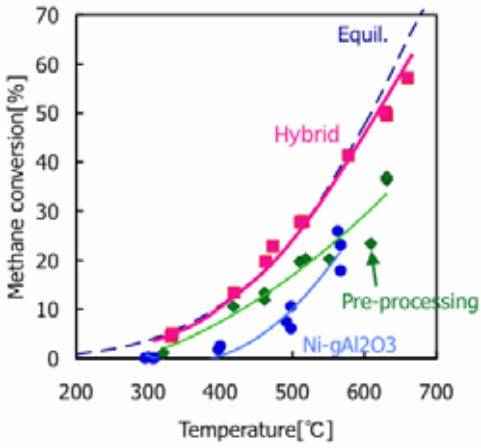

Fig. 8 Methane conversion between hybrid reactor and plasma pre-processing reactor. SV = 10000 hr^{-1}, $CH_4/N_2/H_2O$ = 1100/733/1100 sccm (S/C = 1). Discharge power = 25-120kJ/mol$_{_CH4}$.

6. Contribution of radical injection to the synergistic effect

In this experiment, we used plasma pre-processing reactor in order to separate the effect of heat produced by barrier discharge. Figure 7 describes schematic diagram of plasma pre-processing reactor. All radicals are most likely to be deactivated before flowing into the catalyst bed. On the other hand, the feed gas is heated up by plasma and flows into the catalyst bed. Plasma zone must be placed right in front of the catalyst bed in order to minimize heat loss thorough reactor wall. The results obtained by pre-processing reactor are shown in Fig. 8, comparing (1) Ni/γ-Al_2O_3 (without plasma), (2) hybrid (plasma and Ni/γ-Al_2O_3), and (3) plasma pre-processing reactor. The pre-processing reactor adds only thermal energy and methane conversion increases up to equilibrium when bed temperature is lower than 450°C. The hybrid reactor supplies both radicals and thermal energy, and methane conversion in hybrid reactor is larger than those obtained in pre-processing reactor: the differecen between those result corresponds to the effect of radical injection. Non-thermal plasma mainly produces heat and radicals. The heat produced by non-thermal plasma maintains bed temperature at desired level, while radical injection promotes chemical conversion process at given temperature. However, contribution of radical injection become remarkable when bed temperature is higher than 450°C.

7. Conclusion

We developed combustion-free, low-temperature steam reforming of low-calorie fuels using barrier discharge and catalyst hybrid reactor. Some of the important aspects are as follows:

[1] Synergistic effect between barrier discharge and Ni/γ-Al_2O_3 catalyst was observed. Methane conversion is enhanced at lower temperature than normal reforming condition. The chemical conversion process can be enhanced by both radical injection and heat generated by plasma. On the other hand, contribution of secondary products such as C_2H_2 and C_2H_6 is negligible small.

[2] Non-thermal plasma also works as an excellent heat source. It has remarkable effect between 300°C and 450°C of bed temperature. Heat is released uniformly through reactor volume. Unlike auto-thermal reforming, non-thermal plasma does not require additional oxygen to burn out a part of feed gas. Therefore it is free from catalyst oxidation and additional CO_2 which may be a cause of coking problem.

[3] Radical injection has remarkable effect when the bed temperature exceeds 450°C. Although radical species can be decomposed at lower temperature, it still requires at least 450°C of bed temperature.

[4] When $P \approx Q$, where Q is endothermic enthalpy and P is discharge power, temperature of catalyst bed is maintained uniform. If $P >> Q$, temperature of the bed increases significantly from the downstream of catalyst bed.

Abstract
A non-equilibrium modeling of argon-oxygen and argon-hydrogen induction thermal plasmas was performed without thermal and chemical equilibrium assumptions. Reaction rates of dissociation and recombination of diatomic gas and ionization were taken into account. A substantial deviation from LTE exists near the torch wall in argon-oxygen induction plasmas under atmospheric pressure, while small deviation in argon-hydrogen plasmas results from the large collision frequency electrons and hydrogen atoms.

1. Introduction

Induction thermal plasma approach has been applied for many fields. Attractive recent applications are treatment of harmful materials and recovery of useful material from wastes [1]. Another important application is production of high-quality and high-performance materials, such as synthesis of nanoparticles, deposition of thin films, and plasma spraying. In these applications, thermal plasmas with adding reactive gas are desirable to enhance the chemical reactivity of the plasmas.

Sophisticated modeling considering chemical reaction has been required for industrial applications. However, thermal plasmas have been mainly treated with equilibrium conditions. The purpose of this work is to develop two-temperature chemically non-equilibrium (2T-CNE) modeling of induction plasmas, comprising argon-oxygen and argon-hydrogen mixtures. This formulation including finite-rates of the dissociation and ionization is presented using higher-order approximation of the Chapman-Enskog method [2] for the estimation of the transport properties.

2. Numerical formulation

2-1 Thermodynamic and transport properties

Up to now, modeling of induction thermal plasmas has been performed with the first-order approximation of the Chapman-Enskog method because higher-order of Sonine polynomial expansion requires many kinds of collision integrals resulting in the complex formula. The first-order approximation may cause errors especially for electrical conductivity and thermal conductivity of electron translational contribution over

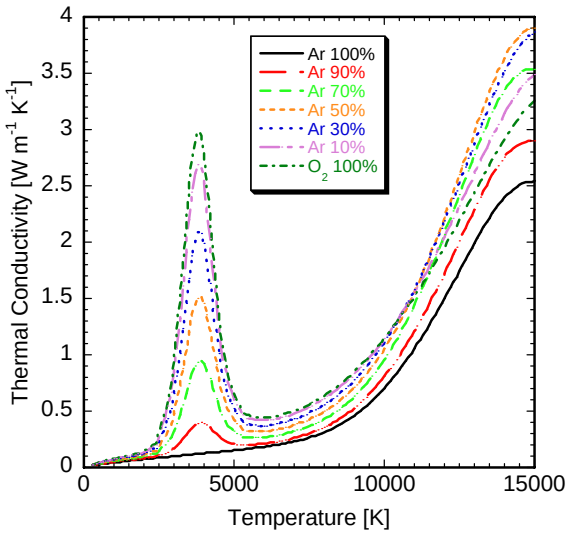

Fig. 1 Thermal conductivity of mixtures of argon and oxygen.

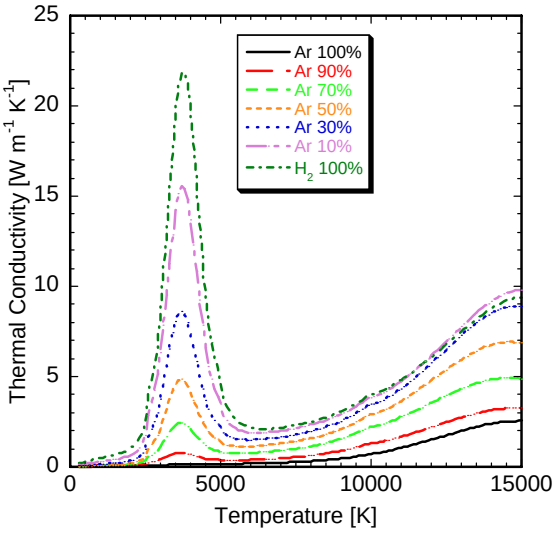

Fig. 2 Thermal conductivity of mixtures of argon and hydrogen.

10000 K [3]. Therefore, higher-order approximation is used according to the required accuracy in this study. The collision integrals were taken from the reference data which provide inter molecular potential and fitting data. Detailed descriptions of the estimation method of viscosity, thermal conductivity and electrical conductivity are given by Watanabe and Sugimoto [3].

Thermal conductivity of mixtures of argon-oxygen and argon-hydrogen are shown in **Figs. 1** and **2**, respectively. Thermal conductivity has high value where the dissociation and ionization occur. In mixture of argon and oxygen or hydrogen, thermal conductivity is proportional to the composition of their mixture. Viscosity of mixtures of argon-oxygen and argon-hydrogen are presented in **Figs. 3** and **4**. Viscosity has the maximum at 10000 K where the ionization begins to play important roles. In mixture of argon and hydrogen, viscosity decreases with hydrogen addition due to small mass of hydrogen.

In CNE model, the transport and thermodynamic properties are strongly related to the temperature and the composition of plasmas. Therefore, the transport and thermodynamic properties should be estimated considering the diffusion of species in plasmas at each calculation step until the convergence.

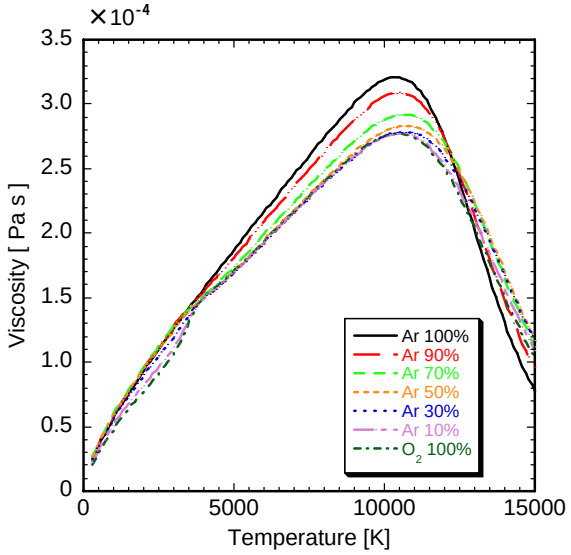

Fig. 3 Viscosity of mixtures of argon and oxygen.

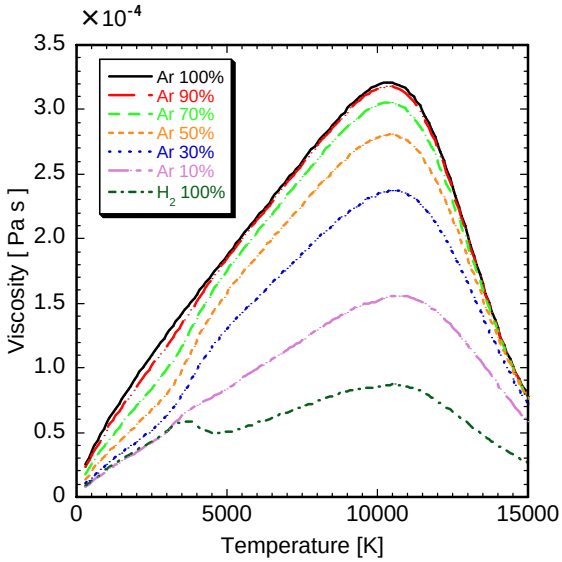

Fig. 4 Viscosity of mixtures of argon and hydrogen.

2-2 Kinetic rate constants

The equilibrium composition was estimated by FACT (Center for Research in Computational Thermochemistry), considering six species of Ar, Ar^+, O_2, O, O^+, and e^- in argon-oxygen plasmas and six species of Ar, Ar^+, H_2, H, H^+, and e^- in argon-hydrogen plasmas in this study. **Tables 1** and **2** summarize Ar-O_2, Ar-H_2 plasma reactions considered in this study, respectively. Twelve reactions comprising 6 forward reactions for each plasma and their backward reactions were taken into account. The reaction rates for the forward direction are given by Arrhenius equation.

$$k_l^f = a_l T^{b_l} \exp(-c_l / T) \tag{1}$$

For Ar ionization reaction, the reaction rate can be calculated with Eq. (2) [4].

$$k_l^f = 1.68\times10^{-20} T^{1.5} (135300/T + 2) \exp(-135300/T) \tag{2}$$

Table 1 Chemical reactions in argon-oxygen plasmas.

$Ar + e^- \rightarrow Ar^+ + e^- + e^-$	k_l^f was calculated by Eq.(2)		

2-3 Calculation model and assumptions

The geometry of calculation domain of the induction plasma torch is shown in **Fig. 5** and operating conditions are summarized in **Table 3**. Plasma gas and sheath gas composition were mixtures of argon and oxygen (3%) or argon and hydrogen (3%). The plasma torch consists of a water-cooled quartz tube, and is surrounded by a water-cooled induction coil. The coil consists of three turns and applies the induction frequency at 4 MHz to the plasma. The actual power level was assumed to be 5 kW.

The calculations are based on the following assumptions to derive the governing equations: (a) steady-state laminar flow; (b) axial symmetry; (c) optically thin; (d) negligible viscous dissipation in energy equation; (e) negligible displacement current in comparison with the conductive current; (f) negligible flow-induced electric field.

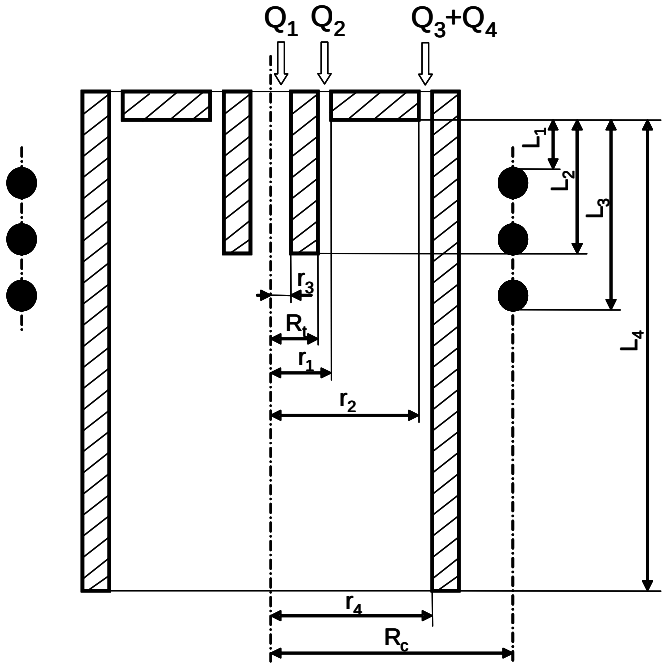

Fig. 5 Geometry of calculation domain of induction plasma torch.

Table 3 Torch characteristic dimensions and operational condition.

Torch Power	5 kW
Work Frequency	4 MHz
Reactor Pressure	101.3 kPa
Coil Radius	32 mm
Coil turn number	3
Wall thickness of quartz tube	1.5 mm
Distance to frontal end of coil (L_1)	19 mm
Distance to rear end of coil (L_3)	65 mm
Insertion length of probe (L_2)	45 mm
Torch length (L_4)	190 mm
Outer radius of inner slot (r_1)	6.5mm
Outer radius of outer slot (r_2)	21 mm
Inner radius of injection tube (r_3)	1 mm
Inner radius of quartz tube (r_4)	22.5 mm
Outer radius of injection tube (R_t)	4.5 mm
Flow rate of carrier gas (Q_1)	0 l/min
Flow rate of plasma gas (Q_2)	3 l/min
Flow rate of plasma gas (Q_3)	10l/min
Flow rate of sheath gas (Q_4)	20 l/min

2-4 Governing equations and boundary conditions

The field of flow, temperature and concentration in induction thermal plasmas were calculated by solving the two-dimensional continuity, momentum, energy (heavy particle and electron), and species conservation equations coupled with the Maxwell's equations. Reactions of the dissociation and recombination as well as the ionization were taken into account in this modeling.

Continuity:

$$\nabla \cdot (\rho \mathbf{u}) = 0 \tag{3}$$

Momentum:

$$\rho \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + \nabla \tau + \mathbf{J} \times \mathbf{B} \tag{4}$$

Energy (heavy particle):

$$\rho \mathbf{u} \cdot \nabla h = \nabla \cdot \left(\lambda_h^{tr} \nabla T_h\right) + \sum_{i(i \neq e)}^{N} \nabla \cdot \left(\rho D_i h_i \nabla Y_i\right) - \sum_{l(\beta_{el}^f \cdot \beta_{el}^r)}^{L} \Delta Q_l + E_{eh} \tag{5}$$

Energy (electron):

$$\frac{5}{2} k \nabla (\mathbf{u} n_e T_e) = \nabla \cdot \left(\lambda_e^{tr} \nabla T_e\right) - \frac{5}{2m_e} k \nabla (T_e \Gamma_e) - \sum_{l(\beta_{el}^f \cdot \beta_{el}^r \neq 0)}^{L} \Delta Q_l + \mathbf{J} \cdot \mathbf{E} - q_r - E_{eh} \tag{6}$$

Species:

$$\rho \mathbf{u} \cdot \nabla Y_i = \nabla \cdot \left(\rho D \nabla Y_i\right) + R_{ri} \tag{7}$$

Electromagnetic:

$$\nabla^2 \mathbf{E} - \xi\sigma\frac{\partial \mathbf{E}}{\partial t} = 0 \qquad (8)$$

The boundary conditions along the centerline were set to insure the axial symmetry. At the wall of the plasma torch, no slip conditions are maintained for the velocity, and the concentrations have zero gradient.

2-5 Calculation procedure

The governing conservation equations were solved using SIMPLER (Semi-Implicit Method for Pressure Linked Equation Revised) algorithm [5]. The governing equations and the electric field intensity equation with the associated boundary conditions were discretized into finite difference form using control-volume technique. Non-uniform grid points 30 by 30 were used for radial and axial directions, respectively. Grids were made finer close to the center and the coil region. Thermodynamic and transport properties were calculated from the temperature and compositions at each position in the calculation domain at each iteration step.

3. Result and discussion

The calculated temperature fields with the 2T-CNE model were presented in **Fig. 6 (a)**. The left is the heavy particle temperature (T_h), and the right is the electron temperature (T_e). The electron temperature near the torch wall of coil region is higher than the heavy particle temperature, although $T_e = T_h$ at the high-temperature region near the torch center. Radial temperature distributions by three models (LTE, 1T-CNE, 2T-CNE) in an argon plasma at the center of the coil are shown in **Fig. 7**. The electron temperature is 4000 K higher than the heavy particle temperature at r = 20 [mm]. In contrast, the distributions of the heavy particle temperature estimated from the three models are almost the same. These results reveal that substantial thermal non-equilibrium exists near the torch wall of the coil region in an argon plasma. The calculated streamlines were presented in **Fig. 6 (b)**. The left is the 2T-CNE result, and the right is the LTE result. The streamlines are almost the same between the results by the 2T-CNE and the LTE model.

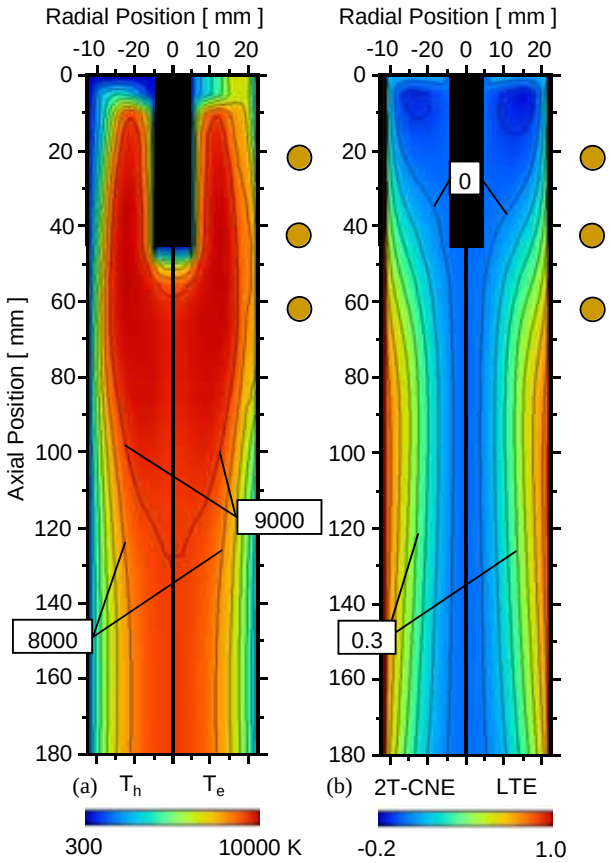

Fig. 6 (a) Heavy particle (left) and electron temperature (right), (b) streamlines by 2T-CNE (left) and LTE (right) model in an argon plasma.

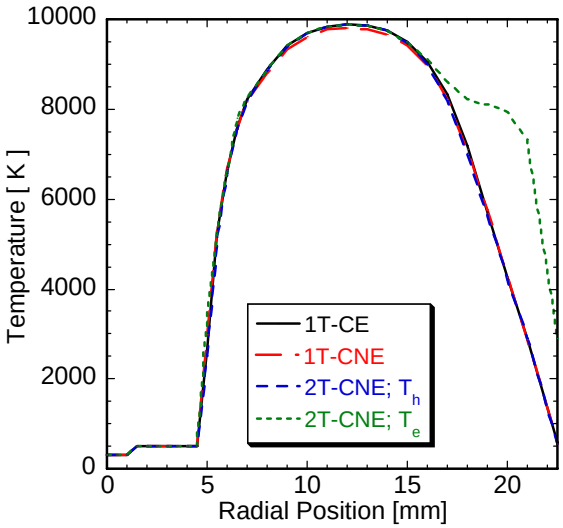

Fig. 7 Radial temperature distributions by three models in argon plasma at the center of the coil.

The calculated temperature (a), streamlines (b), and concentration contours of oxygen atom (c) in an argon-oxygen plasma are shown in **Fig. 8**. The electron temperature near the torch wall of the coil region is higher than the heavy particle temperature, indicating the same trend in an argon plasma. Oxygen atoms distribute broadly in the torch due to the low dissociation energy of O_2. Comparison of the number densities estimated by the 2T-CNE and the LTE model in an argon-oxygen plasma at the center of the coil are shown in **Fig. 9**. Deviation from the equilibrium composition exists near the torch wall, because the diffusion rate is larger than the recombination rate in this region.

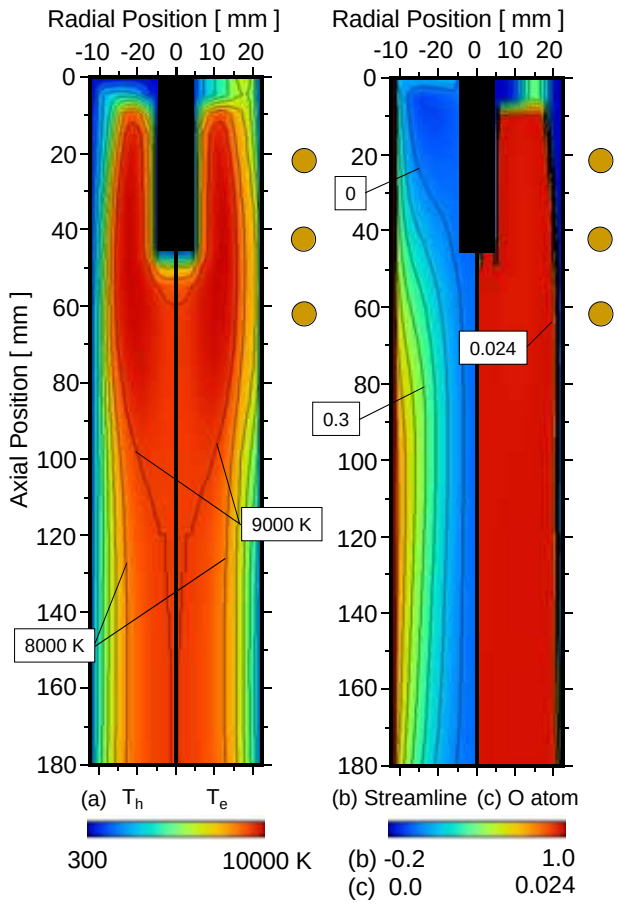

Fig. 8 (a) Heavy particle (left) and electron temperature (right), (b) streamlines (left) and oxygen atom distribution (right) in an argon-oxygen plasma.

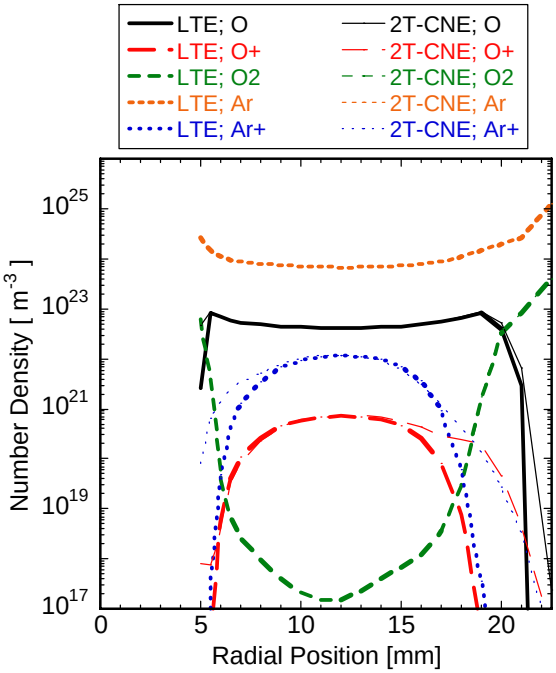

Fig. 9 Comparison of number densities between LTE and 2T-CNE model in an argon-oxygen plasma.

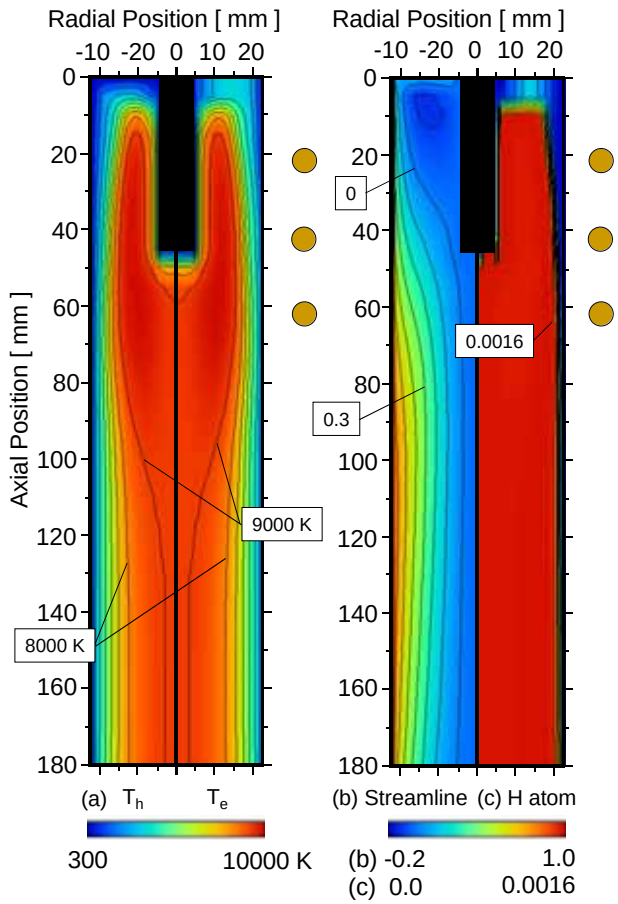

Fig. 10 (a) Heavy particle (left) and electron temperature (right), (b) streamlines (left) and hydrogen atom distribution (right) in an argon-hydrogen plasma.

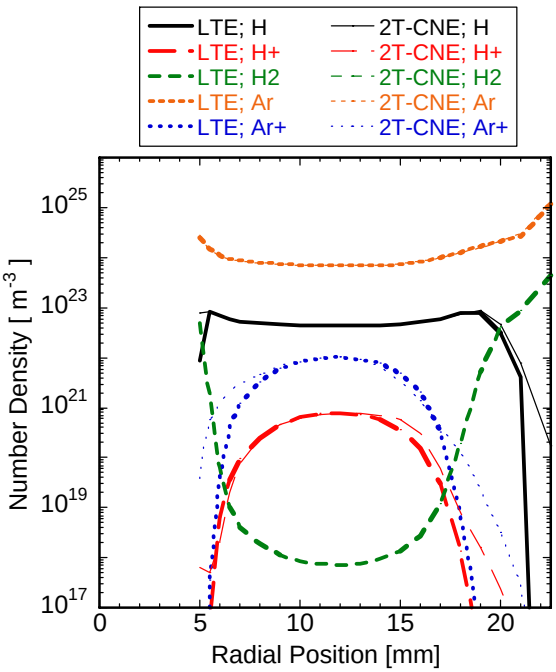

Fig. 11 Comparison of number densities between LTE and 2T-CNE model in an argon-hydrogen plasma.

The calculated temperature (a), streamlines (b), and concentration contours of hydrogen atom (c) in an argon-hydrogen plasma are illustrated in **Fig. 10**. Deviation between the electron temperature and the heavy particle temperature is small near the torch wall. The streamlines are almost the same with an argon and an argon-oxygen plasma. Hydrogen atoms distribute broadly in the torch due to the low dissociation energy of H_2. Comparison of number densities by the LTE with the 2T-CNE model in an argon-hydrogen plasma at the center of the coil are shown in **Fig. 11**. The deviation from the equilibrium composition exists near the torch wall, resulting in the similar characteristics in an argon-oxygen plasma.

Thermal non-equilibrium presented by the calculated results can be explained from the electron energy balance. The energy exchange from electrons to heavy particles is balanced to Joule heating rate in the region of $T_h \neq T_e$.

$$\sum_{i \neq e} \frac{3}{2} k(T_e - T_h) \frac{2 m_i m_e}{(m_i + m_e)^2} \nu_{ei} = \mathbf{J} \cdot \mathbf{E} \qquad (9)$$

In an argon-hydrogen plasma, the collision frequency (ν_{ei}) between electrons and heavy particles is higher than that of an argon and an argon-oxygen plasma near the torch wall due to larger collision integral between electrons and hydrogen atoms. Therefore, thermal non-equilibrium is weak in an argon-hydrogen plasma.

The degree of CNE (chemical non-equilibrium), δ, and Damkohler number, ζ, were introduced to evaluate chemical non-equilibrium in plasmas,

Degree of dissociation: $\delta^d_{O_2} = \dfrac{[O]^2}{[O_2]K_d}$ (10), Degree of ionization: $\delta^i_O = \dfrac{[O^+][e^-]}{[O]K_i}$ (11),

Damkohler number: $\varsigma = \dfrac{\delta_d}{\delta_r}$ (12).

where τ_d and τ_r are the characteristic times of diffusion and reaction, respectively. In these definition, $\delta = 1$, $\zeta \to \infty$ express equilibrium, $\delta \neq 1$, $\zeta \to 0$ indicates non-equilibrium.

The Damkohler number and the degree of CNE due to dissociation at the center of the coil region are shown in **Fig. 12**. The result of an argon-nitrogen plasma was taken from Ref. [6]. Near the torch wall, the degree of dissociation is high, then the corresponding Damkohler number is small. Consequently, the Damkohler number is strongly related to the degree of CNE. In an argon-nitrogen plasma, chemical non-equilibrium is more noticeable near the torch wall than that in an argon-oxygen and an argon-hydrogen plasma due to high dissociation energy of N_2. The corresponding Damkohler number is smaller in an argon-nitrogen plasma. Therefore, Damkohler number can be used as the indication to evaluate the degree of chemical non-equilibrium.

As a result, the present modeling reveals that thermal non-equilibrium and chemical non-equilibrium exist near the torch wall. Furthermore, Damkohler number is useful indication to evaluate the degree of chemical non-equilibrium in plasmas.

Abstract
Characteristics of 100%-steam plasma with DC discharge were investigated for the application of halogenated hydrocarbon decomposition. The presented steam plasma system is portable light-weight plasma generation system that does not require gas supply unit. The system has high-energy efficiency resulting from the unnecessity of water-cooling. The decomposition efficiency of 99.9% was obtained up to 0.43 mmol/kJ of the ratio of HFC-134a feed rate to the arc power.

1. Introduction

Halogenated hydrocarbons have been used widely as refrigerant, working fluid, foaming agent for plastics and insulating material, solvent, because of inflammability, no toxicity, and chemical stability. However, chlorofluorocarbons (CFCs) are revealed to be the matter of global warming and ozone depleting. Therefore, manufactures of CFCs have been prohibited by Montreal Protocol since 1987. Destruction of CFCs as well as research for the alternatives has been required.

CFCs can be effectively decomposed by reaction with hydrogen and oxygen; hydrogen combine with halogen to form halogenated hydrogen, oxygen combine with carbon to form CO and CO_2 to prevent reformation of by-products. Thus, destruction of CFCs with hydrogen and oxygen was demonstrated by argon plasmas [1]. However, hydrogen has disadvantage of high cost and explosibility, therefore steam plasmas that produce hydrogen and oxygen at high temperature are more favorable for industrial application of waste treatment. Radio frequency (RF) steam plasmas have performed high level destruction with ppm range concentration of destructed CFCs or halon in the exhaust gas [2]. Besides, small microwave steam plasmas for CFCs destruction have been used commercially [3].

Direct current (DC) plasma can be generated efficiently with simpler configuration than RF and microwave plasmas. Applications of DC argon plasma for CFCs destruction have already been operated with injection of oxidizing gas such as steam and oxygen [4-6]. DC steam plasma process was also applied to various waste treatments such as decomposition of PCB [7]. Nevertheless, the electrodes require protection from erosion derived from high reactivity of steam plasmas. In the PCB decomposition, tungsten cathode is protected by nitrogen or argon. In the steam plasma generation with several plasma gases, thoriated tungsten cathode is protected by using hydrogen [8].

Plasma generation system generally requires complex sub-equipments such as gas supply unit or cooling system. Especially steam plasma system requires sub-equipments such as heater to prevent condensation of steam through the reactor. Thus, efficient steam plasma generation system has been required for industrial application. The purpose of this paper is to generate stable steam plasma using portable light-weight DC plasma system without water-cooling and gas supply unit. Another purpose is to investigate decomposition mechanism of hydrofluoroethylene (HFC-134a) by the steam plasma.

2. Thermodynamic consideration

Thermodynamic equilibrium was calculated from the minimization of Gibbs free energy of the system with assumption that complete thermodynamic equilibrium is achieved. The chemical composition obtained from the calculation is probably not practical, however the thermodynamic equilibrium is useful to assess the important species in CFC decomposition. Thermodynamic equilibrium was calculated by FACT (Centre for Research in Computational Thermochemistry, Canada) to determine the species in plasma. FACT is database software for searching chemical equilibrium composition in which Gibbs free energy is the lowest.

Thermal equilibrium composition of pyrolised HFC-134a is shown in **Fig. 1**. CF_4 is the stable by-product under 2500 K, while HFC-134a does not exist. In the destruction of HFC-134a, suppresion of CF_4 production is strongly required, because the global warming potential (GWP) of CF_4 is 6500 times higher than that of CO_2. Chemical composition of water is shown in **Fig. 2** as function of temperature. H_2O dissociates to O and H at 3500 K. These dissociated O and H play important roles in the reformation control of undesirable

by-products.

Thermal equilibrium composition of HFC-134a decomposition with steam is presented in **Fig. 3**. The ratio of HFC-134a to steam is decided from the stoichiometric coefficient of following reaction.

$$C_2H_2F_4 + 4H_2O \rightarrow 4HF + 3H_2 + 2CO_2$$

Hydrofluorine is the most stable fluoride under 3800 K without undesirable by-products. Therefore, steam plasmas are suitable for decomposition of HFC-134a. HFC-134a with steam produces H_2 and CO from 800 K to 3500 K, resulting in reduction atmosphere.

Thermal equilibrium composition of HFC-134a decomposition is shown in **Fig. 4** in the case of low supply of steam:

$$C_2H_2F_4 + 2H_2O \rightarrow 4HF + H_2 + 2CO.$$

Hydrofluorine is the most stable fluoride under 4400 K without undesirable by-products.

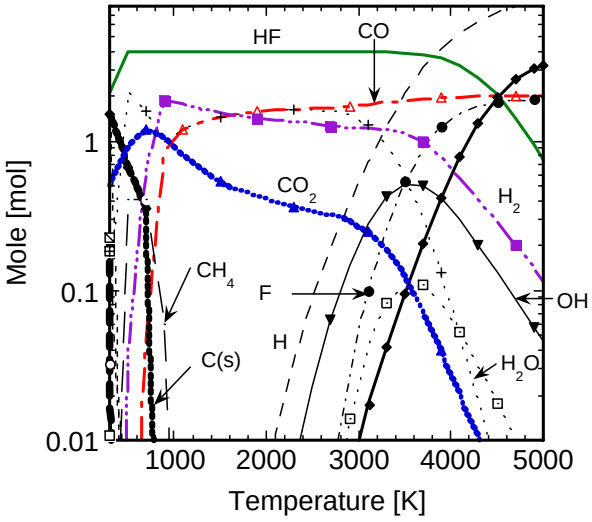

Fig. 3 Equilibrium composition of 20mol% HFC-134a and 80mol% steam.

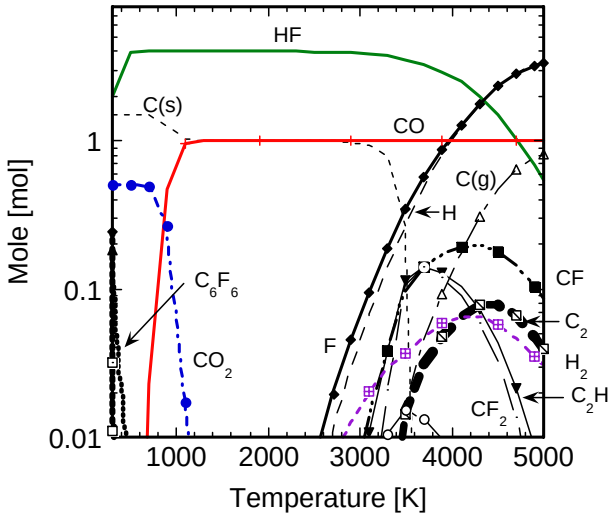

Fig. 4 Equilibrium composition of 33mol% HFC-134a and 67mol% steam.

3. Steam Plasma Generation

The steam plasma torch is a DC thermal plasma generator of coaxial design with a cathode of hafnium embedded into the copper rod and a nozzle-type copper anode. When steam plasmas are applied to waste treatment, the use of additional steam generator is unsuitable, because the steam generator requires larger and complicated system including the heating-up of the water feeding line preventing steam from condensation. The presented plasma torch can generate 100%-steam plasma without commercially available steam generator.

The configuration of the DC steam plasma torch is presented in **Fig. 5**. The advantage of the presented steam plasma torch is generation of 100%-steam plasma by DC discharge. The features of the torch result from the simple steam generation; water from the reservoir is heated up and evaporated at the anode region to form the plasma supporting gas. Simultaneously, anode is cooled by the water evaporation, therefore the electrodes do not require additional water-cooling. The distinctive steam generation method provides the portable light-weight plasma generation system that does not require the gas supply unit, as well as the high energy efficiency resulting from the unnecessity of the additional water-cooling.

The arc power was 0.65-1.47 kW with the arc current of 4.0-7.0 A. During the arc discharge, water feed rate is set at 325 mmol/min.

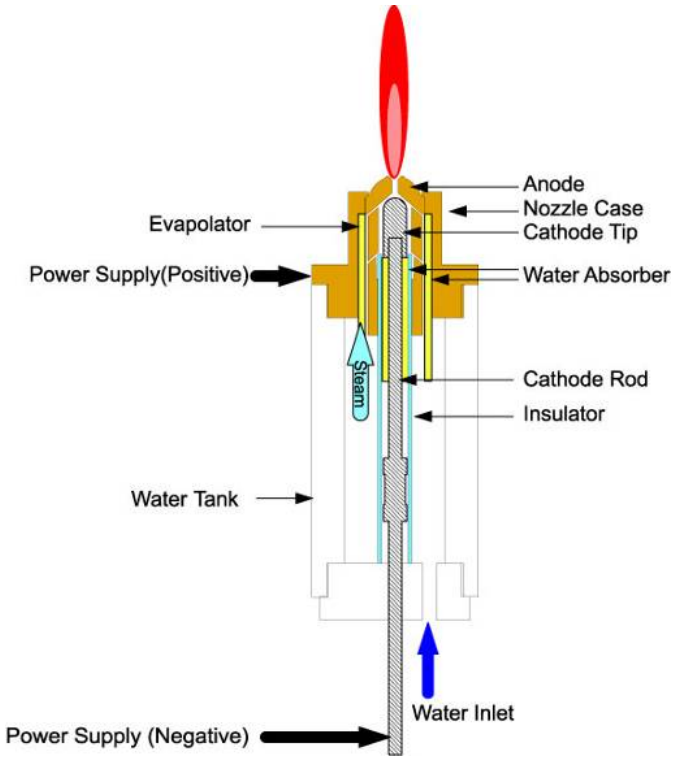

Fig. 5 Schematic diagram of steam plasma torch with DC discharge.

4. CFC Destruction System

Reaction tube and neutralization vessel are presented in **Fig. 6**. Reaction tube is water-cooled Inconel C-276 tube with inside diameter of 14 mm. Inconel C-276 is used as corrosion resistance material. HFC-134a was injected from the water-cooled tube at 8 mm upper from the nozzle exit of the steam plasma and at 7 mm outer from the center. Neutralization vessel is combined to the reaction tube to absorb F_2 and HF generated from the HFC-134a decomposition. Neutralization vessel is filled with pure-water monitored with pH meter. The destruction was performed with changing the feed rate of HFC-134a up to 185 mmol/min. The gas chromatography for monitoring of the exhaust gas indicated that productions of by-product such as CF_4 were not found. After the decomposition of HFC-134a, total organic compounds (TOC) and organic compound (OC) were measured to estimate the by-product concentration in the water with the pH measurements by

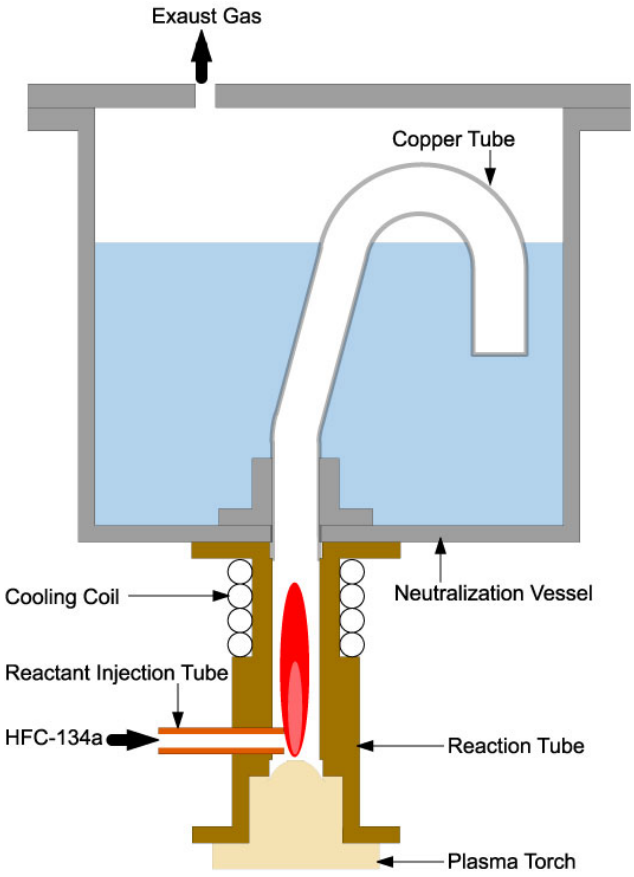

Fig. 6 Schematic diagram of CFC destruction system with steam plasma generator and neutralization vessel.

neutralization titration.

5. CFC Decomposition Results

The decomposition efficiency of HFC-134a can be evaluated from the recovery of the fluorine which is produced from the decomposition. Fluorine in the decomposition gas easily dissolves in water, therefore the recovery of fluorine is a good indication of the HFC-134a decomposition. The exhaust gas composition also provides the decomposition efficiency, however the estimation of the decomposition efficiency is complicated owing to the unknown peaks of the gas chromatographs and to the calibration of all peaks.

The decomposition results of HFC-134a with different injection locations are presented in **Fig. 7**. The recovery of fluorine was estimated from the pH measurements by neutralization titration of the water for the exhaust gas treatment after the HFC-134a decomposition. The injection of HFC-134a at the 8 mm from the nozzle exit of the steam plasma gives the complete recovery of fluorine, indicating the complete decomposition of HFC-134a. More downstream injection of HFC-134a leads to a decrease in the recovery of fluorine, because the plasma temperature decreases with the distance form the nozzle exit.

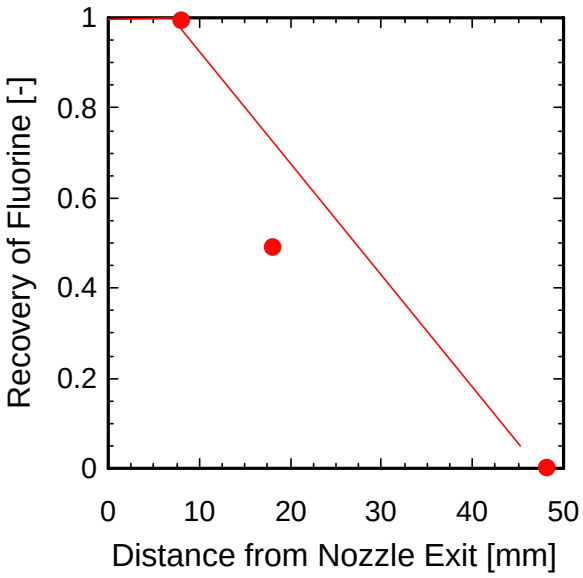

Fig. 7 Effect of HFC-134a injection location on recovery of fluorine. Arc power: 1.10 kW.

The effect of injection location of HFC-134a on the exhaust gas composition is shown in **Fig. 8**. HFC-134a injection at shorter distance from the nozzle exit leads to larger production of CO and CO_2. These results indicate the enhanced decomposition can be obtained from the HFC-134a injection at higher temperature. Besides, the selectivity of CO decreases with the distance, because the selectivity of CO decreases with a decrease in the decomposition temperature. This trend can be also expected from the equilibrium composition as shown in Figs. 3 and 4.

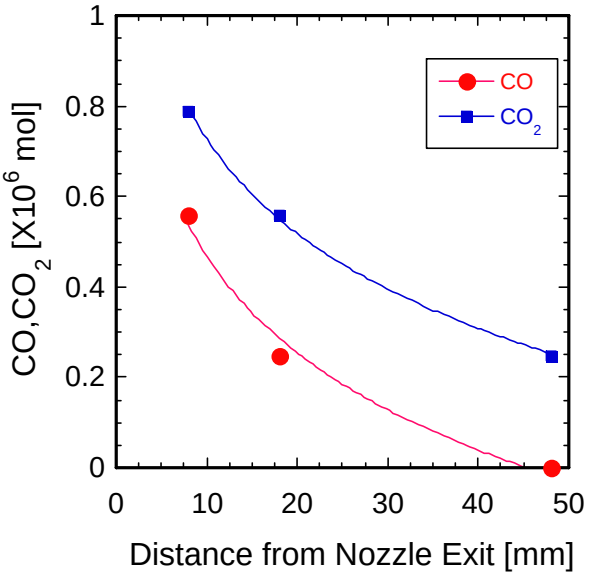

Fig. 8 Effect of HFC-134a injection location on CO and CO_2 production. Arc power: 1.10 kW.

The feed rate of HFC-134a into the high-temperature region has critical effect on the decomposition, because the maximum feed rate of HFC-134a depends on the enthalpy of the plasma. The effect of the feed rate on the recovery of fluorine is presented in **Fig. 9**. The recovery of fluorine at 99.9% can be obtained at 23 mmol/min of HFC-134a feed rate and at 1.47 kW of the arc power. The feed rate of HFC-134a over the threshold brings about the sudden decrease in the recovery of fluorine.

The effective decomposition is related to the feed rate of HFC-134a as well as the arc power, therefore the ratio of the feed rate to the arc power was calculated to estimate the decomposition efficiency. The effect of the ratio of the feed rate to the arc power on the recovery of fluorine is shown in **Fig. 10**, showing the comparable decomposition efficiency of the presented system with other CFC destruction systems. The recovery of fluorine with 99.9% can be obtained up to 0.43 mmol/kJ, hence the maximum feed rate is estimated to be 160 g/h at 1 kW of the arc power.

Effect of the feed rate of HFC-134a on CO_2 and CO production in the exhaust gas is shown in **Figs. 11** and **12**, respectively. Larger feed rate of HFC-134a leads to decreasing of CO_2 and CO production. This is

due to the temperature decrease owing to the larger feed rate of HFC-134a and to the insufficient mixing of HFC-134a at the high-temperature region of the steam plasma. Moreover, larger amount of CO is produced at higher arc power, resulting from the enhanced decomposition.

Fig. 13 presents the effect of feed rate of HFC-134a on the selectivity of CO in the exhaust gas. The selectivity of CO decreases with increasing of the feed rate of HFC-134a and with decreasing of the arc power, because CO is more stable than CO_2 at higher temperature. The temperature decrease in the plasma resulting from larger feed rate of HFC-134a is predictable from Fig. 13.

Analysis of by-product from the HFC-134a decomposition is presented in **Fig. 14**. Total organic carbon (TOC) in the water for the exhaust gas treatment was measured after the decomposition. There is a tendency of a decrease in TOC with increasing of the feed rate of HFC-134a, but the TOC can be negligible compared with the solubility of HFC-134a in water (1.5×10^{-2} mol/L). The measured organic carbon (OC), which is not shown, is also negligible in the water. Therefore, the main component in the water is HF after the HFC-134a decomposition.

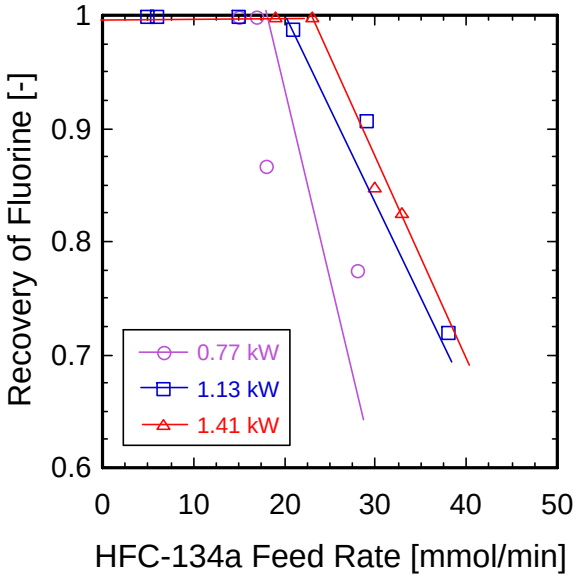

Fig. 9 Effect of HFC-134a feed rate on recovery of fluorine.

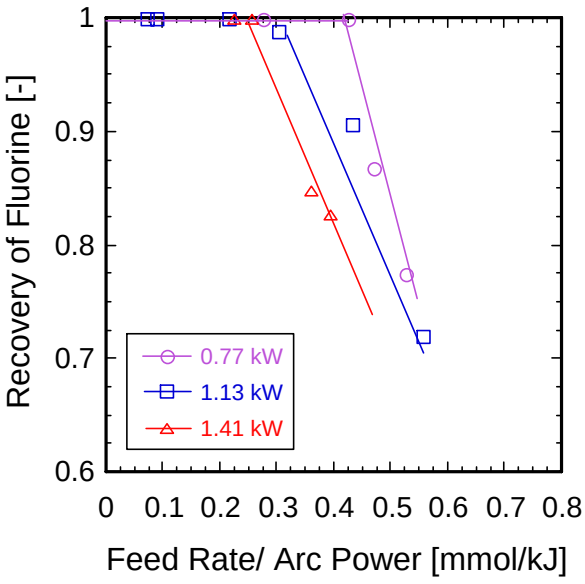

Fig. 10 Recovery of fluorine as a function of the feed rate normalized to the arc power.

6. Conclusions

Stable DC 100%-steam plasma generation under atmospheric pressure was developed for CFC decomposition.

Decomposition of HFC-134a produces CO, CO_2, and H_2 in the exhaust gas, and HF which can be recovered in the water of the neutralization vessel. The total organic carbon as the by-products after the decomposition can be negligible in the water. The decomposition efficiency of 99.9% can be obtained up to 0.43 mmol/kJ of the ratio of HFC-134a feed rate to the arc power, hence the maximum feed rate is estimated to be 160 g/h at 1 kW of the arc power. More detailed investigation is required to optimize the plasma system for industrial application.

Thermal plasmas such as steam would provide more capability for waste treatments, if thermal plasmas are utilized effectively as chemically reactive gas. Application of plasma systems for waste treatment is expected to downsize the system, reduce hazardous substances in exhaust gas, finally low cost of waste treatment.

Abstract

We have investigated the temporal and spatial resolved optical emission properties of the TiO_2 plasma plume generated by laser ablation using Nd:YAG laser. Emissions are dominated at neutral and ionic Ti (Ti I, Ti II) or neutral O (O I), and there are no emission species such as molecular TiO, TiO_2 and ionized molecular O_2. Ti I and Ti II species move with high speed of 1×10^4 m/s at the distance of 0.5 mm from the target. 2-dimentional ICCD images of plume emission indicated that spatial distributions of Ti I and Ti II species were different to each other.

Keywords: Laser ablation; Plasma plume; Titanium dioxide; Optical emission spectroscopy

1. Introduction

Pulsed laser ablation (PLA) has been used to prepare functional thin films. In order to fabricate high quality functional thin films and nano-structure materials, it is required to investigate the properties of pulsed laser ablation plumes. Especially, it is important to know the correlation between the plasma properties and characteristic of the deposited films. Optical emission spectroscopic (OES) analysis has been used to measure the plasma plume. OES measurement can monitor the in-situ ablation process without the external affect [1].

Titanium dioxide (TiO_2) has attracted much attention for its photocatalytic applications in the field of environmental sanitation. In previous research, we prepared TiO_2 thin films at various deposition parameters (ambient gas, substrate temperature, target materials, post-annealing) by using PLD technique and reported on the relationship between the deposition parameters and film properties such as crystalline structure, morphology, chemical composition and decolorization ability [2]. Recently, the development of photocatalysts shows a high activity under visible and/or solar light irradiation. Visible light photoactivity has been introduced to TiO_2 by doping of nitrogen or transition metals such as Cr and Pt. We have also attempted to synthesize nitrogen doped $TiO_{2-x}N_x$ thin films using TiN target in a nitrogen/oxygen gas mixture by PLD [3]. In photocatalytic test using methylene blue solution, the deposited $TiO_{2-x}N_x$ thin film was energized by visible light irradiation as well as UV light irradiation. However the correlation between the properties of the deposited films and the plasma characteristics has not been found.

This paper demonstrates a detailed spectroscopic investigation of plasma plume produced during the film deposition in order to estimate the processing plasma state and prepare high quality TiO_2 or $TiO_{2-x}N_x$ thin films. The temporal and spatial distributions and the optical emission species of plasma plume at various states using target materials and ambient gases were observed through a spectrometer and an ICCD camera.

2. Experimental

Experimental setup for measuring laser-ablated plasma plumes is shown in Fig. 1. A Nd:YAG laser (Continuum SureliteIII; wavelength of 532 nm, pulse duration of 3.5 ns, maximum output energy of 340 mJ) with a laser fluence of 4 J/cm^2 and a repetition rate of 10 Hz was used for ablating Ti (purity 99.99 %), TiN (purity 99.9 %) and TiO_2 (purity 99.99 %) targets. The vacuum chamber was evacuated to a base pressure of 5×10^{-4} Pa by a turbomolecular pump, and then filled with O_2 gas or N_2 gas or a mixed (O_2+N_2) gas of 10Pa at a flow rate of 20 sccm. Optical emission spectra were recorded through a spectrometer (Hamamatsu Photonics PMA-11) in the range of 200-800 nm at time delays (τ_d) varying from 50 to 1500 ns and distances (d) of 0.5-10 mm from the target surface. Two-dimensional plasma emission images were observed through an ICCD camera (Hamamatsu Photonics PMA-11). The gate width of 20 ns was kept fixed for the optical emission spectra and ICCD images measurements.

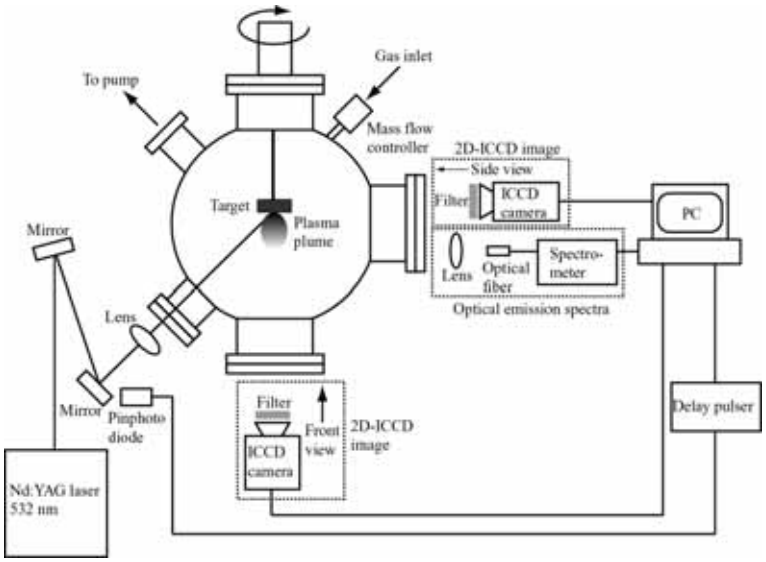

Fig.1 Schematic diagram of the experimental setup.

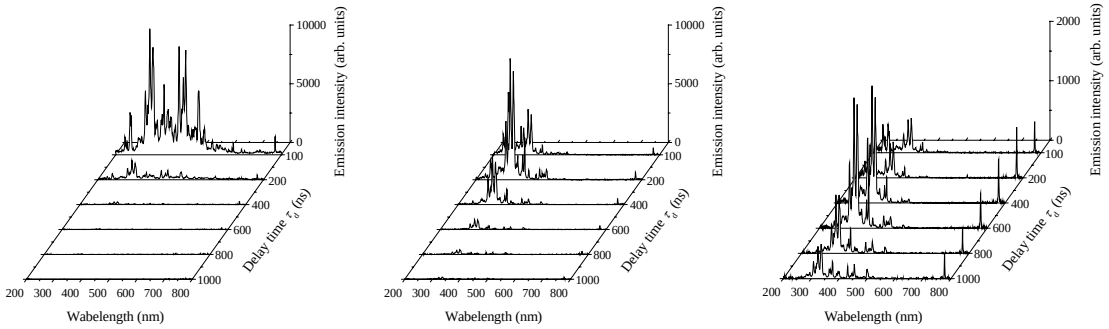
3. Results and discussions

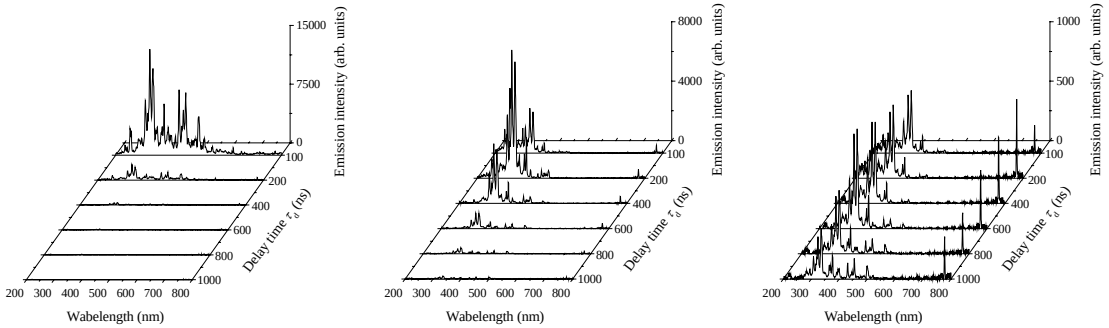
The optical emission spectra of the plume produced by ablating Ti, TiN and TiO_2 targets in O_2 gas of 10 Pa are shown in Fig. 2. These spectra were measured at the distances (d) of 1-10 mm away from the target with the delay times (τ_d) varying 100-1000 ns after the laser irradiation. Mainly the neutral/ionized titanium species and the neutral oxygen species are seen. However, the molecular species such as TiO, TiO_2, O_2 or molecular oxygen ions were not detected. This worked well with the optical spectroscopic results of the plume emission during a KrF excimer laser (wavelength of 248 nm) ablation process with supplied radio frequency power [4]. Many series of TiO molecule in the range of 550-750 nm were obtained by ablating the Ti target using an ArF excimer laser (wavelength of 193 nm) in accordance with Ref. [5]. However, the emission intensity of the spectra from these molecular species was very weak as compared with other monoatomic species. At d=0.5 mm in Fig. 2 (a), (d) and (g), the strong emission spectrum is observed at τ_d=100 ns, although it becomes weak rapidly after 200 ns. The peak intensity at d=5 mm in Fig. 2 (b), (e) and (h) is maximum at τ_d =200 ns, and it delays further at

d=10 mm of (c), (f) and (i). It was found that the emission plasma plume moved forward from the target.

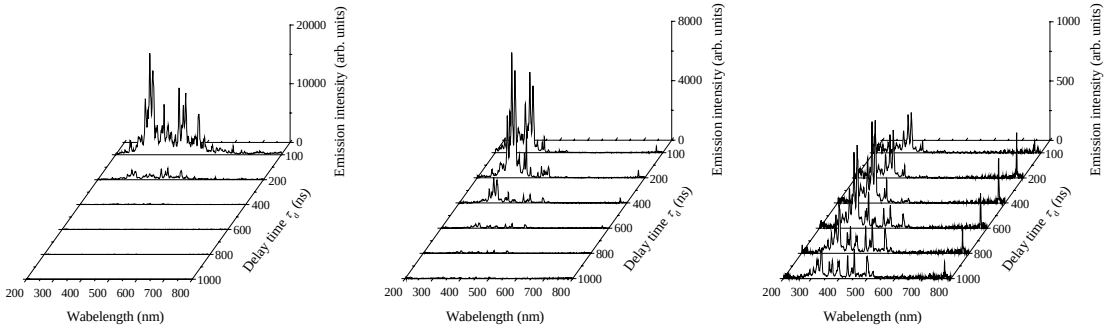
Figure 3 shows the time delay (τ_d) differences of emission spectral lines of Ti atoms (Ti I, λ=430 nm), Ti ions (Ti II, λ=323 nm), and O atoms (O I, λ=777 nm) at peak intensity as a function of the distance (*d*) from the target. The spectra in the plume generated by ablating TiO_2 targets in O_2 gas of 10 Pa were observed. At near the target surface (*d*=0.5~3 mm), the emission species have high velocities because the peak rises sharply. The velocities of



(a) TiO_2 target, *d*=0.5 mm (b) TiO_2 target, *d* =5 mm (c) TiO_2 target, *d* =10 mm



(d) TiN target, *d* =0.5 mm (e) TiN target, *d* =5 mm (f) TiN target, *d* =10 mm



(g) Ti target, *d* =0.5 mm (h) Ti target, *d* =5 mm (i) Ti target, *d* =10 mm

Fig.2 Optical emission spectra of the plasma plume generated by ablating TiO_2, TiN and Ti targets in oxygen gas of 10Pa. Distances *d* from the target surface were varied from 0.5 to 10 mm. Delay times τ_d after the laser irradiation were changed from 100 to 1000 ns.

Ti atoms and ions at d=0.5 mm are 1×10^4 m/s and the kinetic energies are estimated about 50 eV. At further away from the target surface (d=5~10 mm), the peak rises steadily. It was considered that the emission species in the plasma plume lost the kinetic energy by collisions to the ambient gas, so that these species moved with various velocities. The emission intensity of O atoms was very weak compared with Ti atoms and ions over d=1 mm, and there was no dissociation reaction to the ambient O_2 gas.

Figure 4 shows the relationship between the distances (d) and time delays (τ_d) when the intensities of Ti I, Ti II emission lines are at a maximum. The species of Ti atoms and Ti ions reach high velocities immediately after the laser irradiation and later become saturated at τ_d due to collision of excited species and ambient gas. This behavior can be demonstrated with a drag model, which is used to analyze optical emission spectroscopy in the plume during the PLD process of ambient gas [6]. The velocities of Ti ions ablated from TiO_2, TiN and Ti targets are almost same, but the velocities of Ti atoms are different depending on the target.

In order to investigate the distribution of Ti atoms or ions in the plasma plume, the band path filters (Ti I: λ=323 nm, FWHM=10 nm; Ti II: λ=430 nm, FWHM=10 nm) which pass Ti atoms or ions emission from the spontaneous plasma plume emission were mounted in front of the ICCD camera as shown in Fig. 1. Figure 4 shows the side of the plasma plume images ablated from TiO_2, TiN and Ti targets in O_2 gas of 10 Pa at τ_d=100ns. It is found that the distributions of Ti atoms are divided between the tip of the plume and the point near the target although those of Ti ions exist near the tip of the plasma plume. It seems that Ti ions are emitted from the target with the separated velocities. The distribution difference of the Ti atoms or ions depending on the target is observed due to the difference of the ablation process.

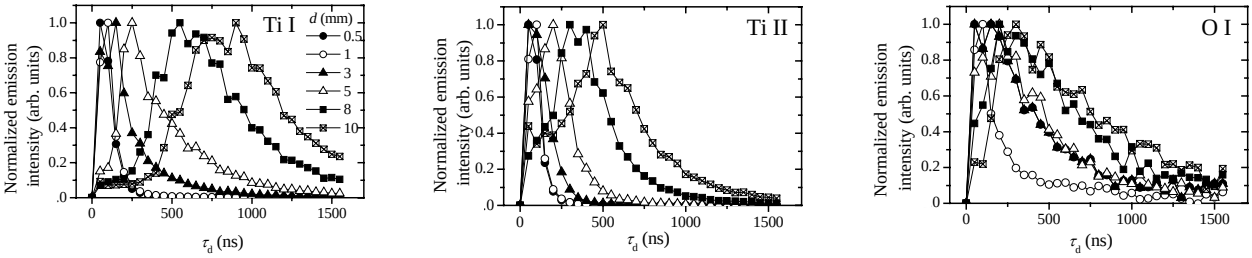


Fig.3 Delay times (τ_d) dependence of the normalized emission intensity of Ti I, Ti II and O I peaks at different distances (d) from the target.

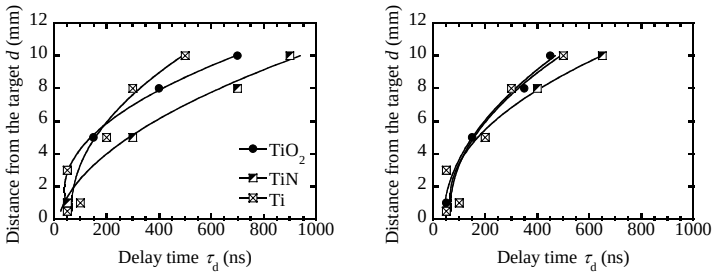

Fig.4 Relation between distances (d) and delay times (τ_d) of Ti I and Ti II emission lines in the plasma plume generated by ablating TiO_2, TiN and Ti targets.

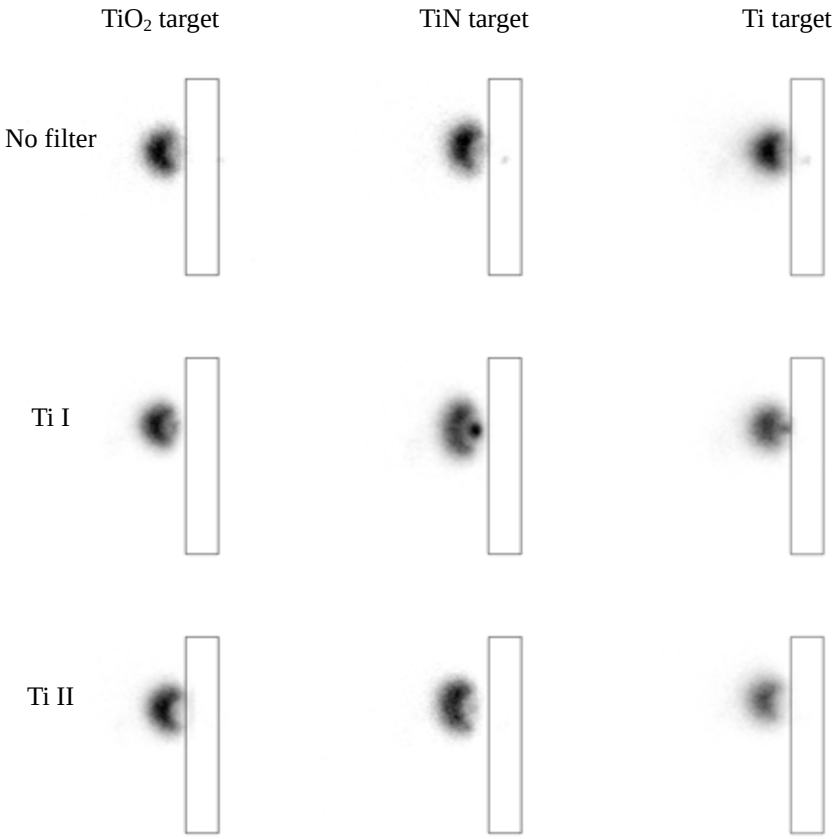

Fig.5 2-dimentional ICCD images of the plasma plume generated by ablating different targets of TiO_2, TiN and Ti using the band path filter.

4. Conclusions

Optical emission spectra of the plume generated by ablating TiO_2, TiN and Ti targets in various ambient gases were predominantly observed Ti atoms and ions. It is revealed that the behavior of Ti atoms and ions in the plume is different by both optical emission spectroscopy and ICCD images.

Abstract
In this work, thin silicon oxide films obtained in dielectric barrier discharges fed with nitrogen (N_2), nitrous oxide (N_2O) as oxidizer gas, and small admixtures of silane (SiH_4) or hexamethyldisiloxane vapor (HMDSO) as deposit precursor, have been investigated. The aim is to evaluate the importance of the reactivity of the precursor on the deposit properties in order to contribute to a better understanding of the reactive transport taking place in such process.
Keywords
Dielectric barrier discharge (DBD), Atmospheric Pressure Townsend Discharge (APTD), coating, silane, hexamethyldisiloxane (HMDSO), heterogeneous and homogeneous growth, ellipsometry, FT-IR

1. Introduction

The development of a PECVD process working at atmospheric pressure and allowing an easy on-line treatment of films, fibbers and plates is a challenge of great interest. The successful solution will avoid batch treatments and significantly reduce the cost of the coating, allowing an expansion of the use of plasma technologies outside microelectronics. The main questions to be solved are how to get a well controlled thin film in terms of chemical composition, structure and thickness? How to get a high growth rate? Previous to the process development, the main difficulties concern the plasma homogeneity, the gas injection over large dimensions, the control of the atmosphere in the plasma area while the substrate is moving at speed up to 800m/min and the efficiency of the transfer of the reactive species to the surface taking into account the very low diffusion of the neutral radicals.
In case of two dimensional materials like roll of thin polymer films, metal foils or glass plates, dielectric barrier discharge (DBD) appears like the more suitable discharge because it is cold, robust and not disturbed by the movement of the substrate. Furthermore, roll to roll process allowing a very good control of the atmosphere in the DBD is already commercialised. This solution is in competition with remote plasmas but knowing that the quenching of excited state drastically increases with the pressure, as far as the substrate can be moved inside the discharge without inducing perturbation, remote plasmas have to be avoided.
Today, DBDs can be separated in two families: the filamentary one and the homogeneous one which are atmospheric pressure glow discharge (APGD) in noble gases and atmospheric pressure Townsend discharge (APTD) in nitrogen [1]. The reactive gas used for the coating formation is diluted in a main gas which is usually helium, argon or nitrogen. The content of reactive gases or vapours is in the range of 1 to 1000 ppm. In such conditions, several authors obtained uniform coatings [2, 3, 4] but the question of the control of the reactive transport is still open. The aim of this paper is to contribute to answer to that question.
The approach consists in a comparison of silicon oxide thin film obtained with a very reactive gas, the silane (SiH_4) and a more stable vapour, the hexamethydilsiloxane (HMDSO).

2. Experimental

The experimental set-up has been previously described [5]. The discharge being realised between two parallel plates and the gas injection being a longitudinal one, the study is done as a function of the gas residence time in the discharge. The main gas is N_2 and N_2O is the oxidant one. The gas flow, the precursor rate and Si/O ratio as well as the discharge power are the other main parameters. Thin films have been mainly characterised by FT-IR spectroscopy, ellipsometry, SEM and thickness profile.

3. Results and discussion

3.1. Effect of the discharge regime

Attention has been first paid on the effect of the discharge regime on the deposit homogeneity. Usually the DBD consists in microdischarges i.e. different channels of local plasma with mean radius up to 100 µm, but in N_2 a Townsend breakdown leading to a Townsend transient homogeneous discharge (APTD) is obtained in specific conditions:

- If the voltage variation with time is slow enough i.e. for a sinusoidal excitation if the voltage amplitude and frequency are limited. This limitation depends on the power supply and solid dielectric characteristics as well as on the intrinsic cathode secondary emission coefficient of the material in contact with the discharge [1]. More precisely, during Townsend discharge development, the gas impedance drastically changes and then the load connected to the power supply changes from the capacitance due to the solid dielectrics and the gas before breakdown to the capacitance due to the solid dielectric after breakdown. If this variation is too quick, power supply oscillations and then transition to filamentary discharge occur. Moreover, when the Townsend regime is reached, for a given configuration of the discharge cell, the current amplitude is determined by the slope of the applied voltage. If it is too high the streamer development can occur when the cathode secondary emission coefficient decreases due to the removal of the electrons trapped in shallow traps during the previous discharge.

- If an opportune choice of the gas chemical composition is done, which determines the lifetime of the N_2 metastables. This life time has to be long enough to induce a continuous emission of electrons from the cathode during the time between two consecutive discharge pulses. This is an essential condition to get a Townsend breakdown before the electrical field is high enough to have a streamer development.

For these reasons, in the conditions of this study, APTD is obtained for power up to about 2 W/cm^2 (20 W/cm^3), due to a limit frequency of 6 kHz, and for HMDSO or SiH_4 rate lower than about 50 ppm.

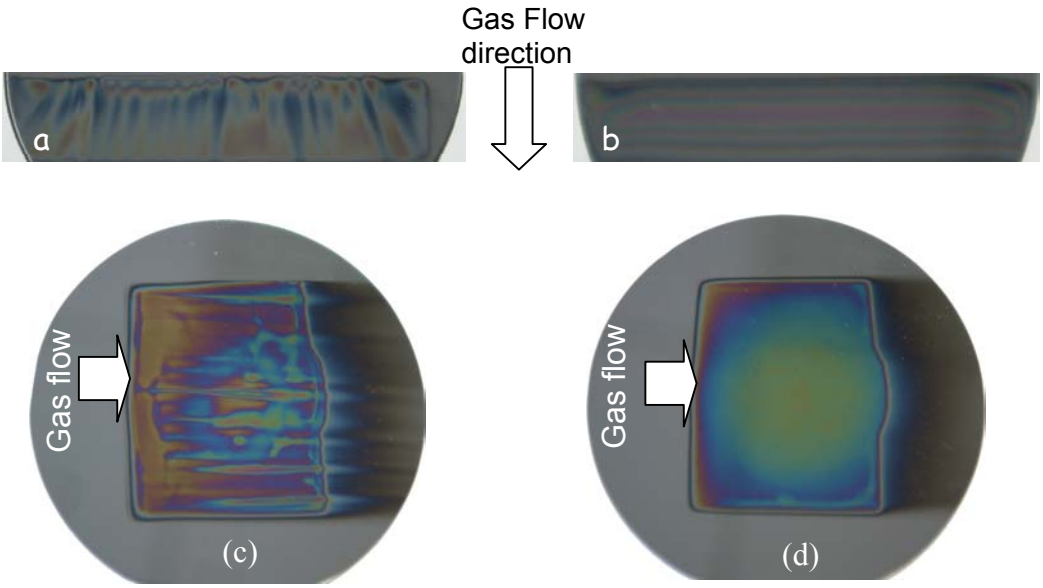

Figure 1: Comparison of silicon oxide coatings made on a silicon wafer with **a)** a $SiH_4/N_2O/N_2$ filamentary DBD, **b)** $SiH_4/N_2O/N_2$ Townsend DBD **c)** a HMDSO/ N_2O/N_2 filamentary DBD **d)** HMDSO/N_2O/N_2 Townsend DBD. The colour is proportional to the thickness showing that whatever the coating precursor, the APTD leads to thin layer uniform in one direction, then if the substrate is moved perpendicularly to this direction, the coating will be uniform.

Photos of the coatings obtained in the two different discharge regimes are reported on the figure 1 for HMDSO and SiH_4. The transition from Townsend to filamentary DBD has been obtained by increasing the HMDSO rate and by increasing the power in case of SiH_4 coating. On the pictures, the color is proportional to the thickness. The coatings thickness appears completely different. In case of filamentary discharge the coating thickness is a fair reflection of the number and localization of the micro-discharges. This is explained by the high density of electrons in a micro-discharge: typically 10^{14}/cm^3, which efficiently dissociates the HMDSO or SiH_4 inducing a local increase of the coating growth. The distribution of the micro-discharge is not uniform enough to ensure a uniform coating. In case of Townsend discharge, the coating is rather

uniform in the direction perpendicular to the gas flow. There is only a small decrease of the thickness close to the wall which is explained by the decrease of the gas flow. This effect is more pronounced with HMDSO than with SiH_4. Obviously, in the direction of the gas flow, the deposit is not homogeneous because of the precursor consumption which is quicker for SiH_4.
The important point to realize a homogeneous coating on a large and flat substrate that can be moved is to be able to make a coating uniform in one direction which will be the direction perpendicular to the substrate displacement. According to our results this is only possible with the APTD. However, some authors report about uniform coatings obtained with a filamentary discharge [6]. Such a result supposes a uniform and reproducible distribution of the micro-discharges which is not so easy to get. Then, the conclusion is that it is easier to get uniform coatings with an APTD than with a filamentary discharge. Consequently, only results concerning deposits obtained using an APTD are further discussed in this work.

3.2. Properties of the deposit using an APTD in standard conditions

The coating properties have been first studied has a function of the position in the gas gap along the direction of the gas flow for given conditions. HMDSO coating is made with 4 ppm of HMDSO, a N_2 gas flow of 5 l/min and 96 ppm of N_2O in order to have a $[N_2O]/[HMDSO]$ equal to 24 which is the stoichiometric ratio for obtaining SiO_2. A dissipated power in the discharge is equal to 0.5 W/cm^2 and the deposition time is 20 minutes. SiH_4 coating is made in similar conditions: 5ppm of SiH_4, a N_2 gas flow of 5 l/min, a SiH_4/N_2O ratio equal to 20, a dissipated power in the discharge equal to 0.35 W/cm^2 and a deposition time of 20 minutes. The length of the electrode in the direction of the gas flow is slightly different: 32 mm for SiH_4 and 25 mm for HMDSO.

Physical properties

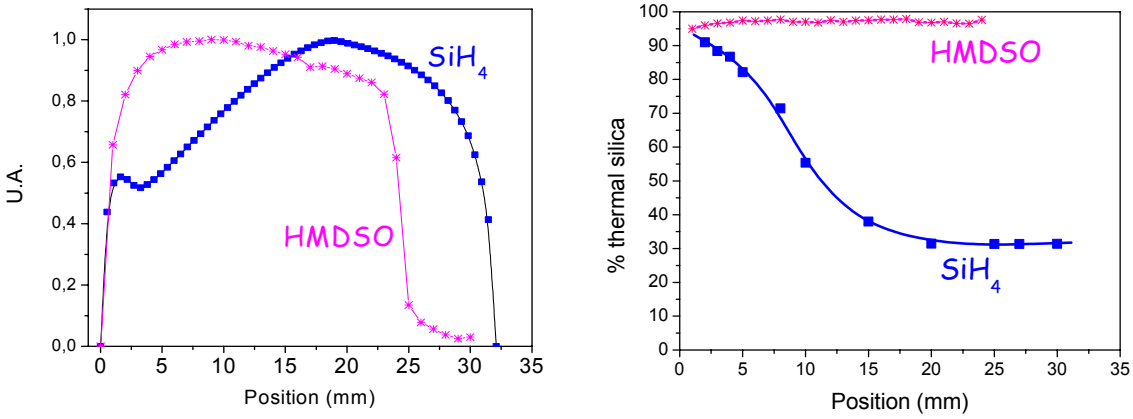

Figure 2: Normalised thickness and percentage of thermal silica deduced from ellipsometry measurements for coating realised with SiH_4 or HMDSO mixed with N_2 and N_2O in the following conditions. HMDSO: 4ppm, N_2O/HMDSO=24, power: 0.5W/cm^2, t=20min ; SiH_4: 5ppm, N_2O/SiH_4=80 , power: 0.34W/cm^2, t=20min. The electrode length is 25 mm for HMDSO and 32 mm for SiH_4. The substrate is not heated and the maximum thickness is about 200nm in the two cases.

The thickness profile is measured with a profiler and is also deduced from ellipsometry assuming the Bruggeman approximation (Figure 2). The deposited layer is generally considered as a mixture of SiO_2 and voids. It clearly shows a very different behaviour for the two precursors. The 2 maxima observed in the case of SiH_4 are no more present in the case of HMDSO while the theoretical percentage of thermal silica largely varies with SiH_4 and not with HMDSO. This large variation has been attributed to the relative contribution of homogeneous and heterogeneous growth [5]. In the SiH_4 case, the thin layer at the gas entrance is due to radicals while for longer gas residence time in the discharge, the contribution of particles becomes dominant. The particle accumulation at the surface forms a very porous layer which explains the small percentage of silica. In HMDSO particles are not formed, and only the radicals participate to the growth. This large difference is due to the reactivity of the precursor in the gas phase. When silane radical is created, it can react

with the surface or with silane in the gas bulk. The competition between these two possibilities limits the contribution of radicals to the thin film growth.
These results are similar to those obtained in low pressure plasma but what is amazing is that the distribution of the particles size is very thin, the mean diameter being around 30nm, and this whatever the discharge regime. The detailed study of the formation and the transport of these particles (through SEM, TEM and laser diffusion) shows that they are constituted of clusters of 10nm in diameter which can grow up to the point where their size is large enough to support a fixed electrical charge. Then, the electrostatic force becomes the most important and pushes them to the surface, as long as the frequency excitation is low enough. In the APTD, even for high power discharges, the time needed to reach the critical size is of some ms and this is why it is possible to get a dense layer without any particles at the entrance of the discharge. Our results show that this is not possible with a filamentary discharge, even for lower power, because the local energy density is so high that the high radicals density induces a quasi-instantaneous particles growth.
The study of the particles shows that the transport to the surface of all the charged species, including of course the ions, is efficient as far as the frequency is maintained to a low value. But the case of the neutral radicals is different as the diffusion is limited. According to the numerical modelling of the reactive transport, under the conditions of this study, using a longitudinal injection, only the SiH_3 created in a boundary layer of about 30µm reach the surface before leading to the particle formation. Then a more efficient injection system has to be found in order to increase the radical contribution to the deposit.

Chemical properties

Whatever the precursor, the same infrared absorptions are observed through FT-IR spectroscopy. The highest absorption at 1070 cm^{-1} is due to stretching vibrational mode of Si-O-Si group that mainly characterizes the film, but not negligible absorption is also attributed to Si-OH group, H-bounded and free, respectively at 3450 cm^{-1} and 3650 cm^{-1}. The film is completely inorganic and there is no nitrogen.

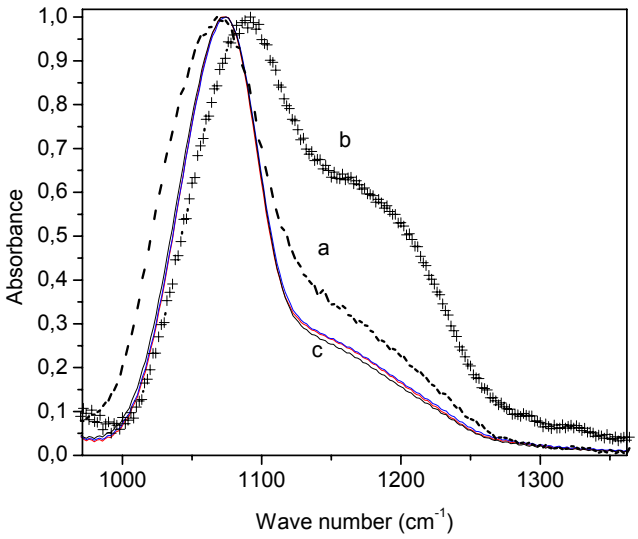

Figure 3: Normalized FT-IR Si-O-Si stretching peak of **a)** SiH_4 coating at the first maximum **b)** SiH_4 coating at the second maximum **c)** HMDSO coating at different positions

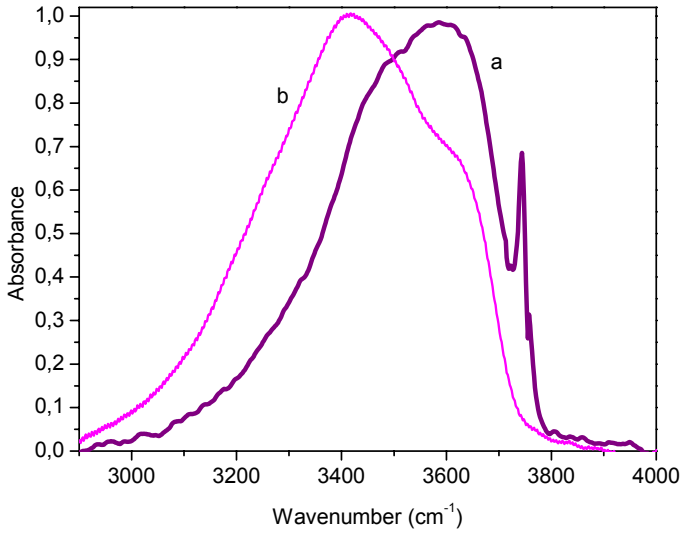

Figure 4: Normalized FT-IR OH band between 3000 and 3800 cm^{-1} of **a)** SiH_4 coating at the second maximum **b)** HMDSO coating at the maximum thickness

With the increase of residence time, from the beginning to the end of the discharge area, a slight increase of Si-OH groups absorption is observed for HMDSO coating. This variation is more significant for SiH_4 coating. However, the main differences concern the shape and the position of the maximum absorption peak attributed to Si-O-Si stretching mode (figure 3). The shape of this peak is characterized by the ratio of the peak shoulder intensity, due to AS2 mode and the main peak intensity, due to the AS1 mode. The position of this peak is related to the angle of the Si-O-Si bonds [7]. Lower is the wave number smaller is the angle and higher is the stress of the Si-O-Si bonds. In coatings obtained in SiH_4 containing plasmas, the

constraint is lower in the particles coming from the homogeneous radical recombination processes than in the thin film grown on substrate thanks to the heterogeneous reactions. The value of 1070 cm^{-1} found for coatings obtained in case of HMDSO-N_2O-N_2, whatever the position in the discharge area is the typical one of thermal silica. Concerning the ratio AS2/AS1, higher is this ratio higher is the disorder of the silica network [8]. In film obtained in SiH_4 containing APTD, this ratio increases with the gas residence time and the consequent contribution of the particles to the film growth. Because of the corresponding higher absorption of Si-OH peak absorption in FT-IR spectra, it is possible to conclude that powders are richer in silanol groups than the dense film. In comparison, coatings obtained using HMDSO have demonstrated to be more similar to thermal silica though a discrete absorption due to silanol groups is observed.

The OH absorption between 3000 and 3800 cm^{-1} also presents some differences (Figure 4). The concentration of non-bounded Si-OH between 3560 and 3800 cm^{-1} is higher in case of porous layer (2nd maximum of SiH_4 coating) and even the surface non-bounded Si-OH are observed at 3750 cm^{-1}, while in HMDSO coatings (due to a radical growth) the bounded Si-OH absorption around 3450 cm^{-1} dominates.

3.3. Influence of process parameters

Among the different process parameters, the precursor concentration and the power have been studied because they usually largely influence the growth rate.

Effect of precursor concentration in the discharge

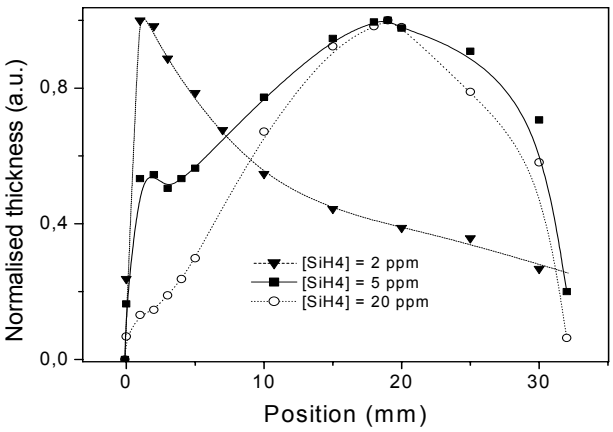

Figure 5: SiH_4 coating thickness profile normalized on their maximum as a function of the distance from the gas inlet for different SiH_4 concentrations all the other conditions being the standard one.

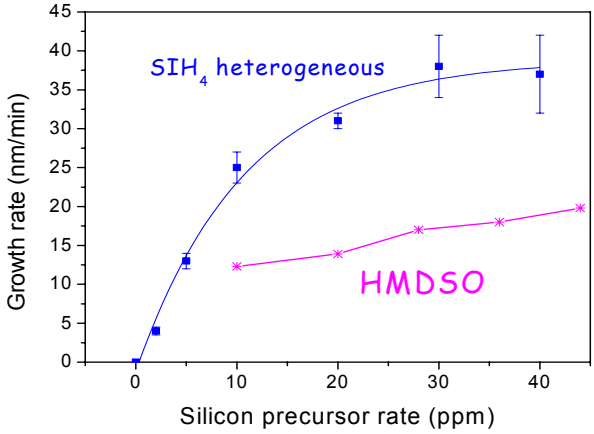

Figure 6: Evolution of the maximum of the heterogeneous growth rate of SiH_4 and HMDSO coating with the precursor concentration all the other conditions being the standard one.

Keeping the N_2O rate equal to 400 ppm, the SiH_4 rate has been increased up to 40ppm. The chemical composition of the layer is not significantly affected. As shown in figure 5, the two maxima position does not changed even if the growth kinetic significantly increases, from 15 to 35 nm/min for the first maximum (figure 5) and from 26 to 800nm/min for the second one. When the SiH_4 partial pressure becomes very low (0.2 Pa for 2ppm) the homogeneous growth i.e. the formation of particles is drastically reduced compared to the heterogeneous growth: this is explained by the decrease of the probability of interaction of a SiH_4 radical and an other silicon compound in the gas phase. This competition between gas and surface reactions also explains the saturation of the increase of the heterogeneous growth rate with the SiH_4 concentration.

The effect of HMDSO content on the discharge and film properties has been studied for [N_2O]/[HMDSO] ratio equal to 24 and a fixed power of 0.5 W/cm^2. Increasing the HMDSO concentration from 4 ppm up to 44 ppm, (partial pressure from 0.4 up to 4.4 Pa) a Townsend discharge is always obtained and no modification is observed on the film chemical composition. The maximum growth rate increases almost linearly as a function of HMDSO concentration (figure 6), with a slope of 0.2 nm/min per HMDSO concentration unit (ppm). This variation is very slow compared to that observed in case of SiH_4. A possible explanation of this behaviour is that the growth rate is limited by the HMDSO activation, the slowest step of

the overall deposition process. An easy way to check this hypothesis consists in increasing the power i.e. the density of energetic species like electrons and nitrogen metastables.

Effect of discharge power

For a given rate of precursor (4ppm of HMDSO, 5ppm of SiH_4), the power has been varied by a factor close to ten: from 0.166 W/cm^2 to 1.45 W/cm^2 in SiH_4 case and from 0.2 up to 2 W/cm^2 (2 to 20 W/cm^3) in HMDSO case. In SiH_4, higher is the power, quickest is the formation of powder but also of the radicals and the separation between the two mechanisms becomes clearer and clearer. This can be attributed to a larger dissociation of SiH_4 molecules. In the same time, the growth rates at both maxima increases (Figure 7). However, the rate of the heterogeneous growth saturates for high power values while the homogeneous growth rate increases linearly. This can be explained taking into account the fact that radicals leading to the heterogeneous growth have to be created in a boundary layer close to the surface. The thickness of this boundary layer is defined (i) by the diffusion coefficient of the radicals and the gas flow which determines the radicals trajectory and (ii) by the volume reactivity of the radicals which determines the radicals lifetime. Then, the power does not directly affect it. Then the results observed in figure 6 suggest that the SiH_4 contained in this layer is entirely decomposed and transferred to the surface when the power is increased.
In HMDSO, the maximum growth rate increases almost with a linear trend when the power increases from 0.2 up to 2 W/cm^2 (2 to 20 W/cm^3) and a value of 36 nm/min is reached for a discharge power of 1.9 W/cm^2. There is no saturation. Even if the HMDSO rate is lower than the SiH_4 one, more silicon radicals reach the surface showing that the boundary layer is larger. This is in agreement with lower volume reactivity. This linear dependency on the power also confirms that HMDSO dissociation is the slowest step of the overall deposition process.

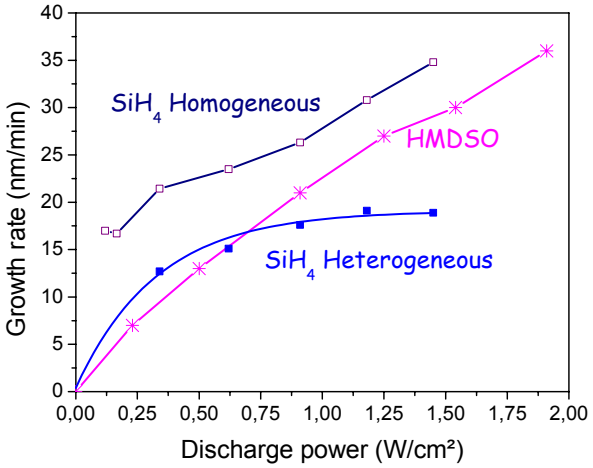

Figure 7: Maximum growth rate as a function of the discharge power at the first (heterogeneous) and second (homogeneous) maximum for SiH_4 coating and for HMDSO

4. Conclusion

The comparison of the properties of thin film coatings obtained with SiH_4 and HMDSO clearly shows that the reactivity of the precursor in the gas phase largely defined the properties of the coating and the ability to get a homogeneous layer. It also largely influences the boundary layer thickness from which radicals can reach the surface. Lower is the reactivity of the precursor in the gas phase, larger is this boundary layer and longer should be the discharge length to allow the radicals to reach the surface.

Investigation of interaction of polymer-Coated chamber wall and oxygen plasma in an ICP discharge by time resolved visible and VUV spectroscopy

Zhi-Gang Guo, Zhen-Dong Yu and Yi-Kang Pu
Department of Engineering Physics, Tsinghua University, Beijing 100084, China

Abstract:

The process of cleaning nitrogen-containing hydrocarbon polymer films on chamber wall employing O_2/N_2 discharge is investigated using vacuum ultraviolet (VUV) and optical emission spectroscopy. Electron temperature and relative concentration of various atomic species are measured as a function of process time. The measurement results suggest that the ion loss rate is highest on polymer surface, lower on quartz and lowest on stainless steel.

Keywords: plasma cleaning, chamber wall condition, polymer coating, electron temperature, ion loss rate

I. Introduction

Organic polymers often deposits on chamber wall in plasma etching of silicon dioxide and plasma enhanced chemical vapor deposition (PECVD) when fluorocarbon or hydrocarbon compound is employed as an etchant or precursor. Concentration of active species is greatly influenced by polymer coating on chamber wall [1, 2]. This may lead to fluctuation in etching or deposition rate and poor process reproducibility [3, 4]. Therefore, oxygen or oxygen-containing compound is commonly used for polymer removal from chamber wall or their formation control in gas phase [5, 6].

In the present work, a nitrogen-containing hydrocarbon polymer thin film, deposited on stainless steel cylinder wall during a CH_4/N_2 discharge, is being removed by an O_2/N_2 plasma. Relative concentrations of various species in cleaning process are monitored by VUV and optical emission spectroscopy (OES) as function of cleaning time. Time resolved electron temperature is obtained by line ratio technique through molecular nitrogen emissions. Three phases in the polymer removal process are identified and variation of these parameters during these phases is analyzed.

II. Experiment

Figure 1 is a schematic diagram of our MPS2000 ICP reactor and optical diagnostic apparatuses used in this experiment. The reactor consists of a quartz tube (with inner diameter 17 cm and height of 40 cm) and stainless steel chamber (inner diameter 60 cm and height of 40 cm) with many ports. An rf power supply (13.56 MHz, 0-1000 W) is coupled to the plasma in the quartz tube through an induction coil (4.5 turns). A Faraday shield is mounted outside of the quartz tube to reduce the effect of capacitive coupling. A small stainless steel cylinder (inner diameter 15 cm and height 35 cm) is placed in the center of stainless steel vacuum chamber to confine the plasma and polymer film is deposited on its inner surface. A rectangle window (15mm width and 40 mm height) on the small cylinder wall allows VUV emission entering the slit

of the spectrometer through one of the ports on the large vacuum chamber. With a 500 l/s turbo pump, a base pressure of 10^{-7} Torr is achieved without baking. The operating pressure is monitored by a capacitance diaphragm gauge (CMR264, Balzers Inc.).

The VUV emission intensity is measured by a grazing incidence monochromator (Model 248, McPherson Instrument Inc.). A gold-coated 300 grooves/mm grating allows a wavelength range of 30 to 180 nm with a spectral resolution of 0.3 nm when the slit width is 150 μm. The detector system consists of a sodium salicylate-coated window and a photomultiplier tube operating in photon counting mode (Model 76915, Oriel Inc.). A two-stage differential pumping system is used so that the pressure inside the VUV monochromator is less than 10^{-5} Torr. Intensities of O 130 nm ($3s\ ^3S—2p^4\ ^3P$), H 121 nm ($2p\ ^2P—1s\ ^2S$), N 120 nm ($3s\ ^4P—2p^3\ ^4S$) and C 115 nm ($2p^3\ ^3D—2p^2\ ^3P$) resonance lines are measured.

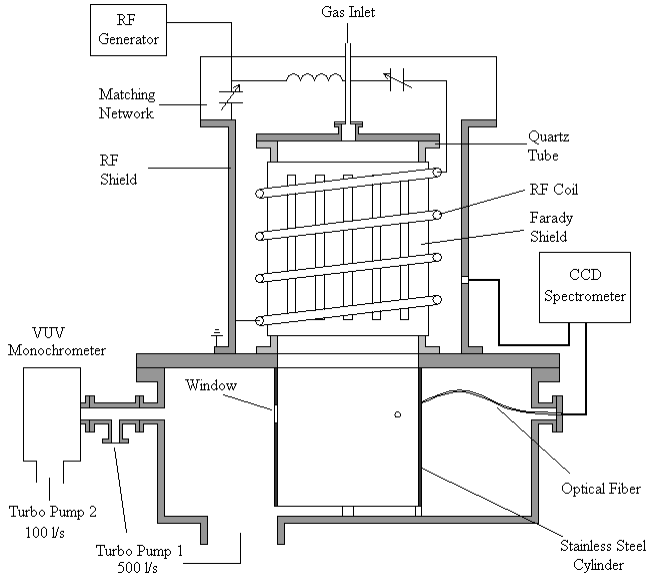

Figure 1. Schematic diagram of experimental setup and diagnostics apparatus.

Optical emission from both the source and downstream regions is monitored by a four-channel CCD spectrometer (SQ2000, Ocean Optics Inc.) through an optical fiber probe mounted inside the vacuum chamber and another fiber mounted outside of the quartz tube, as shown in figure 1. An optical collimator (with a hole of 1 mm diameter and collimation length of 4 cm) is used to prevent polymer coating on the optical fiber probe. The collimator, the optical fiber and the spectrometer are intensity-calibrated all together by a tungsten filament lamp within its wavelength range of 350 nm to 900 nm.

The nitrogen-containing hydrocarbon polymer thin film is deposited by using a CH_4/N_2 discharge under the following condition: total flow rate is 30 sccm, volume percentage of CH_4 is 42%, gas pressure is 10 mTorr, rf power is 200 W and deposition time is 1 hour. The deposited film is removed by O_2/N_2 plasma under the following condition: total flow rate is 30 sccm, O_2 volume percentage is 80%, gas pressure is 10 mTorr, rf power is 200 W and process time is 50 minutes. The VUV emission intensities at four resonance lines of O, H, N and C are recorded in every three minutes in cleaning process. Optical emission intensity is recorded every 30 seconds. The emission intensity ratio between molecular nitrogen first positive series of 762.5 nm and first negative series of 391.4 nm is used to calculate the electron temperature along the line of sight in the downstream and source regions.

III. Results and discussion

1. Time resolved VUV emission spectroscopy

VUV emission in wavelength range of 90~150 nm in O_2/N_2 plasma is shown in figure 2. The atomic resonance lines of O (130.4 nm), H (121.6 nm), N (120.0 nm and 113.4 nm) and C (115.8 nm) can be identified. Time resolved relative intensity of these lines (except N 113.4 nm) is shown in figure 3 as a function of process time. As can be seen from figure 3, the cleaning process can be considered as a combination of three different phases: a cleaning phase, a transition phase and a finish phase, separated by two dashed lines located at about 18 minutes and 30 minutes respectively. The emission intensity of O 130 nm increases rapidly in cleaning phase, and then slowly increases in transition phase and remains a constant in finish phase. Correspondingly, the emission intensity of H 121 nm decreases throughout the cleaning and transition phase (except a small peak at the cleaning/transition boundary) and stabilizes in finish phase. The emission intensity of C 115 nm stays constant in the cleaning phase and decreases continuously in transition phase and finish phase. The boundary of the three phases is best marked by the change of emission intensity of N 120 nm, whose values are highest in the transition phase.

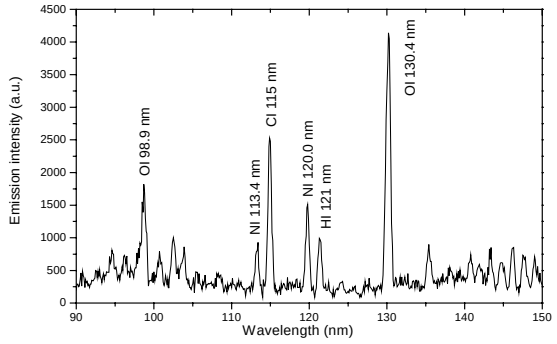

Figure 2. Main VUV emission lines in O_2/N_2 plasma.

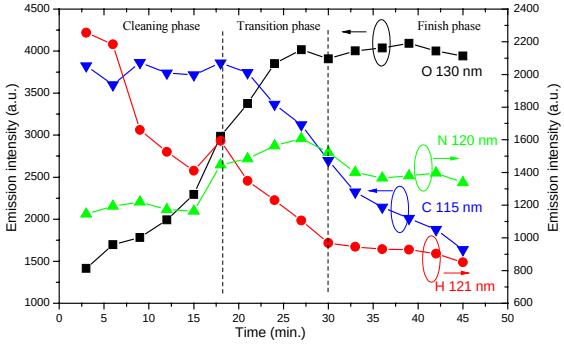

Figure 3. The time resolved relative intensity of VUV emissions of atomic O, H, N and C.

Variations of intensities of the four VUV lines with cleaning time suggest the possible existence of transition phase in the cleaning process. This may be caused by the non-uniformity of polymer-coating layer or etching rate along axial direction of the stainless steel cylinder due to variation of species concentration in downstream region. At the beginning of transition phase, polymer film on the top part of cylinder wall will be removed out first due to higher oxygen atom density. Density of atomic H and C will decrease in gas phase because of the chemical reaction involved and their source (polymer film) being depleted. This results in the rapid decrease of their VUV emission intensities. This trend will last until the polymer film is removed from the entire inner surface of the cylinder and this marks the end of the transition phase. In this phase, the stainless steel wall is covered partially by an electrically insulating polymer. The total area of stainless steel that is in direct contact with the plasma increases with time as a result of etching. Plasma parameters like electron temperature will change continuously due to the change of loss rate of charged species on the wall, as indicated by the measurement of electron temperature using line-ratio technique (described in the next section). Furthermore, this may be the reason why there is a peak in emission intensity of N in transition phase, even though more detailed study is required to verify this argument.

2. Time resolved electron temperature and relative atomic concentration in downstream and source area by OES

Time resolved OES from both downstream and source regions is employed to monitor relative species' density and electron temperature. Species' density is derived from optical actinometry by emission intensity ratio between interested species and argon (volume percentage less than 5%) used as an actinometer. Emissions of O at 844 nm ($3p\ ^3P—3s\ ^3S$), H at 486 nm (Balmer series, β) and Ar at 811 nm ($2p_9—1s_5$) are selected to determine actinometry signal because their peaks are strong and are away from other emission lines. The excitation thresholds of O and H lines (11 eV and 12.75 eV) approximates to that of Ar line (13.08 eV), which is a necessary condition to apply actinometry [7].

Relative concentration of O and H in downstream region is shown in figure 4 as a function of cleaning time. The concentration of H has the same trend as its VUV intensity. But the oxygen concentration has a different trend from its VUV emission by showing a high peak in cleaning phase and slowly increasing in transition and finish phases. At this time, we do not know how to interpret this measured result.

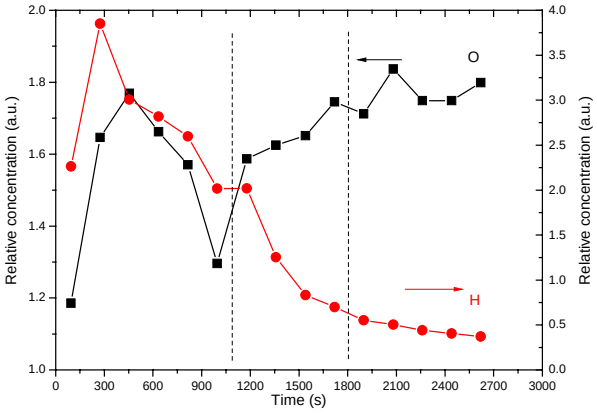

Figure 4. Relative concentration of O and H by optical actinometry in O_2/N_2 plasma with cleaning time (downstream region).

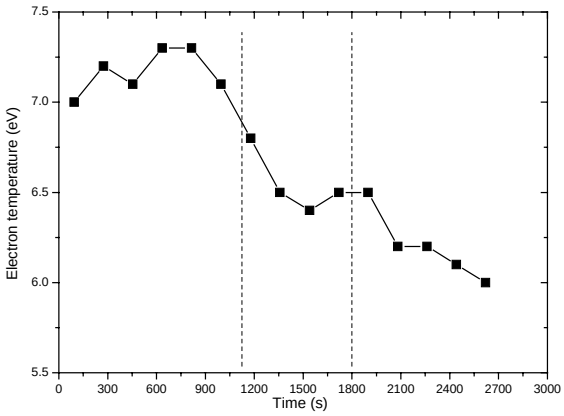

Figure 5. Electron temperatures in O_2/N_2 plasma in downstream region as a function of cleaning time.

The electron temperature of O_2/N_2 plasma in downstream region is shown in figure 5 as a function of cleaning time. Electron temperature is highest in cleaning phase. It decreases in both transition and finish phases, even though its rate of decrease is somewhat lower in finish phase. The higher electron temperature in cleaning phase than in finish phase indicates a higher loss rate of ions when polymer is coated on the chamber wall, according to Global Model [8].

Similar measurements are performed in source area of our ICP device. Results of atomic concentration and electron temperature with cleaning time are shown in figure 6 and figure 7 respectively. The concentration of O shows stable low value in cleaning phase, rapid increase in transition phase and saturation in finish phase. This transition can be simply explained as more loss of O in cleaning phase due to reaction with organic polymer film. It also indicates two stable states of plasma with and without the polymer film on the cylinder wall and there is a transition region between them. The increasing electron temperature in cleaning phase in figure 7 is attributed to measurement error using line ratio technique and is caused by continuous thickness reduction of polymer film, whose absorption of plasma emissions depends on wavelength. Taking this into

account, the true electron temperature should be along the dotted line in the figure. As mentioned before, higher electron temperature when polymer coating is present suggests a higher ions loss rate on polymer surface than on quartz surface. Notice that, in the source region, the difference in electron temperature between the two cases (polymer coated wall and quartz wall) is small (about 0.8 eV). While in the downstream region the difference is larger (about 1.2 eV) when the wall changes from a polymer coated one to its original stainless steel wall. This may suggest that stainless steel wall has the smallest ion loss rate, followed by quartz and polymer.

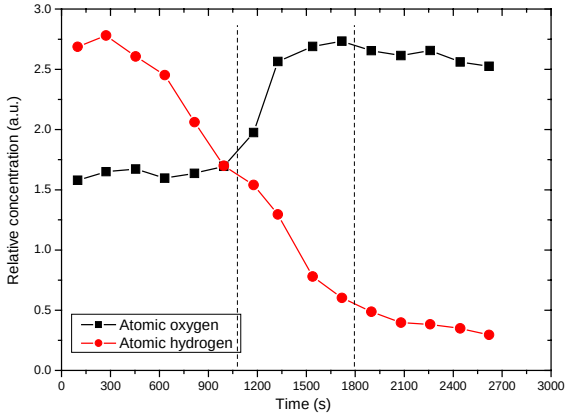

Figure 6. Relative concentration of O and H by optical actinometry in O_2/N_2 plasma with cleaning time (source region).

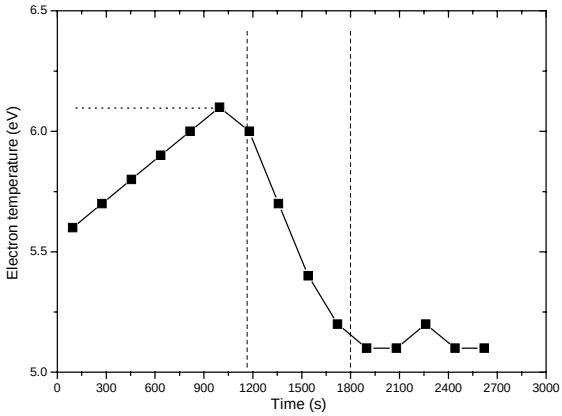

Figure 7. Electron temperatures in O_2/N_2 plasma in source region as a function of cleaning time.

IV. Conclusion

The process of cleaning nitrogen-containing hydrocarbon polymer films on chamber wall employing O_2/N_2 discharge is monitored and investigated using VUV and optical emission spectroscopy. Electron temperature and relative concentration of H and O are obtained by line ratio technique and optical actinometry, respectively. Three phases during the polymer removing process are identified: a cleaning phase, a transition phase and a finish phase. Experimental results show that polymer coating has a strong effect on electron temperature and concentration of different species in the plasma. The preliminary results also imply ion loss rate is the highest on polymer surface, followed by quartz and stainless steel has the lowest loss rate.

Numerical modeling and spectroscopic diagnostics of an Ar-H_2 inductively coupled plasma under pulse-modulated power conditions were carried out. It was found that the predicted and measured electron number densities were in good agreement in the central region of the torch; while the observed discrepancies between them in the fringes of the plasma suggested the presence of departure form local thermodynamic equilibrium in those regions. The nonequilibrium effect became more appreciable in the plasma operated under the pulsed power conditions.

1. Introduction

Pulse-modulated inductively coupled plasmas (PM-ICPs) are characterized by their nonequilibrity and relatively high concentrations of chemically reactive radical species. Under pulsed power conditions, their enthalpies can be easily controlled by adjusting the high-low power ratio and the duty factor of pulsation, and their radiation losses can also be considerably reduced, compared with those of continuous plasmas [1-5]. These features are crucial to avoiding the overheating of specimen when processed in such environments with high heat fluxes. The PM-ICPs have shown some prominent advantages in materials processing, such as the doping of hydrogen into functional ceramics [6, 7].

In the past few years, a number of theoretical and experimental studies on induction plasmas operated under pulsed power conditions have been carried out [4, 8-10]. Most of those researches were concentrated on the dynamic behavior of PM-ICPs. The nonequilibrium phenomena in those plasmas were interpreted in terms of the temporal behavior of line emission intensities. However, work involving direct comparisons between experimentally and theoretically obtained results for pulsed power plasmas is likely lagging behind. In the present study, numerical modeling and spectroscopic diagnostics of an Ar-H_2 pulse-modulated inductively coupled plasma were carried out. The numerical modeling was performed using a renormalization group (RNG) *k-e* turbulence model with the local thermodynamic equilibrium (LTE) assumption [11]. The electron number densities were measured by using Stark broadening. Since the experimentally detected electron population densities were independent of the equilibrium conditions in the plasma, a comparison between the predicted LTE profiles of the plasma temperatures and the electron number densities and the measured ones should reveal more conceivable information on the nonequilibrium situations in such thermal plasma generators operated under pulsed power conditions.

2. Experimental set-up

The plasma torch and spectroscopic diagnostics systems for the present work are schematically shown in Figure 1. A voltage-control-type solid state amplifier (MP-22CY, Denki Kogyo Co., Ltd.) was used in the generation of pulsed power plasmas. An invert-type power source supplied an electric power of 22 kW continuously at a nominal frequency of 1 MHz. The power source and the load were electrically matched by using a phase-locked loop (PLL) with variable frequencies and an LC matching circuit. The radio frequency (RF) power was pulse-modulated by using an external pulsed signal generated by a pulse generator (HP-8116A)

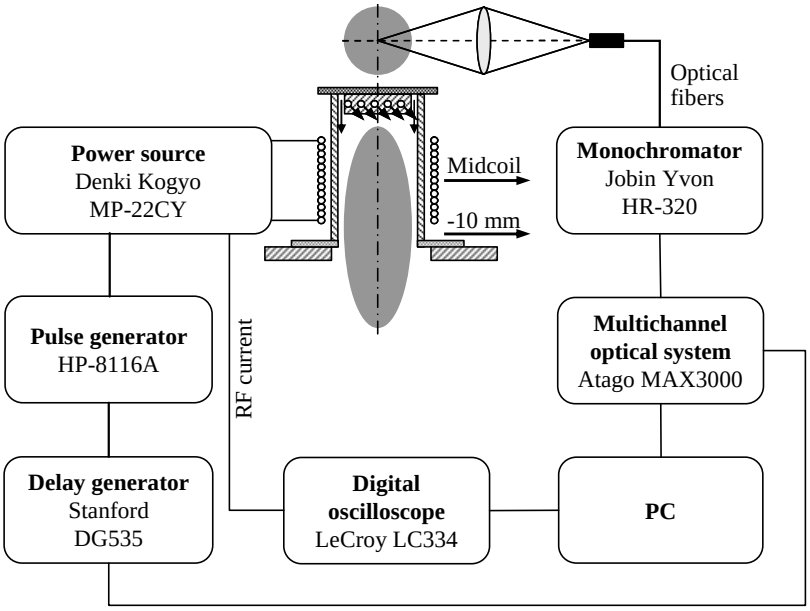

Figure 1. Schematic of the plasma generation and optical diagnostics systems.

to switch a static induction transistor in the power source. The rise time of the power source was less than 1 μs. The plasma was firstly generated at continuous power level of 13 kW and chamber pressure of 200 Torr. Then, the external pulse signal was imposed to switch the plate power from the continuous operating mode to the pulse-modulated one with pulse-on and pulse-off times of 10 and 5 ms, and high and low power levels of 13 and 4 kW, respectively.

The plasma line emissions were monitored at the middle of the RF coil and 10 mm below the last coil in the downstream direction. The optical systems for the measurements of the emission intensities were calibrated using a halogen lamp. The lights emitted from the plasma were focused by an optical system with a spatial resolution of 0.5 mm, and were transmitted to the monochromators through optical fibers. In order to obtain the radial profiles of the plasma emissions, the optical system was mounted on a displacement frame driven by a step motor. For the measurement of the electron temperature, the focused plasma radiations were monochromated using a JOBIN YVON HR-320, and the light signals for two hydrogen atomic lines (H_α: 656 nm and H_β: 486 nm) and were processed in a multichannel detection system (Atago MAX-3000). The time-resolved measurement was performed with a gate period of 10 μs, in which the delayed signal was given by a delay generator (Stanford DG535). The net emission intensities for the two spectral lines were obtained by subtracting the continuum component from the measured line intensities, and the temperature was then calculated using the two-line method. For the measurement of electron number density, the signal of the H_β line at 486 nm were processed. The coil current signals were stored in a PC through a digital oscilloscope (LeCroy LC334). The electron number density was determined using Stark broadening, and the coefficients used in the calculation were taken from Hill [12]. Abel inversion was performed to obtain the radial profiles of the plasma temperature and the electron number density.

3. Mathematical model

The plasma is considered axisymmetrical and in local thermodynamical equilibrium. The two-dimensional, time-dependent governing equations consist of the conservation of mass, energy, momentum, electromagnetic field, as well as those of the turbulent kinetic energy and the dissipation rate of the turbulent kinetic energy, which are based on the renormalization group (RNG) *k-e* turbulence model. The model equations are written into a general form:

$$\frac{\partial}{\partial t}(rf)+\frac{\partial}{\partial z}(ruf)+\frac{1}{r}\frac{\partial}{\partial r}(rrvf)=\frac{\partial}{\partial z}\left(\Gamma_f\frac{\partial f}{\partial z}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_f\frac{\partial f}{\partial r}\right)+S_f\,. \tag{1}$$

Table I. Variables, coefficients and source terms for the conservation equations.

f	Γ_Φ	S_Φ
1	0	0
u	m_e	$-\frac{\partial p}{\partial z}+\frac{\partial}{\partial z}\left(m_e\frac{\partial u}{\partial z}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(rm_e\frac{\partial v}{\partial z}\right)+F_z$
v	m_e	$-\frac{\partial p}{\partial z}+\frac{\partial}{\partial z}\left(m_e\frac{\partial u}{\partial r}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(rm_e\frac{\partial v}{\partial r}\right)-\frac{2m_e v}{r^2}+\frac{rw^2}{r}+F_r$
w	m_e	$-\frac{w}{r}\left(rv+\frac{m_e}{r}+\frac{\partial m_e}{\partial r}\right)$
h	$k/C_p+m_t/\mathrm{Pr}_t$	P_0-P_R
k	$a_k m_e$	$G-re$ *
e	$a_e m_e$	$\frac{e}{k}(C_{e1}G-C_{e2}re)-R$ **

* $G=m_t\left\{2\left[\left(\frac{\partial u}{\partial z}\right)^2+\left(\frac{\partial v}{\partial r}\right)^2+\left(\frac{v}{r}\right)^2\right]+\left(\frac{\partial w}{\partial r}-\frac{w}{r}\right)^2+\left(\frac{\partial w}{\partial z}\right)^2+\left(\frac{\partial v}{\partial r}+\frac{\partial u}{\partial r}\right)^2\right\}$

** $R=\frac{C_m r h^3(1-h/h_0)}{1+bh^3}\frac{e^2}{k}$

$h\equiv Sk/e$, $S^2=G/m_t$, $m_e=m_m+m_t$, $m_t=rC_m k^2/e$, $h_0=4.38$, $b=0.012$,

Table II. Torch dimensions and operating conditions.

Inner radius of central tube (R_1)	1.0 mm	Central gas flow rate (Q_1)	0 slpm
Outer radius of central tube (R_2)	2.0 mm	Plasma gas flow rate (Q_2)	0 slpm
Radius of sheath tube (R_3)	27.0 mm	Sheath gas flow rate (Q_3)	98 slpm (Ar)
Inner radius of torch (R_0)	27.5 mm		6 slpm (H_2)
Radius of RF coil (R_c)	44.0 mm	Plasma power (P_0)	4–13 kW
Position of first RF coil (L_1)	60.0 mm	Pressure (p)	27 kPa
Position of last RF coil (L_2)	145.0 mm	Numer of RF coil (N_c)	13 turn
Length of torch (L_3)	170.0 mm	Operating frequency (f)	1 MHz
Thickness of torch wall (d_w)	7.5 mm		

The dependent variables, the transport coefficients and the source terms are summarized in Table I, and detailed descriptions of the model and the solution method are found in Ref. 11.

4. Results and discussion

Computations were performed for the PM-ICP under the operating conditions given in Table II. In Figure 2, the left-hand side depicts the predicted isotherms under the continuous power condition (13 kW), and another side presents the time-averaged ones over one pulse cycle (15 ms) under the pulsed power condition. Compared to the continuous plasma, the high temperature zone was much smaller in the pulsed power plasma, and the

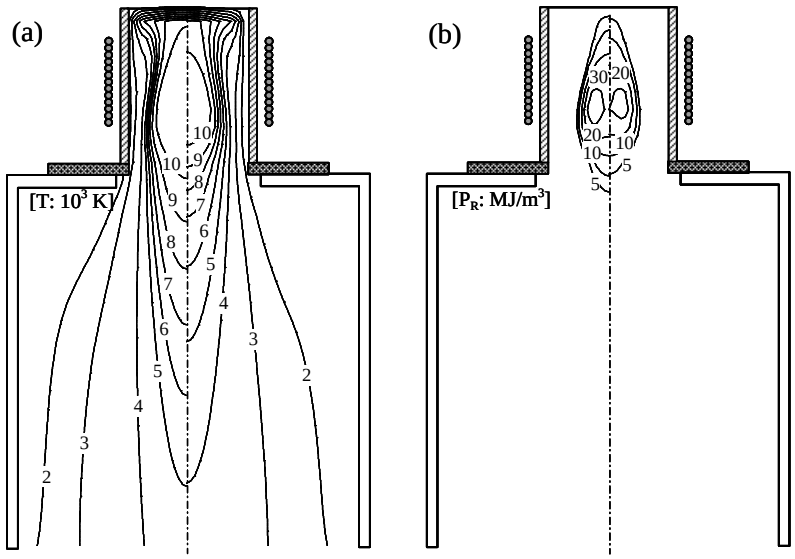

Figure 2. Predicted temperature fields (a) and volumetric radiation power (b) for the continuous plasma (left-hand side) and the pulse-modulated plasma (right-hand side).

plume length of the time-averaged plasma was also much shorter. Along the axis, in the downstream of the torch the time-averaged temperatures were 1000–1500 K lower than those of the steady-state at the same axial position. The volumetric radiation power was also reduced considerably in the pulsed power plasma. Consequently a specimen can be put closer to the discharge zone of the pulse-modulated plasma and better irradiation effects may be achieved.

Figure 3 illustrates the predicted and measured profiles of plasma temperatures at 10 mm below the end of the coil (z=155 mm). Although the measured plasma temperatures were found scattered around, most of them were about 1000–2000 K higher than the predicted ones. This phenomenon could be attributed to the fact that the measured temperatures were actually the excitation temperatures which were closer to those of the electrons, and therefore were higher than the heavy particle temperatures. In addition, under the pulsed power condition, the radial temperature gradients became less steep, and more uniform plasma temperature profiles could be obtained.

The electron number densities under given pressure and temperature conditions were calculated using a chemical reaction kinetics model [12]. In Figure 4, the predicted and measured time-averaged electron number densities were very close to each other in the central region of the torch (r<12 mm), but the differences between these two densities increased with the radial position. The measured electron number densities only had slight decreases at the boundaries of the plasma where the emission signals could be detected. However, the predicted ones dropped significantly in the fringes of the plasma. The differences between the predicted and measured results were beyond the ranges of experimental errors, and could be ascribed to the presence of nonequilibrium phenomena in these regions. Taken into account the radial diffusion of species, the electron temperatures and number densities at the boundaries under nonequilibrium conditions should be much higher than those values under equilibrium conditions owing to the high mobility of electrons [13]. Consequently, rather than using the LTE temperature, the electron number densities should be evaluated using nonequilibrium models that could include the effects of temperatures for different species. In Figures 4 and 5, we may find that the departure from LTE became more significant as the plasma flowed downward and cooled down.

Moreover, the results indicated that the deviation from equilibrium became more noticeable under the pulse-modulated operating condition. The nonequilibrium regions even extended into the central region where the plasma was normally in equilibrium under the continuous operating condition, see Figure 5. For example, at

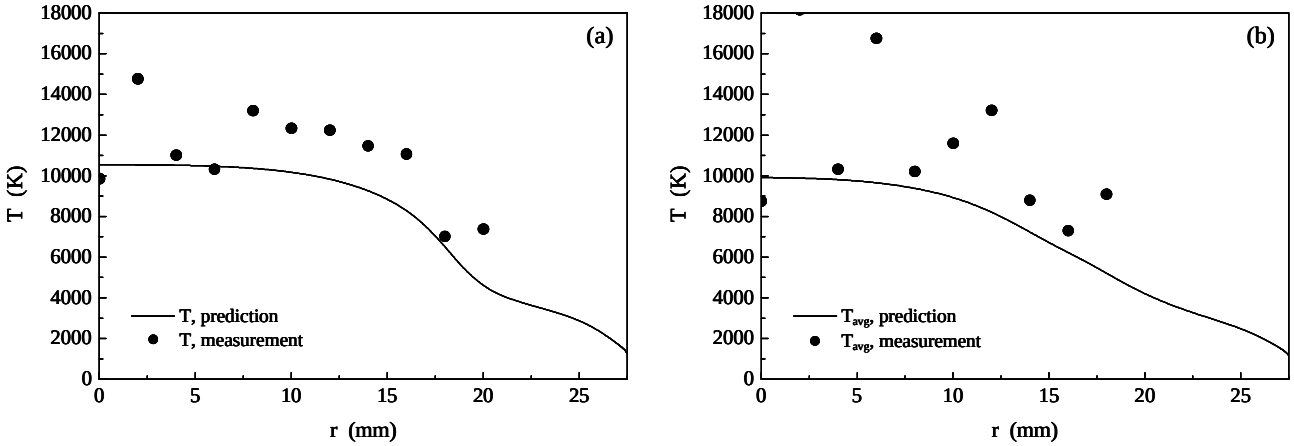

Figure 3. Predicted and measured temperatures at 10 mm below the end of the coil (z=155 mm): (a) steady-state, and (b) time-averaged.

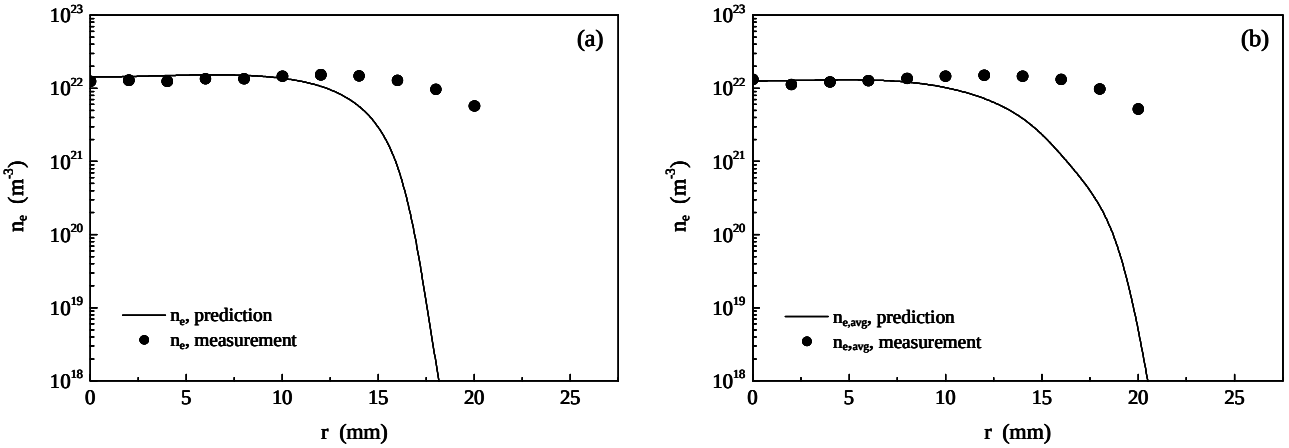

Figure 4. Predicted and measured electron number density at the midcoil (z=102.5 mm): (a) steady-state, and (b) time-averaged.

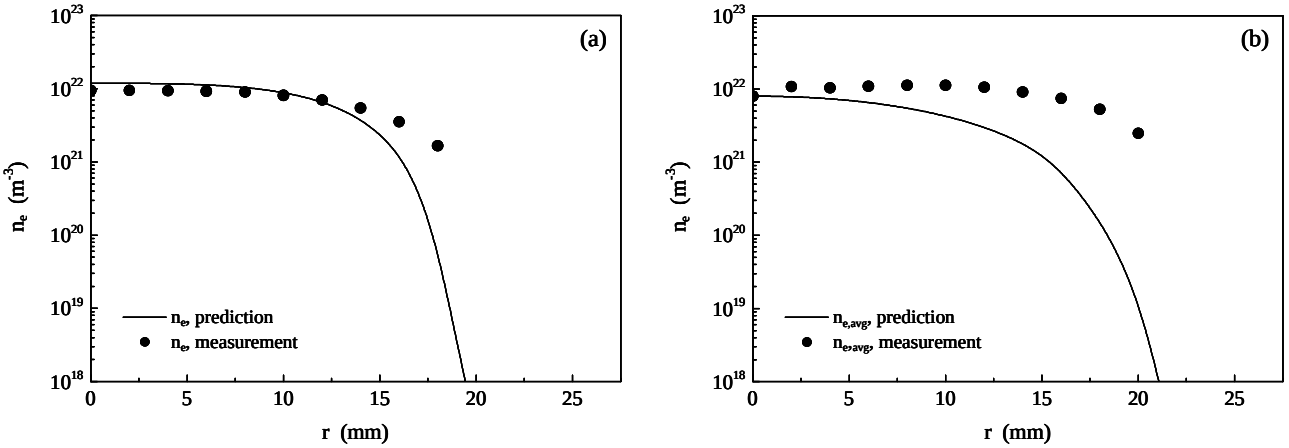

Figure 5. Predicted and measured electron number density at 10 mm below end of the coil (z=155 mm): (a) steady-state, and (b) time-averaged.

r=10 mm, the measured and predicted electron number densities were respectively 1.1×10^{22} and 4.1×10^{21} m^{-3}, the former was 2.7 times as high as the latter. This difference was due to the fact that the electrons reacted to the changes in the input power much faster than the heavy particles did, the electron temperature had a quick increase at the stage of pulse-on, and the degree of departure from LTE was enhanced under the pulsed power condition. However, the effect of electron temperature on the plasma properties was not considered in the LTE model, and the plasma composition was estimated based on the equilibrium temperature. As a result, the electron number densities might be underestimated when the plasma deviated from equilibrium.

5. Conclusion

In summary, the predicted results showed that the time-averaged temperature of the PM-ICP was much smaller than that of the continuous plasma. The measured plasma temperatures had similar radial profiles to the predicted ones, although the former were a bit higher. The agreement between the theoretical and experimental electron number densities was satisfactory in the central region of the torch, but the discrepancies became larger in the fringes of the plasma where the deviation from LTE was the most pronounced. It was suggested that the LTE model might not be accurate enough to adequately describe the behavior of plasmas under such pulsed power conditions. Our work involving the development of non-LTE models for PM-ICPs is on-going.

Abstract
Plasmacatalytic reaction for methane conversion was carried out in a dielectric-barrier discharge (DBD) reactor at atmospheric pressure. Pt catalysts supported on the Al_2O_3 and TiO_2 were tested, and the catalysts were prepared by sol-gel-derived synthesis. Plasma-assisted reduction (PAR) was applied to reduce the prepared metal catalysts in DBD reactor. Plasma assisted reduction (PAR) was applied to the prepared metal catalysts as a method of catalyst reduction, which is novel method to reduce metal oxide catalyst in DBD reactor. Prepared metal oxide catalysts are reduced using plasma energy, and Pt/TiO_2 and Pt/Al_2O_3 catalysts were successively reduced by PAR. The main products of methane conversion were the light alkanes such as C_2H_6, C_3H_8 and C_4H_{10} when the catalytic plasma reaction was carried out with catalyst. Methane conversion reached 53% depending on Pt loading and calcination temperature.

1. Itroduction

Natural gas is one of the most useful resources in the world due to the greatness of the amount and wideness of its distributions. As fossil fuels such as oil and coal are depleting, the value of natural gas as an alternative fuel is becoming greater and greater[1-3]. This is the reason why many researchers have been trying to convert methane, the main component of natural gas, to liquid fuels or more useful chemicals. But, there are a lot of difficulties in doing so because of the stability of methane. Natural gas can be indirectly converted to liquid fuels or other chemicals by way of synthesis gas, or directly transformed to C_2 hydrocarbon or methanol. Most of commercial natural gas converting processes convert methane to synthesis gas by steam reforming, and then synthesize methanol or gasoline using this synthesis gas as an intermediate. Since the process producing synthesis gas by steam reforming of natural gas requires much endothermic heat, it needs lots of energies and high temperature over 800 ℃. To overcome these problems, there have been lots of studies on the direct conversion method. Oxidative coupling[4-8], thermal coupling[9], plasma[1,7,10-13] and so on have been tried for direct methane conversion.

Methane conversion with plasma has been widely researched nowadays as an alternative method. Especially, methane conversion and methane reforming with CO_2 were extensively studied[2-3,8,14-17]. Methane activation with non-thermal plasma is very effective not only in that methyl radicals could be easily made by the high energy of plasma, but also in that various kinds of chemical reactions could be induced through the high energy [14,16-18]. The methyl radicals produced from plasma make C_2, C_3 and C_4 hydrocarbons by coupling with other methyl radicals[1,14]. However, the conversion was limited by the plasma power and the plasma reaction produced various kinds of by-product. Recently, to solve these problems, heterogeneous catalysts were introduced into the plasma reaction.

Liu et al.[14,15,18] investigated the effect of Zeolite on the plasma methane conversion. Also, metal oxide catalysts were widely used for producing high value-added compounds from methane[13,19-21]. Moreover, preparation of catalyst and surface treatment of catalyst have been attempting using plasma energy[22-23]. Li et al.[22] reported that conversion of methane was increased 5-10% by plasma treatment of Ni catalyst, maintaining the same selectivity of synthesis gas. Liu et al.[23] also reported that Pd/HZSM-5 catalyst treated by glow discharge showed high catalytic activity and durability. In their work, the conversion of methane was almost 100% at 450 ^oC while the conversion was 50% without plasma treatment at the same conditions. In our previous work[24-26], the plasma-assisted reduction (PAR) of novel metal catalyst was proposed using dielectric-barrier discharge (DBD). The reduction of catalyst was completed rapidly in the plasma, and the selectivity of alkane such as ethane and propane was highly increased.

Although the above mentioned plasma-catalytic reactions showed improved results, the catalysts used are in powder forms. For practical applications in large scale, spherical catalysts having the desired pore structures are preferred. In this study, Plasmacatalytic reaction for methane conversion was carried out in a dielectric-barrier

discharge (DBD) reactor at atmospheric pressure[1-3]. Pt catalysts supported on the Al_2O_3 and TiO_2 were tested, and the catalysts were prepared by sol-gel-derived synthesis[4]. Plasma-assisted reduction (PAR) was applied to reduce the prepared metal catalysts in DBD reactor. Plasma assisted reduction (PAR) was applied to the prepared metal catalysts as a method of catalyst reduction, which is novel method to reduce metal oxide catalyst in DBD reactor. Prepared metal oxide catalysts[5-7] are reduced using plasma energy. The effect of catalyst on methane conversion and product selectivities was studied.

2. Experimental

A schematic diagram of the experimental apparatus is shown in Figure 1. Quartz tube with an i.d. of 8mm and the length of 270mm was used for Dielectric-Barrier Discharge (DBD) reactor. Two stainless steel wires with a diameter of 0.45mm were installed in the quartz tube as an inner electrode. The outer surface of quartz tube was coated with silver paste as another electrode, and the length of coated silver paste was 200mm. An AC pulse power supply (ITM) with [0-10kV, 10-40kHz, 2-5μs] was used in this experiment. The flowrate of methane was controlled by the mass flow controller (Bronkhorst, B-5534-FA). The reaction products of hydrocarbons were analysed with the gas chromatograph (HP 5890 equipped with a Haysep Q packed column and FID detector). Gas chromatograph (Younglin M600D) equipped with TCD was used to analyse the produced hydrogen. The peaks were identified when the retention times compared with those of standard gases (CH_4, C_2H_2, C_2H_4, C_2H_6, C_3H_4, C_3H_6, C_3H_8 and C_4H_{10}) with a purity above 99.5%.

For preparation of Al_2O_3 and TiO_2 xerogel, sec-butanol, aluminium tri-sec-butoxide (ATB; $Al[O(CH_3)C_2H_5CH]$), and titanium tetraisopropoxide(TTIP; $Ti(OC_3H_7)_4$) were used as precursor. $H_2PtCl_6 \cdot 6H_2O$ was used as a metal precursor. Catalysts were prepared with sol-gel method, and prepared sol was drying at 120℃ for 24hr.

Prepared catalyst was sieved 20~42mesh and then calcined between 400℃ and 600℃ for 2hr with oxygen flowrate of 100ml/min. The catalyst of 0.3g was packed with the lower part of DBD reactor for catalytic plasma reaction, while the upper part remained blank. Below the catalyst-packed volume, i.e. at the lower non-plasma zone, glass beads were packed. All experiments were carried out under atmospheric pressure.

The catalyst of 0.3g was packed with the lower part of DBD reactor for catalytic plasma reaction, while the upper part remained blank. Below the catalyst-packed volume, i.e. at the lower non-plasma zone, glass beads were packed. All experiments were carried out under atmospheric pressure.

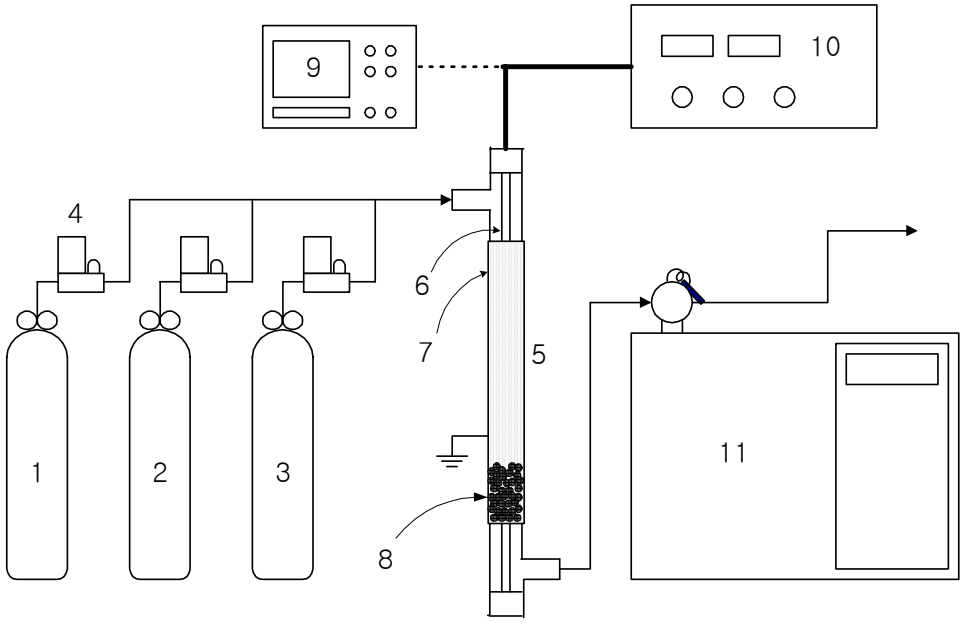

Figure 1. Schematic diagram of experimental apparatus.

The methane conversion is defined as:

$$\text{CH}_4 \text{ conversion} = \frac{\text{moles of CH}_4 \text{ consumed}}{\text{moles of CH}_4 \text{ introduced}} \times 100 .$$

The selectivities and yields of C_2, C_3 and C_4 hydrocarbons are:

$$\text{Selectivity of } C_xH_y = x \cdot \frac{C_xH_y}{\text{moles of CH}_4 \text{ consumed}} \times 100 .$$

The selectivity of hydrogen is:

$$\text{Selectivity of H}_2 = 0.5 \times \frac{\text{moles of H}_2 \text{ formed}}{\text{moles of CH}_4 \text{ consumed}} \times 100 .$$

The yields of hydrocarbons are:

$$\text{Yields of } C_xH_y = \text{Conversion of CH}_4 \times \text{Selectivity of } C_xH_y .$$

3. Results and Discussion

Plasma treatment is one of novel methods for preparation and reduction of catalysts. Non-thermal plasma makes large amount of free electrons which have high energy. Produced high energy electrons are used to activate other molecules. In a plasma state, hydrogen can be easily activated due to high-energy electron, which can lead to reduce metal oxide catalyst. Generally, metal oxide catalysts are reduced at high temperature in the hydrogen atmosphere. The catalyst surface (metal oxide) in contact with the highly activated hydrogen can be reduced. In this work, plasma was applied to reduce prepared Pt/γ-Al_2O_3 catalysts in dielectric-barrier discharge reactor.

Plasma assisted reduction was applied to reduce Pt-based catalyst at the flow rate of 10 ml/min of 20 vol% H_2 in N_2. The rate of hydrogen consumption was monitored by a thermal conductivity detector. The applied voltage was fixed at 3.0 kV, and then the power input was in the range of 37-39 W with the variations of experimental conditions. The prepared catalyst was successively reduced by PAR. PAR was an effective method to reduce metal oxide catalyst in DBD reactor. Plasma catalytic reaction was carried out after PAR. Typical PAR pattern of Pt/Al_2O_3 was shown in Figure 2. The selectivity of C_2H_6, C_2H_4 and C_2H_2 was higher among the produced hydrocarbons when the methane conversion was carried out in the absence of catalyst. In the presence of a Pt catalyst, the main products of plasma catalytic reaction were the light alkanes such as C_2H_6, C_3H_8 and C_4H_{10}.

The effects of metal loading and calcination temperature on methane conversion and product selectivity were examined. Prepared catalysts were reduced by PAR at 3.0 kV for 2h with reduction gases. After reduction, the plasma catalytic reaction of methane was carried out *in situ* with flow rate of 30 ml/min at the applied voltage of 3.0 kV. All experiments were carried out with 0.3 g catalyst. In order to verify the effect of catalysts, blank experiment was carried out without catalysts. Methane conversion was not much difference depending on calcination temperature and metal loading when the Pt/TiO_2 catalyst was used, but product selectivity was slightly changed with calcination temperatures (Table 1, Table 2). Methane conversion and product selectivity was highly changed depending on calcination temperature and metal loading when sol-gel-derived Ru/TiO_2 catalyst was applied to DBD. The highest methane conversion was 47.35% when 5 wt% Ru/TiO_2 catalyst was calcined at 400 ℃. Anatase phase showed positive effect methane conversion in DBD.

XRD patterns of the Pt/TiO_2 and Pt/Al_2O_3 catalysts were shown in Figure 3 and 4. Pt peaks appeared after 600℃ calcined for 3wt% and 5wt% Pt//γ-Al_2O_3. It is assumed that metal particles migrated to the alumina surface during the calcination, and then sintering occurred. TiO_2 phase was changed from anatase to rutile with the calcination temperature increasing.

CO_2 Reforming of Methane in a Gliding Arc Discharge Reactor

H. K. Song, J.-W. Choi and H. Lee

Clean Technology Research Center, Korea Institute of Science & Technology, Seoul, Korea

Abstract

Experiments for CO_2 reforming of methane using gliding arc discharge were performed. A mixture gas of methane was introduced into gliding arc discharge region to produce more valuable hydrocarbons or synthesis gas. The main products of reactions were synthesis gas and acetylene, and small amounts of other C2 hydrocarbons were observed. The methane conversion rate in a gliding arc discharge reactor was calculated and compared with that of other low temperature plasma reactors. The experimental results showed that gliding arc discharge could be an effective tool for methane conversion reaction.

Keywords

Methane, Carbon Dioxide, Reforming, Conversion, Gliding Arc Discharge

1. Introduction

Natural gas is one of the most useful resources in the world due to the greatness of its amount and wideness of its distributions. As reserves of oil are depleting, the value of natural gas as an alternative fuel is becoming greater and greater. Natural gas can be indirectly converted to liquid fuels or other chemicals by way of synthesis gas, or directly transformed to C2 hydrocarbon or methanol. Most of commercial natural gas converting processes convert methane to synthesis gas with steam reforming, and then synthesize methanol or gasoline using this synthesis gas as an intermediate. However, these processes require extreme reaction conditions of high temperature and pressure, and suffer from the rapid deactivation of catalyst and the carbon deposition on the surface of catalyst. So, many studies on the methane conversion using plasma processes are being performed as a promising tool to overcome these problems [1-6]. In plasma processes, the electrical input energy is transferred to energetic electrons rather than heating gas. Through electron impact ionization, dissociation and excitation, generated are excited atomic and molecular species such as electrons, ions and radicals, which in turn enhance the chemical reaction.

In this study, the performance of methane conversion was investigated in a gliding arc discharge reactor. The gliding arc discharge easily generated between two or more diverging electrodes placed in a fast gas flow is a new interesting subject in the area of the chemical reactive conversion for its power effectiveness and its treatment volume [7-8]. The effects of applied frequency, total flowrate, and methane concentration in feed mixture on the conversion and product selectivities were investigated. The chemical reaction performance of the gliding arc discharge was compared with that of other low temperature plasma reactors.

2. Experiments

Experimental setup for CO_2 reforming of methane using gliding arc discharge was shown in Fig. 1. The gliding arc discharge reactor was made of a quartz tube of inner diameter 45 mm and length 300 mm. The upper and bottom part of the reactor was sealed with Teflon and two electrodes were set up inside the reactor. The electrode made of stainless steel had a triangular form with the height of 100 mm. The narrowest gap distance between two electrodes was about 1.5 mm. The gas mixture was introduced between the electrodes through a capillary tube of inner diameter 0.8 mm. A high frequency AC power supply with a maximum voltage of 10 kV, a frequency of 10~20 kHz and a current of 0~100mA was connected to a gliding arc reactor to generate discharge. The waveforms of input voltage and current were measured with a digital oscilloscope (Agilent 54641A) having analog bandwidth of 350 MHz through a high voltage probe (Tektronics 6145A) and current monitor (Pearson 4997).

Methane with a purity of 99% and carbon dioxide with a purity of 99% were used as feed gas, and the flowrate of each gas was controlled with mass flow controllers. Total flowrate of feed gas was fixed at 1

l/min and the concentration of methane was varied from 20 vol% to 90 vol%. Gaseous products were analyzed with two gas chromatographs. A gas chromatograph (HP5890) equipped with flame ionization detector containing Haysep Q column was used to analyze the light hydrocarbon products. Another gas chromatograph (Younglin 600D) equipped with thermal conductivity detector containing molecular sieve 5A and mixture of Porapak Q and R column was also used to detect hydrogen, carbon monoxide and carbon dioxide.

In all experiments, the performance of a gliding arc discharge reactor was evaluated by conversion and selectivities. The conversion and selectivities are defined as bellows.

$$\text{CH}_4 \text{ conversion} = \frac{\text{moles of } \text{CH}_4 \text{ converted}}{\text{moles of } \text{CH}_4 \text{ in feed}} \times 100$$

$$\text{CO}_2 \text{ conversion} = \frac{\text{moles of } \text{CO}_2 \text{ converted}}{\text{moles of } \text{CO}_2 \text{ in feed}} \times 100$$

$$\text{Selectivity of CxHy} = \frac{x \times \text{moles of } \text{C}_\text{X}\text{H}_\text{y} \text{ produced}}{\text{moles of } \text{CH}_4 \text{ converted} + \text{moles of } \text{CO}_2 \text{ converted}} \times 100$$

$$\text{Selectivity of } \text{H}_2 = \frac{\text{moles of } \text{H}_2 \text{ produced}}{2 \times \text{moles of } \text{CH}_4 \text{ converted}} \times 100$$

$$\text{Selectivity of CO} = \frac{\text{moles of CO produced}}{\text{moles of } \text{CH}_4 \text{ converted} + \text{moles of } \text{CO}_2 \text{ converted}} \times 100$$

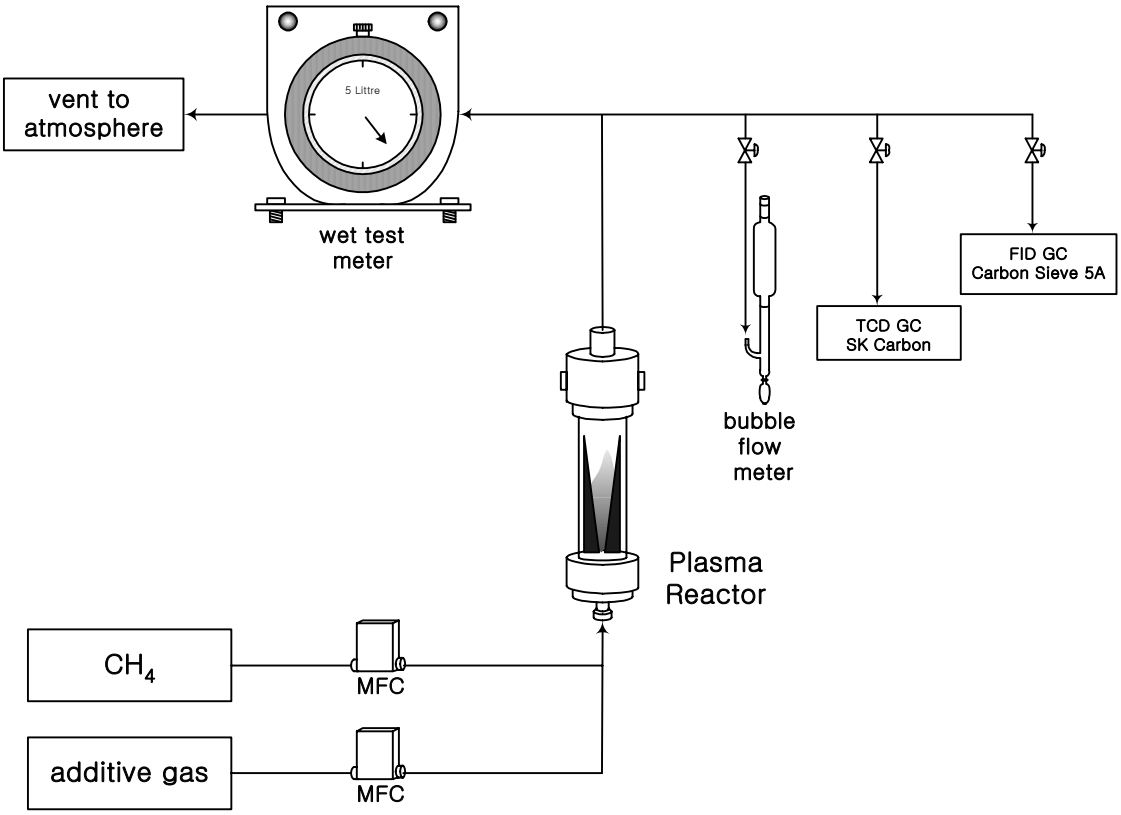

Fig. 1. Experimental setup for methane conversion using gliding arc discharge.

3. Results and Discussion

To investigate the performance of conversion of methane and carbon dioxide in a gliding arc discharge reactor, laboratory experiments were carried out under various experimental conditions. The experimental variables were the input power and the concentration of methane in a feed mixture. Hydrogen, carbon monoxide and acetylene were the main products in a gliding arc discharge reactor and other light hydrocarbons such ethylene and ethane were not observed. Carbon solid material was formed when the concentration of methane was over 50 vol%.

The effect of concentration of methane on conversion was shown in Figure 2. The methane conversion was increased from 35% to 47% although the number of methane molecule was increased. This is mainly due to the introduction of carbon dioxide. In the plasma region, carbon dioxide was decomposed to carbon monoxide, oxygen and atomic oxygen, and this was helpful to destruct the carbon-hydrogen bond of methane molecule. The carbon dioxide conversion was also increased from 26% to 36% with the increase of methane concentration since the total number of carbon dioxide molecule was decreased.

Figure 3 showed the selectivity of plasma products with concentration of methane. The selectivity was strongly dependent on the concentration of methane. The selectivity of hydrogen was decreased from 62% to 37%, and the selectivity of carbon monoxide was rapidly decreased from 93% to 5% when the concentration of methane was increased from 20 vol% to 90 vol%. The selectivity of acetylene showed a maximum value at the methane concentration of 80 vol%. From these results, it was found that the concentration of methane determined the product selectivity and the lower concentration of methane produced more hydrogen and carbon monoxide

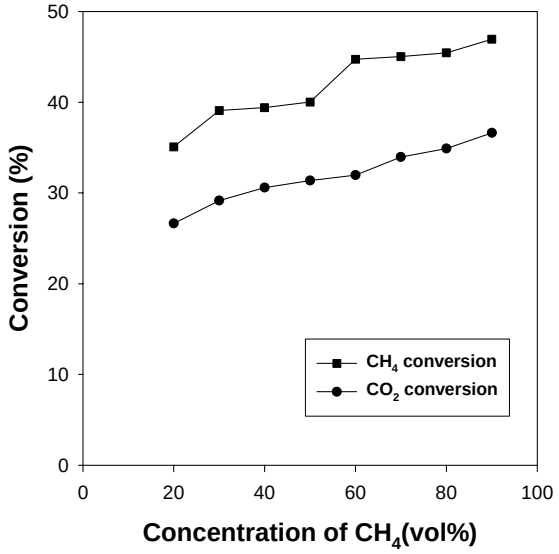

Fig. 2. Effect of CH_4 concentration on conversion.

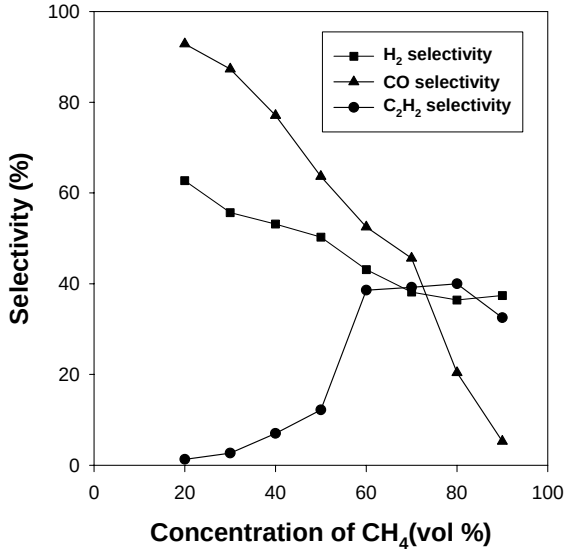

Fig. 3. Effect of CH_4 concentration on selectivity.

To evaluate the reaction efficiency of different plasma source, we calculated the methane conversion rate. Figure 4 showed the consumed power inside a gliding arc discharge reactor with the concentration of methane. The consumed power was decreased from 262W to 162W although the conversion of methane was increased with methane concentration. So, the higher methane concentration was favorable from a viewpoint of energy cost. Figure 5 showed methane conversion rate with some other kinds of plasma sources. The result of microwave was obtained from the literature [9], and those of dielectric barrier discharge were calculated in our previous works [5]. Methane conversion rate obtained in a gliding arc discharge reactor was much higher than those of DBD and microwave discharge. From results, it can be considered that the gliding arc discharge could be an alternative tool for methane conversion reaction.

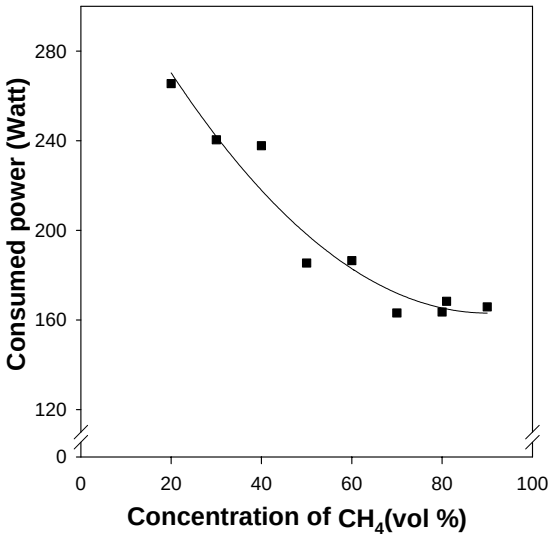

Fig. 4. Consumed power.

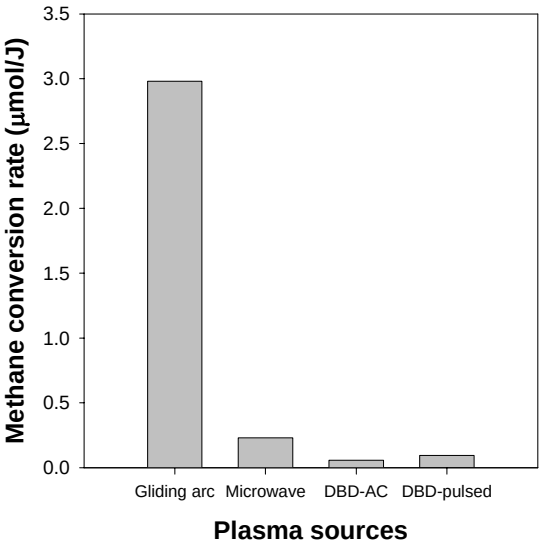

Fig. 5. Comparison of methane conversion rate.

4. Conclusions

Gliding arc discharge is a new interesting subject in the area of the chemical reactive conversion for its high specific throughputs in the reaction zone, and its power effectiveness. In this study, the performance of CO_2 reforming of methane in a gliding arc discharge reactor was experimentally examined and compared with that of other low temperature plasma reactors.

Hydrogen, carbon monoxide and acetylene were the main products in a gliding arc discharge reactor and carbon solid soot were observed when the methane concentration was over 50%. The methane concentration was the key factor to determine the conversion of methane and product selectivities. The lower methane concentration was more favorable to obtain the synthesis gas. The methane conversion rate obtained in this study was much higher than those of dielectric barrier discharge and microwave plasmas.

From these results, it can be considered that the gliding arc discharge could be an alternative tool for methane conversion.

Low Temperature Synthesis of Carbon Nanofiber in Vibrationally Nonequilibrium CO Plasma and Its Carbon Isotopic Contents

S. Mori, M. Fukuya, and M. Suzuki

Department of Chemical Engineering, Tokyo Institute of Technology, Tokyo, Japan

1. Introduction

In glow discharge of diatomic molecules with translational mode cooling and moderate electric field, one can create vibrationally excited plasma. In the moderate electric fields, plasma free electrons excite the vibrational mode of diatomic molecules preferentially and a decrease of translational temperature strongly decreases the vibration-to-translation energy transfer rates, having only minor effect on vibration-to-vibration energy exchange ones [1]. Such vibrationally nonequilibrium plasma have been studied for being applied to an isotope separation method because vibrational states of heavier isotopic species are overpopulated due to the smaller oscillation frequency for the heavier isotopic species [1-3]. Chemical reactions occurring among vibrationally excited molecules are also attractive for some chemical synthesis processes because the activation energy for the reaction is provided by the vibrational energy mode and the gas kinetic temperature can be kept at a value suitable for those processes [4]. In the previous study, we demonstrated the formation of carbon thin film materials enriched in heavier carbon isotopes in the liquid nitrogen cooled CO plasma, which is enriched in heavier carbon isotopes [5, 6].In the subsequent analysis of wall deposits, we have found the formation of microstructured and nanostructured carbons, notably aligned carbon fibers, in the presence of metal catalysts. Here, we present the structure, morphology, and carbon isotopic contents of that carbon thin film materials formed in the liquid nitrogen cooled CO plasma.

2. Experimental

Figure 1 shows the schematic diagram of experimental apparatus. The central component of our experimental apparatus is the U-shaped discharge tube, which consists of 7.0 mm inner diameter Pyrex tube, with liquid nitrogen cooling bath. In the U-shaped discharge tube, there are two electrodes which are connected to the DC power supply; one of them is stainless steel rod with a diameter of 6 mm and located in the lower part of U-tube and the other is nickel rod with a diameter of 1.5 mm and placed in the upper part of U-tube.

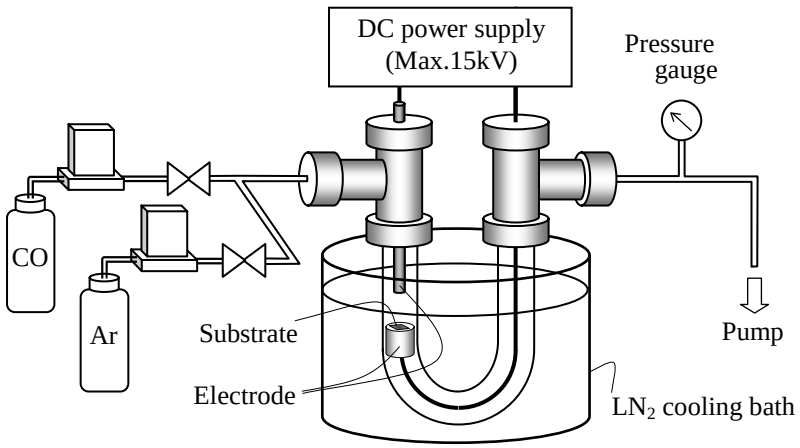

Fig. 1 Schematic diagram of experimental apparatus.

In this study, silicon and glass with a thin nickel catalyst layer were used as substrates. The nickel layer was prepared using DC sputtering process. In the sputtering process, substrates are placed on the lower electrodes (anode) and DC voltage is applied between electrodes spaced 5 mm apart. The detailed parameters for the deposition process are as follows: Ar flow rate: 2.0 sccm, pressure: 100 mTorr, sputtering time: 10-120 seconds. After obtaining Ni thin layer, discharge tube is cooled by liquid nitrogen and the distance and the polarity of electrodes are replaced; in the deposition process lower electrode is the cathode and the distance between two electrodes is set to 20 cm. Then the CO glow discharge plasma is generated between two electrodes. The detailed parameters for the deposition process are as follows: CO flow rate: 10 sccm, Ar flow rate: 10 sccm, total pressure: 6 Torr, deposition time: 10-180 min. Carbon deposits grown on the substrates were observed by scanning electron microscopy and transmission electron microscopy, and analyzed by Raman spectroscopy and Fourier transform infrared spectroscopy. To analyze the isotopic contents of the carbon materials, deposited materials were oxidized to CO_2 and carbon isotopic contents of converted CO_2 were measured by quadru-pole mass spectrometer.

3. Results and discussion

Figure 2 shows the SEM images of carbon nanofibers (CNFs) synthesized on the borosilicate glass substrates after 120-180 minutes deposition time. Aligned carbon nanofibers were synthesized under both room temperature and liquid-nitrogen cooled temperature conditions and the diameter of fibers are several hundreds nanometers and those length are about 10 microns. Figure 3 shows a typical Raman spectrum of the carbon materials formed on the glass substrates. The spectrum for the sample R3 presents two peaks of the graphite structures: the strong G-line peak at approximately 1590 cm^{-1} which indicates crystalline graphene layers and the broad D-line peak at 1350 cm^{-1} which indicates the existence of defective graphene layers such as amorphous carbon layers. However, for liquid nitrogen cooled samples (R1 and R2), both of intensities become very weak. Figure 4 shows a typical FT-IR spectrum of carbon thin film materials deposited on the CaF_2 substrates. There are strong carbonyl band peaks around 1750 and 3400 cm^{-1} for the liquid nitrogen cooled samples (F1 and F2). On the other hand, without liquid nitrogen cooling (F3), carbonyl peaks are weak and aromatic C=C vibration band around 1600 cm^{-1} appears instead. The morphology and structure of the film depend strongly on the metal catalysts, substrate material, substrate temperature, and discharge conditions.

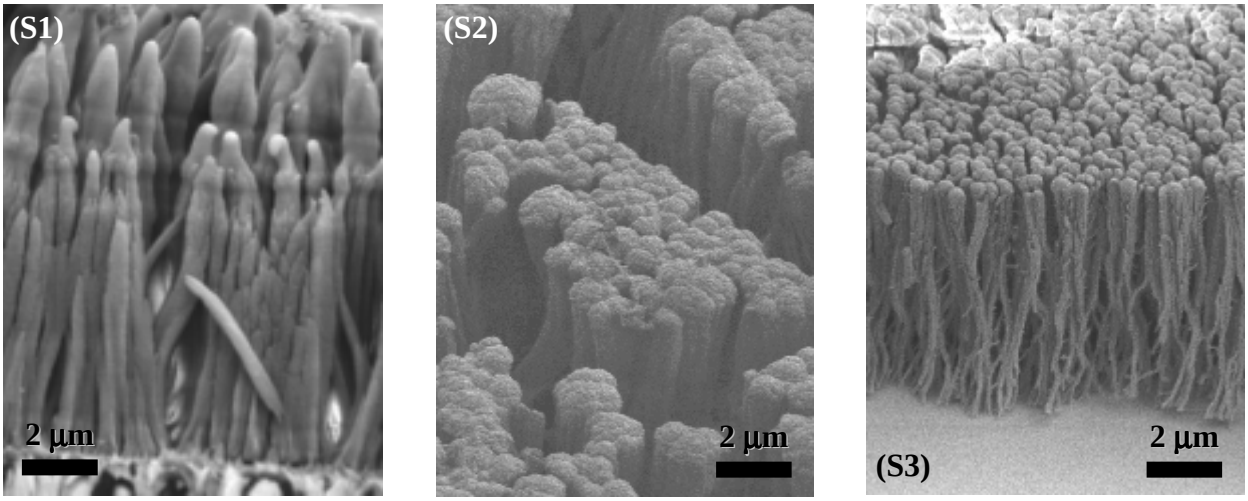

Fig. 2 SEM images of CNFs grown on the glass substrates (S1) with LN_2 cooling and Ni catalyst, (S2) with LN_2 cooling and without Ni catalyst, and (S3) with Ni catalyst and without LN_2 cooling.

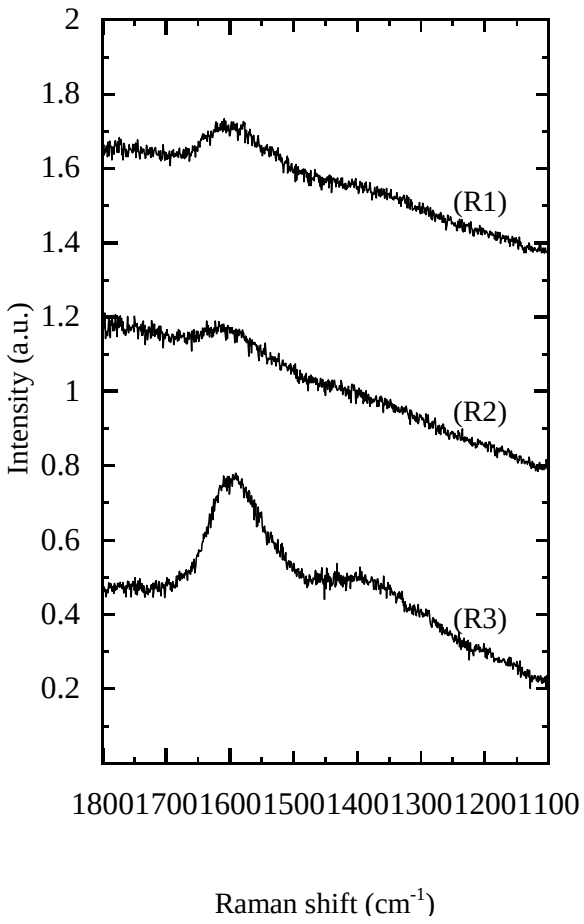

Fig. 3 Raman spectrum: (R1) with LN_2 cooling and Ni catalyst, (R2) with LN_2 cooling and without Ni catalyst, (R3) without LN_2 cooling and Ni catalyst.

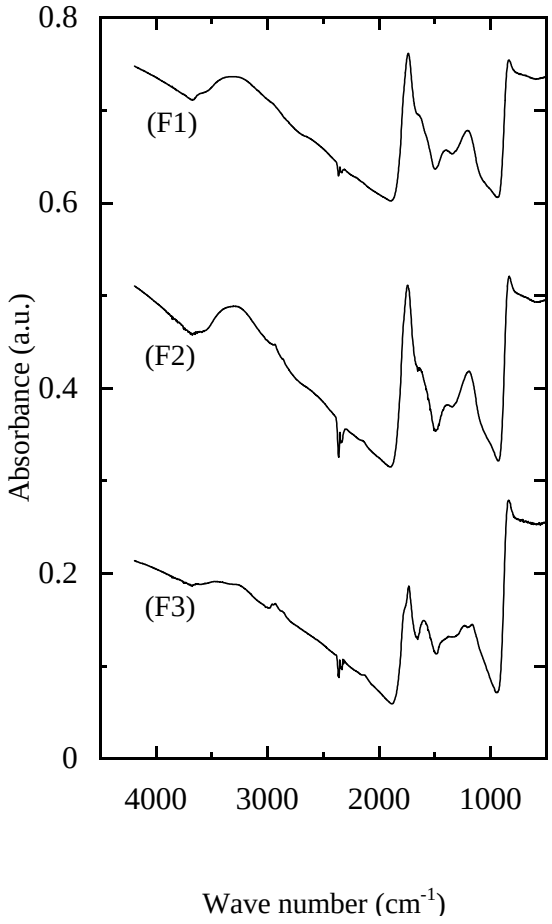

Fig. 4 FTIR spectrum: (F1) with LN_2 cooling and Ni catalyst, (F2) with LN_2 cooling and without Ni catalyst, (F3) without LN_2 cooling and Ni catalyst.

To verify the relation between reaction of vibrationally excited CO molecules and formation of CNFs, carbon isotopic contents in carbon deposits were also analyzed. This is due to the fact that carbon-13 isotope enrichment in carbon deposits results from reactions among vibrationally excited CO molecules [1]. In this study, the isotope enrichment of ^{13}C in the deposits is presented as isotope enrichment coefficient defined as:

$$^{13}\beta_C = (^{13}C/^{12}C)_{deposit} / (^{13}C/^{12}C)_{reactant} , \quad (1)$$

where $^{13}\beta_C$ is the ^{13}C enrichment coefficient in carbon deposit. The relative abundance of ^{13}C in carbon deposit, $(^{13}C/^{12}C)_{deposit}$, is determined by the mass spectrometric peak height at m/e = 44 and 45 of CO_2 converted from the deposit. The relative isotopic abundances in reactant, $(^{13}C/^{12}C)_{reactant}$ is calculated from the mass spectra for ^{13}C at m/e = 44, 45 of natural isotopic abundance CO_2. And only the natural isotopic composition CO was used as a reactant in this study. The carbon isotope enrichment coefficient for CNFs synthesized at room temperature is almost 1, that is, the isotope enrichment is not observed. However, the carbon isotope enrichment coefficient for the CNFs synthesized under the condition of liquid nitrogen cooling is 1.05. From this result, it was suggested that the vibrationally excited molecule perform the key role in this CNFs synthesis process.

4. Conclusion

We have performed the experimental study of low temperature synthesis of carbon nanofibers in nonequilibrium CO plasma. Nanostructured carbon thin film materials, notably well aligned nanofibers, were obtained on the glass substrate at room temperature and liquid-nitrogen cooled conditions in the presence of Ni catalysts. The film contains not only carbon but also oxygen in the structures. Diameter of fibers are several hundreds nanometers. The morphology and structure of the film depend strongly on the metal catalysts, substrate material, substrate temperature, and discharge conditions. To verify the relation between reaction of vibrationally excited CO molecules and formation of CNFs, we have also perfomed the analysis of carbon isotopic contents in carbon deposits. The isotope enrichment is not observed for CNFs synthesized at room temperature. However, the carbon-13 is slightly enriched in CNFs synthesized under the condition of liquid nitrogen cooling. From this result, it was suggested that the vibrationally excited molecules perform the key role in this low temperature CNFs synthesis process.

Modeling Study of Heat Transfer from a Laminar Argon Plasma Jet Impinging upon a Workpiece in Ambient Air

Kai Cheng [1], Hai-Xing Wang [1], Xi Chen [1], Wenxia Pan [2]

[1] *Department of Engineering Mechanics, Tsinghua University, Beijing 100084, China*
[2] *Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, China*

Abstract

Modeling is performed to study the heat transfer for a laminar argon plasma jet impinging upon a workpiece in ambient air. The heat flux density distribution on the workpiece surface obtained from this modeling is then used for predicting the re-melting of the cast-iron workpiece. The effects of workpiece moving speed, Marangoni convection et al on the workpiece heating are included in the workpiece heating study. The predicted width and depth of the molten pool in the workpiece agree reasonably with experimental data.

1. Introduction

Stable and silent long laminar plasma jets have been successfully generated recently with elaborately designed DC arc plasma torches (e.g. see [1]). Since only molecular diffusion mechanism is involved for the laminar case, the entrainment of ambient air into the laminar jet is appreciably reduced, and thus its high-temperature region length is much longer than that for the conventional turbulent plasma jet. The axial gradients of plasma temperature and axial-velocity in the laminar plasma jet are also much smaller. In addition, the laminar plasma-jet length can be easily adjusted by changing the arc current and/or the working-gas flow rate. These merits of the long laminar plasma jet make it very attractive from the viewpoint of materials processing, since it provides a new possibility to achieve low-noise working surroundings, better process repeatability and controllability, and reduced oxidation degree of metallic materials processed in air surroundings. Preliminary attempts [2,3] to use the laminar plasma jet in the preparation of thermal barrier coatings and in the re-melting hardening of cast iron and the stainless-steel surface cladding have shown encouraging results including the fine microstructure, low surface roughness and small porosity of the prepared coatings, the good re-melting process controllability and surface morphologies, as well as the preferable metallurgically bonded clad layer.

With the laminar plasma-jet hardening of cast iron surface [2,3] as the main research background, modeling study is conducted in this paper concerning heat transfer from a laminar argon plasma jet impinging normally upon a workpiece located in ambient air. Typical computed distributions of temperature, axial velocity, argon mass fraction distributions are presented and then a numerical modeling is also conducted to study the heating of the workpiece by the laminar plasma jet. In order to reveal the effects of the workpiece moving speed on the molten pool, three-dimensional modeling approach is used here to study the workpiece heating.

2. Modeling Approach

2.1 Laminar impinging plasma jet

Main assumptions used in the jet modeling study include steady, laminar and axi-symmetrical flow with negligible swirling velocity component; local thermodynamic equilibrium (LTE) and optically thin plasma; the diffusion of ambient air into the plasma jet can be handled by use of the combined-diffusion-coefficient method [4]. The governing equations including the mass, momentum, energy, and gas species conservation

equations in the cylindrical coordinate system are the same as those used in [5] as follows.

$$\frac{\partial}{\partial x}(\rho u)+\frac{1}{r}\frac{\partial}{\partial r}(r\rho v)=0 \tag{1}$$

$$\frac{\partial(\rho uu)}{\partial x}+\frac{1}{r}\frac{\partial(r\rho uv)}{\partial r}=-\frac{\partial p}{\partial x}+2\frac{\partial}{\partial x}\left[\mu\frac{\partial u}{\partial x}\right]+\frac{1}{r}\frac{\partial}{\partial r}\left[r\mu\left(\frac{\partial u}{\partial r}+\frac{\partial v}{\partial x}\right)\right] \tag{2}$$

$$\frac{\partial(\rho uv)}{\partial x}+\frac{1}{r}\frac{\partial(r\rho vv)}{\partial r}=-\frac{\partial p}{\partial r}+\frac{2}{r}\frac{\partial}{\partial r}\left[r\mu\frac{\partial v}{\partial r}\right]+\frac{\partial}{\partial x}\left[\mu\left(\frac{\partial v}{\partial x}+\frac{\partial u}{\partial r}\right)\right]-2\mu\frac{v}{r^2} \tag{3}$$

$$\frac{\partial(\rho uh)}{\partial x}+\frac{1}{r}\frac{\partial(r\rho vh)}{\partial r}=\frac{\partial}{\partial x}\left[\frac{k}{c_p}\frac{\partial h}{\partial x}\right]+\frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{k}{c_p}\frac{\partial h}{\partial r}\right]-U_r-\frac{\partial}{\partial x}\left[(h_A-h_B)J_x\right]-\frac{1}{r}\frac{\partial}{\partial r}\left[r(h_A-h_B)J_r\right]$$

$$-\frac{\partial}{\partial x}\left[\frac{k}{c_P}(h_A-h_B)\frac{\partial f_A}{\partial x}\right]-\frac{1}{r}\frac{\partial}{\partial r}\left[r\frac{k}{c_P}(h_A-h_B)\frac{\partial f_A}{\partial r}\right] \tag{4}$$

$$\frac{\partial(\rho uf_A)}{\partial x}+\frac{1}{r}\frac{\partial(r\rho vf_A)}{\partial r}=\frac{\partial}{\partial x}\left[\Gamma_f\frac{\partial f_A}{\partial x}\right]+\frac{1}{r}\frac{\partial}{\partial r}\left[r\Gamma_f\frac{\partial f_A}{\partial r}\right]+S_f \tag{5}$$

Here u and v are the axial (x-) and radial (r-) velocity components, ρ, μ, k, c_p, h and U_r are temperature- and composition-dependent plasma density, viscosity, thermal conductivity, specific heat at constant pressure, specific enthalpy and radiation power per unit volume of plasma, respectively, p and f_A are the pressure and the argon mass fraction in the argon-air mixture. In Eq. (4), h_A and h_B are the specific enthalpies of gases A (argon) and B (air), respectively, whereas J_x and J_r are the axial (x-) and radial (r-) components of the argon diffusion mass flux vector $\vec{J}_A=-\left(n^2/\rho\right)\overline{m}_A\overline{m}_B\overline{D}_{AB}^{x}\nabla X_A-\overline{D}_{AB}^{T}\nabla\ln T$. Here n is the total gas-particle number density, $\overline{m}_A$ and $\overline{m}_B$ are the averaged particle masses for all the *heavy* gas particles (excluding electrons) coming from argon and those from air, X_A is the mole fraction of argon in the argon-air mixture, whereas $\overline{D}_{AB}^{x}$ and $\overline{D}_{AB}^{T}$ are the combined ordinary diffusion coefficient associated with the argon mole fraction gradient ∇X_A and the combined thermal diffusion coefficient associated with the temperature gradient ∇T, respectively [4]. The transport coefficient in Eq. (5) is expressed by $\Gamma_f=[\overline{m}_A\overline{m}_B/(\overline{MM}_A)]\rho\,\overline{D}_{AB}^{x}$, in which $\overline{M}$ and $\overline{M}_A$ are the averaged gas-particle mass for *all* the gas particles (including electrons) of the gas mixture and that for *all* the gas particles coming from argon, respectively, whereas the source term S_f is [4,5]

$$S_f=\frac{\partial}{\partial x}\left(\Gamma_f\frac{f_A}{\overline{M}}\frac{\partial\overline{M}}{\partial x}\right)-\frac{\partial}{\partial x}\left(\Gamma_f\frac{f_A}{\overline{M}_A}\frac{\partial\overline{M}_A}{\partial x}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_f\frac{f_A}{\overline{M}}\frac{\partial\overline{M}}{\partial r}\right)-\frac{1}{r}\frac{\partial}{\partial r}\left(r\Gamma_f\frac{f_A}{\overline{M}_A}\frac{\partial\overline{M}_A}{\partial r}\right)$$
$$+\frac{\partial}{\partial x}\left(\overline{D}_{AB}^{T}\frac{\partial\ln T}{\partial x}\right)+\frac{1}{r}\frac{\partial}{\partial r}\left(r\overline{D}_{AB}^{T}\frac{\partial\ln T}{\partial r}\right) \tag{6}$$

The computational domain employed in this study is the region A-J-I-H-A shown in Fig. 1, i.e. only a semi-plane of the axi-symmetrical impinging jet. The left-hand side of plane K-D-E is the plasma torch with A-B being the plasma flow inlet. B-C-D is a backward-step region, whereas K-D is the torch outlet. E-F is the annular slot used for the shrouding gas (argon) injection, if a shrouding gas is desirable to be used. I-J is the workpiece surface, whereas G-H and H-I are the free boundaries, respectively.

In the computation, the radial size (AH) of the computational domain is set to be 50 mm, whereas axial size (AJ) is 18 mm. Other sizes adopted are as follows: Inner radius of plasma flow inlet (AB) is 2 mm, torch exit inner radius (KD) 4 mm, wall thickness (BG) 33 mm, backward-step length (CD) 8 mm. SIMPLE algorithm and a non-uniform 92 (x-) × 187 (r-) mesh are employed in the computation with finer mesh spacing near the

jet axis.

The boundary conditions used in the jet modeling include that at the jet inlet A-B, zero radial velocity, argon mass fraction $f_A = 1.0$ and the power-law profiles of axial velocity and temperature are used. The inlet maximum axial velocity and temperature at the jet inlet are 400 m/s and ~14500 K, respectively. Axi-symmetrical conditions are employed along the jet axis A-J; free boundary conditions are employed along G-H and H-I; and zero velocity, fixed temperature and zero diffusion flux are used at the solid surfaces.

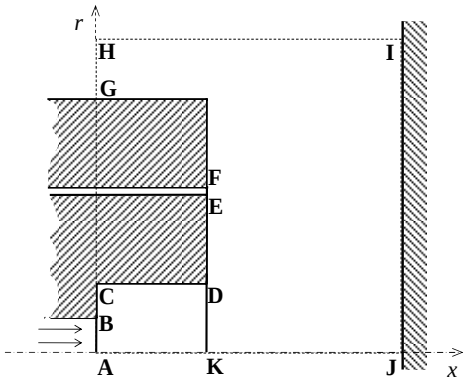

Fig. 1 Computational domain

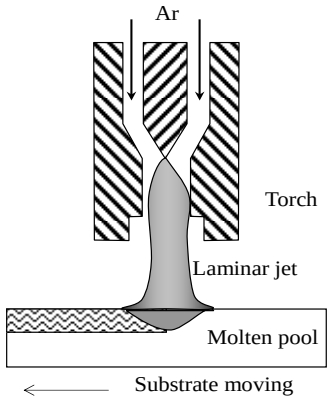

Fig. 2 Schematic diagram of plasma heating system

2.2 Heating of the workpiece by the plasma jet

The schematic diagram for the laminar plasma-jet re-melting hardening of cast iron surface is shown in Fig. 2. The plasma jet impinges normally upon the workpiece with a constant transverse velocity U_s moving relative to the workpiece. In the following computational study of workpiece heating, the coordinate system fixed with respect to the plasma jet is employed.

Main assumptions employed in this study include that the melting process is steady in the coordinate system fixed with the plasma jet; there is no deformation on the top surface of the molten pool. Based on these assumptions, the governing equations in the Cartesian coordinate system (x, y, z) (*x* is in the negative direction of workpiece motion, whereas *z* in the vertical direction) to describe the melt flow and heat transfer in the workpiece are as follows [6,7]:

$$\frac{\partial(\rho u)}{\partial x}+\frac{\partial(\rho v)}{\partial y}+\frac{\partial(\rho w)}{\partial z}=0 \tag{7}$$

$$\rho\left(u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}+w\frac{\partial u}{\partial z}\right)=\frac{\partial}{\partial x}\left[2\mu\left(\frac{\partial u}{\partial x}\right)\right]+\frac{\partial}{\partial y}\left[\mu\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}\right)\right]+\frac{\partial}{\partial z}\left[\mu\left(\frac{\partial u}{\partial z}+\frac{\partial w}{\partial x}\right)\right]-\frac{\partial p}{\partial x}+S_u \tag{8}$$

$$\rho\left(u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}+w\frac{\partial v}{\partial z}\right)=\frac{\partial}{\partial x}\left[\mu\left(\frac{\partial v}{\partial x}+\frac{\partial u}{\partial y}\right)\right]+\frac{\partial}{\partial y}\left[2\mu\left(\frac{\partial v}{\partial y}\right)\right]+\frac{\partial}{\partial z}\left[\mu\left(\frac{\partial v}{\partial z}+\frac{\partial w}{\partial y}\right)\right]-\frac{\partial p}{\partial y}+S_v \tag{9}$$

$$\rho\left(u\frac{\partial w}{\partial x}+v\frac{\partial w}{\partial y}+w\frac{\partial w}{\partial z}\right)=\frac{\partial}{\partial x}\left[\mu\left(\frac{\partial w}{\partial x}+\frac{\partial u}{\partial z}\right)\right]+\frac{\partial}{\partial y}\left[\mu\left(\frac{\partial w}{\partial y}+\frac{\partial v}{\partial z}\right)\right]+\frac{\partial}{\partial z}\left[2\mu\left(\frac{\partial w}{\partial z}\right)\right]-\frac{\partial p}{\partial z}+S_w+S_b \tag{10}$$

$$\rho c\left(u\frac{\partial T}{\partial x}+v\frac{\partial T}{\partial y}+w\frac{\partial T}{\partial z}\right)=\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right)+\frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right)+\frac{\partial}{\partial z}\left(k\frac{\partial T}{\partial z}\right)+S_h \tag{11}$$

Here *u*, *v* and *w* are velocity components in *x*-, *y*- and *z*-directions, *T* and *p* are temperature and pressure,

whereas ρ, μ and k are density, viscosity and thermal conductivity, respectively. In order to account for the solid-liquid phase change in the workpiece, the fixed-grid method suggested by Voller and Swaminathan [8] has been employed. Namely, the heat and momentum transfer on the solid-liquid phase interface are incorporated into the governing equations through introducing suitable volume source terms. The source terms S_u, S_v and S_w introduced in the momentum equations (8) – (10) take the following forms [6,7]:

$$S_u = A(u - U_s), \quad S_v = Av, \quad S_v = Aw, \tag{12}$$

where parameter A depends on material and the liquid-phase fraction f, and $A = -C(1-f)^2/(f^3+q)$ for the materials in which phase change takes place with a mushy region, where q is merely a very small computational constant introduced to avoid division by zero and C is a large constant (e.g. 10^{10}). The liquid mass fraction f is in the range of $0 \le f \le 1$. S_h in Eq. (11) is introduced to account for the latent heat release, and takes the following form:

$$S_h = -\rho L\left(u\frac{\partial f}{\partial x} + v\frac{\partial f}{\partial y} + w\frac{\partial f}{\partial z}\right) \tag{13}$$

in which L is the melting latent heat of cast iron. The additional source term S_b in the momentum equation (10) in the vertical direction is introduced to account for the natural convection in the molten pool, and

$$S_b = \rho_m g\beta(T - T_m) \qquad (\text{for } T > T_m), \tag{14}$$

where Boussinesq approximation has been used. In Eq. (14), β is the volume expansion coefficient, g the gravity acceleration, whereas T_m is the melting point of the workpiece material.

Boundary conditions employed in the study of workpiece heating are as follows: At the upstream boundary, $u = U_s$, $v = 0$, $w = 0$ and $T = T_a$ (T_a is the ambient temperature). At the downstream boundary, $u = U_s$, $v = 0$, $w = 0$ and $\partial T/\partial x = 0$. At the symmetrical plane ($y = 0$): $\partial u/\partial y = 0$, $v = 0$, $\partial w/\partial y = 0$ and $\partial T/\partial y = 0$. At the top surface of molten pool, *i. e.* at $z = h$ (h is plate thickness), since the melt temperature may be high and the melt temperature distribution is often non-uniform, the effects of surface heat loss and surface tension gradient on melt flow are included in the present study. Namely, we employ the conditions $\mu\partial u/\partial z = f(\partial\sigma/\partial T)(\partial T/\partial x)$, $\mu\partial v/\partial z = f(\partial\sigma/\partial T)(\partial T/\partial y)$, $w = 0$ and $k(\partial T/\partial z) = q_j - \varepsilon\Sigma T^4$ at the top surface. Here σ is the surface tension coefficient, ε and Σ are the emissivity and the Stefan-Boltzmann constant, whereas q_j is the local heat flux density from the plasma jet to the workpiece surface. At the bottom surface of workpiece (*i. e.* at $z = 0$), $u = U_s$, $v = 0$, $w = 0$ and $\partial T/\partial z = 0$ are used.

Actual computational domain used in the modeling of workpiece heating is the cylindrical region with sizes $0 \le r \le 15$ mm, $0 \le \theta \le \pi$ and $0 \le z \le 10$ mm. Altogether 36 (r-direction) × 12 (θ-direction) × 36 (z-direction) grid points are employed in the modeling. For this case, at the geometrical axis of the computational domain (r = 0), the averaged values of ϕ_i (i = 1, 2, …, N) at all the N grid points in the θ-direction and on the small circle nearest to the axis in the mesh are employed for the variable ϕ.

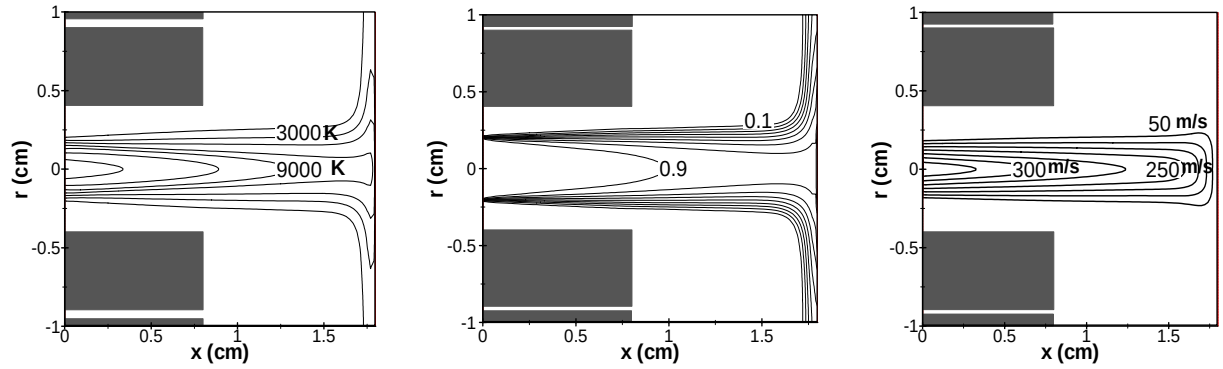
SIMPLE-like algorithm is also used to solve the governing equation for the workpiece regions.

3. Modeling results and discussions

3.1 Modeling results of laminar impinging plasma jet

Typical computed results of the temperature, argon mass fraction and axial velocity distributions in the impinging jet are shown in Fig. 3. The distributions of impact pressure, radial velocity gradient (or viscous stress) and temperature gradient (or heat flux density) on the workpiece surface are also obtained. In the

calculation of surface heat fluxes, the contribution to the heat fluxes of electron-ion recombination at the metallic surface is included besides the convective heat transfer. The heat flux profiles are shown in Fig. 4.



(a) (b) (c)

Figure 3 Computed isotherms (a), Ar mass fraction (b) and axial-velocity distributions. (T_0=13900 K, U_0=400 m/s)

3.2 Modeling results of workpiece melting process

It is expected that the power absorbed by the workpiece of the plasma jet will be used to the solid-phase heating, melting and liquid-phase heating as well as the surface radiation loss of the workpiece material.

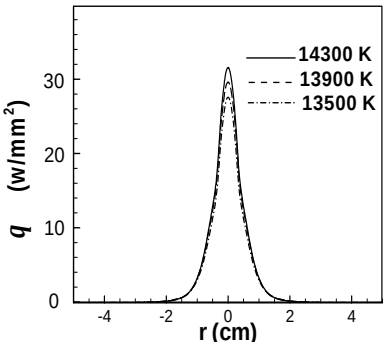


Fig. 4 Heat flux profiles on workpiece surface

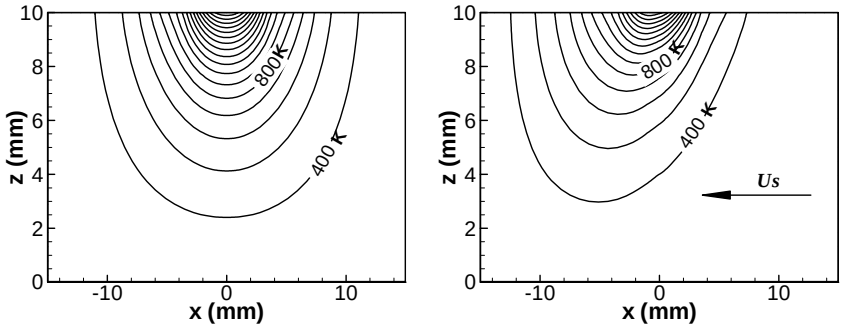

(a) workpiece speed 0 mm/s (b) workpiece speed 5.0 mm/s

Fig. 5 Computed isotherms on the x-z section

Figures 5(a) and 5(b) show the computed isotherms on the x-z section for the workpiece moving speeds of 0 and 5 mm/s. The computed isotherms on the x-y section are shown in and Fig. 6 for 5 mm/s moving speed. All these results are for the case with the maximum axial velocity and temperature at the jet inlet being 400 m/s and 14300 K. From Fig. 5(a) it is seen that the isotherms are symmetrical for this case without workpiece moving, as expected. Non-symmetrical isotherms are obtained when the workpiece is moving, cf. Fig. 5(b) and Fig. 6. The moving speed affects significantly the temperature distribution in the workpiece.

The computed molten pool shapes on x-z plane of the workpiece are compared in Fig. 7 for the cases with the same U_0 (400 m/s) and T_0 (14300 K) but different U_S (workpiece moving speeds), and in Fig. 8 for the cases with the same U_0 (400 m/s) and U_S (1.7 mm/s) but different T_0. It is seen from Fig. 7 that with the increase of the workpiece moving speed, narrower, shallower and more asymmetrical molten pools are obtained. Fig. 8 shows that deeper and wider molten pools are obtained at high jet temperatures (T_0).

We can compare our modeling results with some available experiment data. The plasma torch and associate operating conditions employed in this modeling study are similar to those for the experiment of Pan et al [2]. In their experiment, non-transferred DC laminar plasma jet was used to heat the cast iron for re-melting

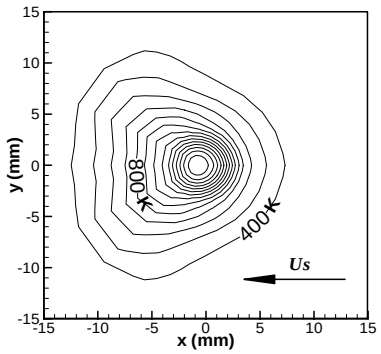

Fig. 6 Isotherms on the x-y section For workpice speed 5 mm/s

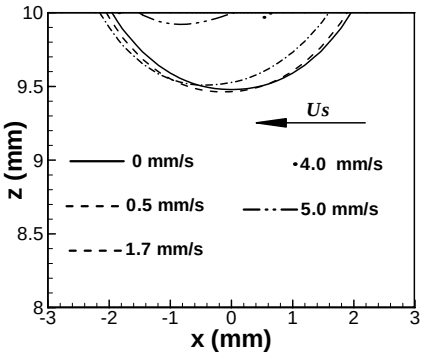

Fig. 7 Molten pool shapes for different workpiece speed U_s

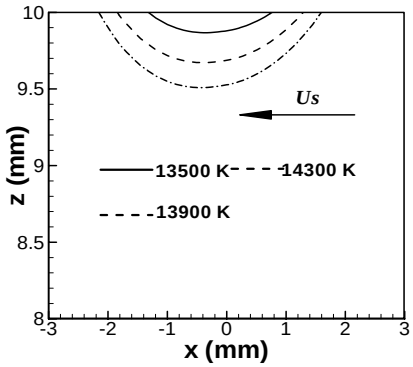

Fig. 8 Molten pool shapes for different jet temaperatures

hardening. The surface treatment conditions were fixed with the distance 9 mm from the torch nozzle exit to the workpiece surface, the workpiece moving speed 0.5~5 mm/s, the gas flow rate 75~220 cm^3/s and the arc current 180~200 A. The molten pool widths observed in their experiment are in the range of 2.0 – 4.0 mm, whereas the thickness of the hardened layer is the range of 0.6~1.7 mm. Because the thickness of the hardening layer is the sum of the molten pool depth and the thickness for the solid phase-change region (about 0.6 mm). So the actual molten pool depth range is 0~1.1 mm, these experimental results agree reasonably with the present modeling predictions.

4. Conclusions

Modeling results are presented in this paper concerning the heat transfer from a laminar argon plasma jet impinging normally upon a workpiece located in air surroundings and concerning the workpiece melting process. The modeling results show that the workpiece moving speed and the maximum temperature at the jet inlet affect significantly the temperature distributions and the molten pool shapes in the workpiece. The predicted sizes of molten pool are reasonably consistent with available experimental data.

Comparison of microwave, radio frequency, and dual mode plasmas: Deposition of SiO_x films from oxygen and hexamethyldisiloxane

A. Bieder, A. Sonnenfeld, Ph. Rudolf von Rohr

Swiss Federal Institute of Technology Zurich, Institute of Process Engineering, CH-8092 Zurich, Switzerland

Abstract

A reactor equipped with a remote 2.45 GHz slot antenna plasma source and a 13.56 MHz-biased substrate holder was used to conduct deposition experiments. This study focuses on the dependence of the gas phase emission on the oxygen-to-HMDSO flow rate ratio, radio frequency and microwave power. The influence of different gas phase species on the barrier performance of SiO_x films is investigated. It was found that the gas phase is dominated by the microwave discharge, but the gas barrier mainly by the substrate self-bias.

Key words: PECVD, silicon oxide, OES, water vapor transmission rate

1. Introduction

In food packaging, medical device, and electronic industries the interest in silicon oxide films has increased [1]. SiO_x thin films are transparent, recyclable, and suitable for the microwave oven. Their chemical and mechanical properties can be varied in a wide range by applying different process conditions [2, 3]. To get an insight into the gas phase, optical diagnostics are often used since they are selective, non-intrusive, and allow time/spacial resolution [4]. For a better understanding of the plasma processes and the influence of the gas phase on the water vapor barrier performance of the deposited silicon oxide film, investigations with optical emission spectroscopy were conducted in this study. The effect of the oxygen-to-monomer flow rate ratio, radio frequency and microwave power input was analyzed and the important factors on the film properties evaluated. As former studies showed, the discharge parameters strongly influence the barrier performance of thin SiO_x films [2, 3].

2. Experimental

All experiments were conducted in a 20 liter batch reactor. The reactor is equipped with a remote microwave (MW) and a direct radio frequency (RF) plasma sources. The 2.45 GHz slot antenna plasma source (Slan I, Plasma Consult) and a 13.56 MHz-biased substrate holder can be ignited separately or simultaneously in so called dual mode. During the experiments, oxygen and argon are fed at the top of the reactor and the monomer hexamethyldisiloxane (HMDSO) is injected through a ring shower in the afterglow of the MW plasma source. The range of variation of process parameters and the default values can be seen in Tab.1. In this study the oxygen-to-HMDSO flow rate ratio, RF, and MW power input were varied. The default settings were deduced from preliminary experiments and correspond to a good oxygen and water vapor barrier performance of the silicon oxide films. In each series one process parameter was varied in the mentioned range, the other parameters were kept constant at the default value. In all experiments the HMDSO flow rate was set 10 sccm. The substrate self-bias depends strongly on the RF power input as shown in Fig.1. Due to different stages of SiO_x coverage of the reactor walls the self-bias was varying by +/- 10 %. Further details are described elsewhere [2, 3].

Table 1: Process parameters with range of variation and default values.

Parameter	Variation range	Default value
Oxygen-to-HMDSO flow rate ratio	1 – 40	15
RF power (substrate holder)	50 – 300 W	200 W
MW power	600 – 3000 W	1500 W
Reactor pressure	0.2 mbar	0.2 mbar
Temperature (substrate holder)	20 °C	20 °C
Temperature (reactor walls)	50 °C	50 °C
Deposition time (film thickness resp.) for permeation measurements	60 s	60 s

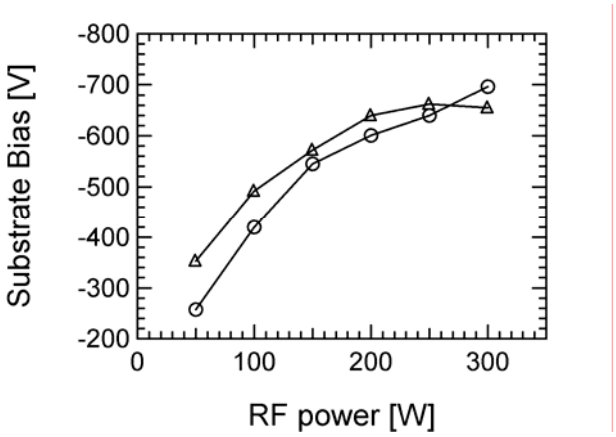

Figure 1: Substrate bias vs. RF power input. RF mode: circles, dual mode: triangles.

The barrier coatings were deposited on 12 µm PET films (Dupont, Mylar Typ A) with deposition rates of approximately 500 nm per minute. For the water vapor transmission rate (WVTR) measurements a Lyssy water vapor permeation tester L 80-5000 (Lyssy AG, Zollikon, CH) was used. The accuracy of the results is +/- 15 %. The quality of the coated PET films was, prior to the WVTR measurements, tested with an Oxtran-100 (Mocon, Modern Controls INC., Minneapolis, USA). This was done, because it is much harder to achieve good barrier coatings against water vapor than against oxygen. The influence of the process parameters on the oxygen transmission rate was studied elsewhere [3]. Unlike WVTR measurements, it is assumed that oxygen permeation measurements do not affect the coating properties and are non-destructive [5].

Plasma analyses were done by optical emission spectroscopy (OES). The emitted light was analyzed with an optical emission spectrometer (Jobin Yvon, Triax 320) equipped with an UV-coated 1024 x 128 CCD and an exit slit with photomultiplier (Hamamatsu, R928). The emitted light analyzed through a quartz window situated 5 cm above the substrate holder. The quartz window is transparent for 200 – 1100 nm. The measurements were conducted with the 1200 mm^{-1} grating for 200 – 350 nm and with the 1800 mm^{-1} grating for 350 – 1000 nm. For all spectroscopic measurements 10 sccm argon was added to the process gas. The emission lines are normalized to the intensity of the 750 nm Ar* line.

3. Results and discussion

3.1. Power variation

By OES the Ar* (750 nm), O (777 nm), O_2^+ (559 nm), SiO (239 nm), and H_α (656 nm) intensity lines were investigated. For pure RF plasmas the noise-to-peak intensity ratio was higher than for MW and dual mode plasmas. As can be seen in Fig. 2, with increasing RF power input the argon emission was increased. Similar tendencies were found for dual mode at constant MW power (1500 W) and varied RF power input (50 – 300 W) and for the variation of MW power (600 – 3000 W) at constant RF power input (200 W).

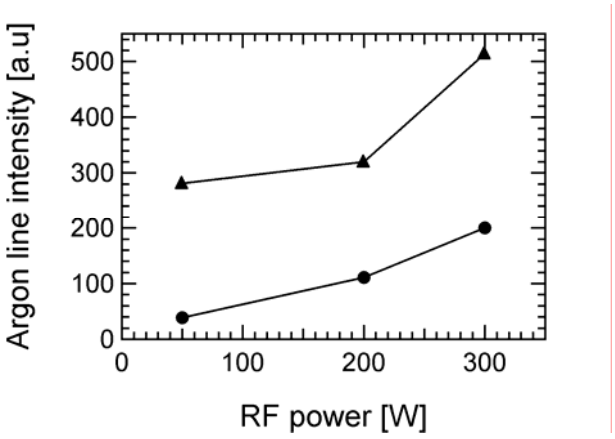

Figure 2: Dependence of the 750 nm Ar* line intensity on the RF power input. For dual mode the MW power was set to 1500W. Similar tendencies were found for dual mode at constant MW power (1500 W) and varied RF power (50 – 300 W) and for the variation of MW power (600 – 3000 W) at constant RF power (200 W). RF mode: circles, dual mode: triangles.

An increase in RF power leads to a decrease of the O_2^+ and SiO intensities and to an increase of the O and H_α line as demonstrated in Fig. 3. This is due to an enhanced fragmentation due to an increased energy input. For dual mode the influence of the RF power variation on the gas phase emission is small since all investigated line intensities varied only slightly. This findings for constant MW power (1500 W) and varied RF power input (50 – 300 W) are in contrast to the results at constant RF power input (200 W) and a variation of MW power (600 – 3000 W). As shown in Fig. 4, an increase was detected for the O and H_α line intensities. Comparing these results with the WVTR measurements, only little similarities could be found. Films deposited from RF or dual mode (constant MW power, varied RF power) plasmas exhibit similar tendencies for WVTR as can be seen in Fig. 5 and OTR (WVTR: factor 150 and OTR: factor 200, resp. improvement). By varying the MW input power at a constant RF power level, it was shown that the deposition is dominated by the substrate bias since no influence on the barrier performance was detected. Despite the stronger influence of the MW than the RF power on the gas phase composition is the substrate self-bias essential for the deposition of an effective gas barrier. This is due to a network densification and an additional energy input. The necessity of substrate self-bias was also shown from preliminary experiments with remote MW plasmas. Films deposited by pure MW plasma led to an improvement of the oxygen barrier (factor 20) but not to an effective barrier against water vapor despite the low organic content in the film [3]. This is due to the missing substrate bias and thus lack of ion bombardment onto the substrate.

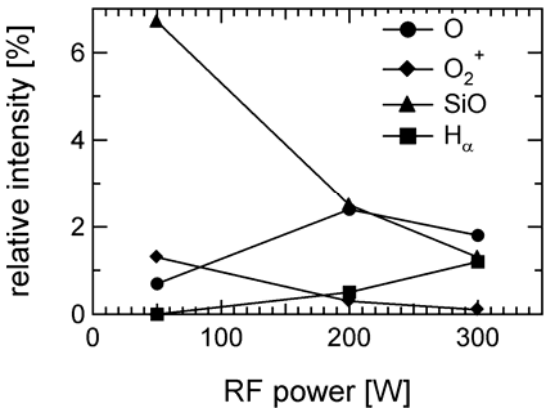

Figure 3: Dependence of the relative emission intensities in a pure RF discharge on the RF power input.

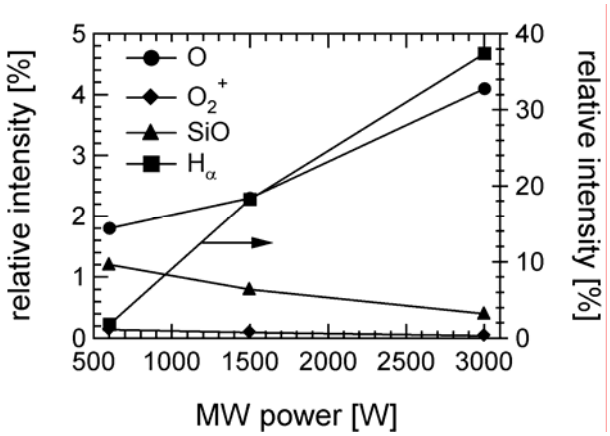

Figure 4: Dependence of the relative emission intensities in a dual mode plasma on MW power input.

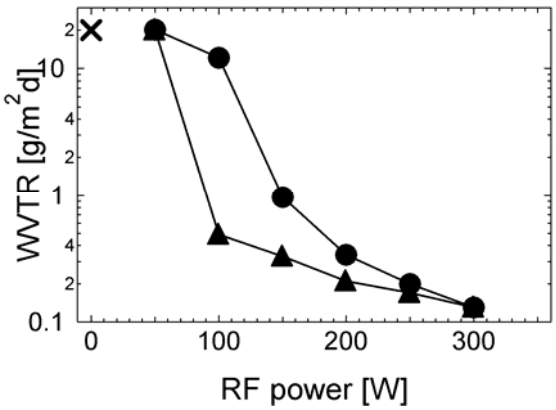

Figure 5: Influence of RF power input on the WVTR for pure RF and dual mode plasmas. RF mode: circles, dual mode: triangles, uncoated PET (reference value): cross.

3.1. Oxygen-to-HMDSO flow rate ratio variation

An increase of the oxygen content in the process gas leads to a decrease of the argon emission intensity for dual mode, whereas no influence could be detected for pure RF plasmas (Fig. 6). This is due to a higher gas flux and thus a reduced exposure time in the MW plasma source with increasing oxygen flow. The pressure was kept constant thus no loss due to enhanced recombination occurred.

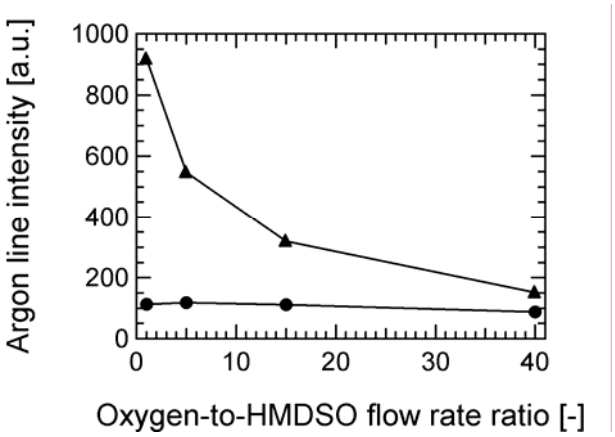

Figure 6: Dependence of the argon line intensity on the oxygen-to-HMDSO flow rate ratio. RF mode: circles, dual mode: triangles.

With increasing oxygen-to-monomer flow rate ratio for RF mode a pronounced increase of the O and SiO line intensities was found. Similar tendencies were found for dual mode but not as strong for the SiO line intensity. For RF mode the O_2^+ and H_α intensities increased only slightly. In contrast, for dual mode an increase up to 150 sccm and then a decrease of the H_α intensity was detected (Fig. 7). The increase of the oxygen line intensities can be explained by the surplus of oxygen. As a result of the decreased activation of the process gas with increasing oxygen-to-HMDSO flow rate ratio the SiO line is increased. The H_α intensity first increases due to an enhanced fragmentation because of the rising oxygen flow and thus energy transport from the microwave to the deposition chamber. After a peak value the decrease is an effect of the reduced activation of the process gases. Compared with the WVTR measurement it is visible that an increase of the oxygen-to-monomer flow rate ratio leads to an enhanced water vapor barrier performance for pure RF mode, whereas for dual mode an increase of the oxygen flow rate above 200 sccm results again in permeable films as can be seen in Fig. 8.

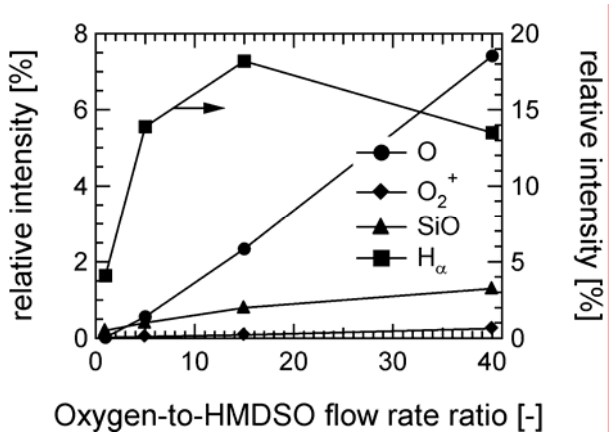

Figure 7: Oxygen-to-HMDSO flow rate ratio vs. relative emission intensities for dual mode plasmas.

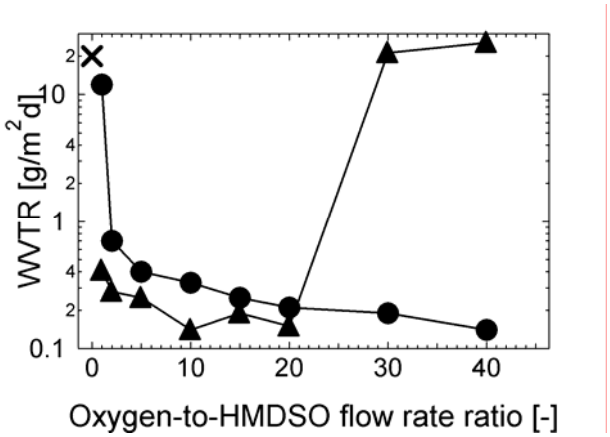

Figure 8: Influence of the RF power input on the WVTR for pure RF and dual mode plasmas. RF mode: circles, dual mode: triangles, uncoated PET (reference value): cross.

4. Conclusions

For a better understanding of the plasma processes and the influence of the gas phase on the barrier performance of the deposited silicon oxide film, investigations with optical emission spectroscopy were conducted. The influence of the oxygen-to-monomer flow rate ratio, radio frequency and microwave power input was investigated.

With increasing RF power input the 750 nm Ar* line emission increased. Similar tendencies were found for dual mode as were for the variation of MW power (600 – 3000 W) at constant RF power input (200 W). An increase in RF power leads to a decrease of the O_2^+ and SiO intensities and to an increase of the O and H_α line. This is due to an enhanced fragmentation because of an increased energy input. From WVTR measurements it can be seen that despite the stronger influence of the MW than of the RF power on the gas phase composition, the substrate bias is essential for the deposition of an effective gas barrier. This is due to a network densification and an additional energy input [3].

An increase of the oxygen content in the process gas leads to a decrease of the argon emission intensity for dual mode whereas no influence could be detected for pure RF plasmas. With increasing oxygen-to-monomer flow rate ratio an increase of the O and SiO line intensities was found. For dual mode an increase up to 150 sccm and then a decrease of the H_α intensity was detected. Compared with the WVTR measurement it was shown that an increase of the oxygen-to-monomer flow rate ratio leads to an enhanced water vapor barrier performance for pure RF mode, whereas for dual mode an increase of the oxygen flow rate above 200 sccm results again in permeable films.

Optical and Electrical Diagnostics of a Miniature Microwave-Excited Plasma Source for an Ultra Small Thruster

Y. Takao, K. Takahashi, K. Ono

Department of Aeronautics and Astronautics, Graduate School of Engineering, Kyoto University, Kyoto, Japan

Abstract
A miniature microwave-excited plasma source for an ultra small thruster has been investigated by optical emission spectroscopy and an electrostatic probe. Experimental results and a numerical analysis have shown that the microplasma source is useful for the miniature thruster, having the electron density of 10^{16}–10^{19} m^{-3}, the rotational temperature of 400–1200 K, and the specific impulse of 60–71 s, in the microwave power range from 2 to 11 W.
Keywords: microthruster, microplasma, microwave, micronozzle, electric propulsion

1. Introduction

In recent years, microplasma sources have attracted increasing attention, aimed at applications in a number of microsystems. Such microplasma sources are obtained by dc [1], capacitively coupled [2], inductively coupled [3], and microwave excited [4, 5] plasma discharges. For space systems, there is an ongoing trend toward miniaturization of spacecraft to reduce the mission costs and risk [6]. Such microspacecraft concept has supported a new approach to develop accurate, reliable, and low-power-consumption micropropulsion systems for high-precision station keeping (requiring a thrust of ~ mN) and attitude control (~ μN).

For such a great interest in both microplasma and micropropulsion, we propose an application of a miniature plasma source excited by microwaves to an ultra small thruster on microspacecraft. Figure 1 shows a schematic diagram of a microplasma thruster, which consists of a microplasma source and a micronozzle. The plasma source is composed of a cylindrical dielectric tube, the outside of which is covered with a metal grounded. The inner radius and the length of the tube are about 1 mm and 10 mm, respectively. Microwaves are injected through a coaxial cable into the plasma chamber, where the propellant gas, argon in this study, is ionized and heated up in the pressure range from 10 kPa to 100 kPa. Such high thermal energy is converted into the kinetic energy through the micronozzle, which has a converging and diverging section, to produce the thrust required. On the basis of this concept, we developed a numerical model for design consideration and estimated the thrust performance [7–10].

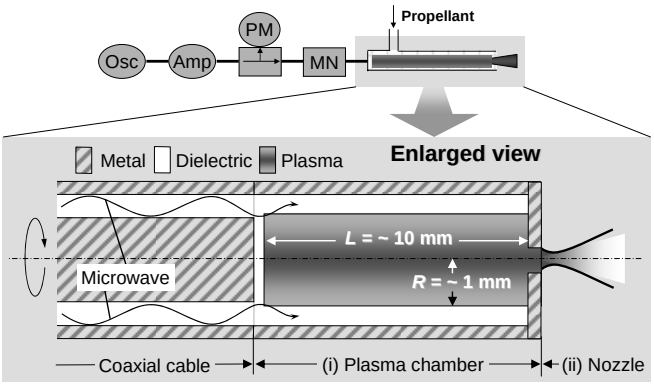

Fig. 1. Schematic of the microplasma thruster using microwave-excited plasmas, consisting of an azimuthally symmetric microplasma source and a converging-diverging (Laval) micronozzle. The working gas is Ar in this study.

In this paper, we present a microplasma source fabricated and the plasma characteristics observed by optical emission spectroscopy (OES) and an electrostatic probe. The OES analysis of the microplasma source indicates that the plasma source is useful for the microthruster in view of the distribution of the rotational temperature inside the plasma chamber. The electrical diagnostics show that the electron density achieved is in the range of 10^{16}–10^{19} m^{-3} at microwave powers of 2–11 W.

2. Experimental

Figure 2 shows a schematic diagram of the experimental setup and a cross-sectional view of the microplasma source. Microwave signals of 2 and 4 GHz generated by an oscillator (Agilent Technologies, 8648D) are amplified through a 4-stage semiconductor amplifier, and then fed through a semi-rigid coaxial cable

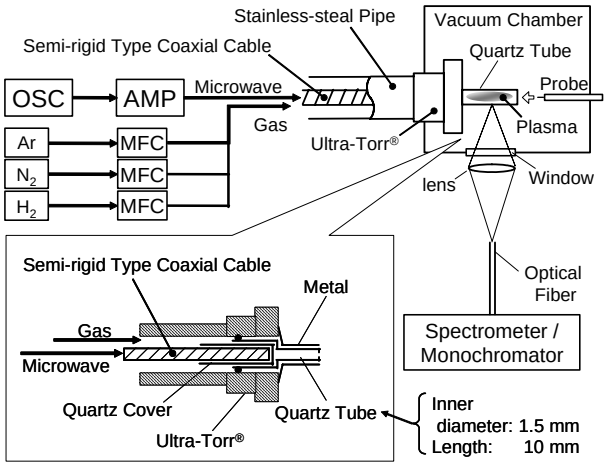

Fig. 2. Schematic of the experimental setup and the cross section of the microplasma source developed (bottom).

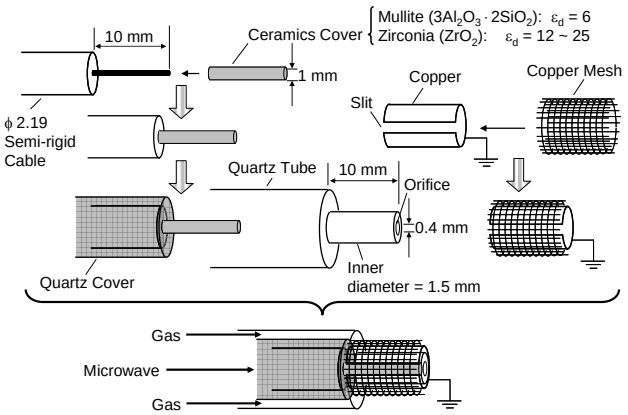

Fig. 3. Assembly of the microplasma source presently developed, which has an orifice at the exit to vacuum. The slit of the copper envelope is for optical diagnostics.

(RG-405/U) into the plasma chamber made of a straight quartz tube, to generate and sustain the plasma discharges therein. Here, the reflection of microwaves power is suppressed by adjusting the cable length. The quartz tube, connected to the stainless-steel pipe through which the working gas is introduced, is inserted into a stainless-steal chamber evacuated by a dry and mechanical booster pump. A pressure gauge, equipped with the stainless-steal pipe before the plasma chamber, is used for measurement of the feed gas pressure, which is assumed to be the pressure inside the plasma chamber.

Figure 3 shows an assembly of the microplasma source presently developed. The center conductor of the semi-rigid coaxial cable, protruding 10 mm beyond the insulator and outer conductor, is covered with a ceramic tube; two types of ceramics, mullite (relative permittivity ε_d = 6) and zirconia (ε_d = 12–25), are employed to investigate the dependence on dielectric constants. The outer conductor is also covered with a quartz tube for the protection against erosion of electrodes. The plasma chamber, made of a quartz tube 10 mm in length and 1.5 mm in inner diameter, has an orifice 0.4 mm in diameter at the exit to vacuum. This structure results in a small conductance to keep the pressure inside the plasma chamber much higher than that in the vacuum chamber. The outside of the plasma chamber is covered with a copper grounded which has a single slit for optical diagnostics. Moreover, a copper mesh prevents microwaves from leaking through the slit.

Emission intensities are measured with a spectrometer (Ocean Optics, HR2000CG-UV-NIR) through a quartz optical fiber, the head of which is directly connected to a window of the vacuum chamber without a lens. In the case of precise diagnostics, the emissions are collected by a lens and transmitted to a 25-cm focal length monochromator (Nikon, P250) with a 1200 grooves/mm grating plate. The light emerging from the fiber is focused onto an entrance slit of the monochromator and detected by a photomultiplier (Hamamatsu, R1509). For electrical diagnostics, a cylindrical Langmuir probe, with the probe tip made of a tungsten wire 0.05 mm in diameter and 0.5 mm long, is positioned at an immediate downstream of the orifice to determine the electron density thereat.

3. Results and Discussion

3.1. Power Dependence of Intensity

Experiments were performed at an Ar flow rate of 50 sccm, a feed gas pressure of 10 kPa, and a vacuum chamber pressure of 9 Pa. Figure 4 shows photograph images of the emission of microplasma discharges, taken for total microwave power P_t = (a) 3.5, (b) 5.0, and (c) 7.0 W with a microwave frequency f = 4 GHz and a mullite tube (ε_d = 6). The plasma was maintained only inside the microplasma chamber at P_t > 0.3 W [Fig. 4(a)], the plasma at P_t > 4 W was found to flow out into vacuum through the orifice at the end of the plasma chamber, forming a supersonic free jet in vacuum [Fig. 4(b)], and at P_t > 6 W the exhausted plasma was sustained around the end of the plasma source [Fig. 4(c)].

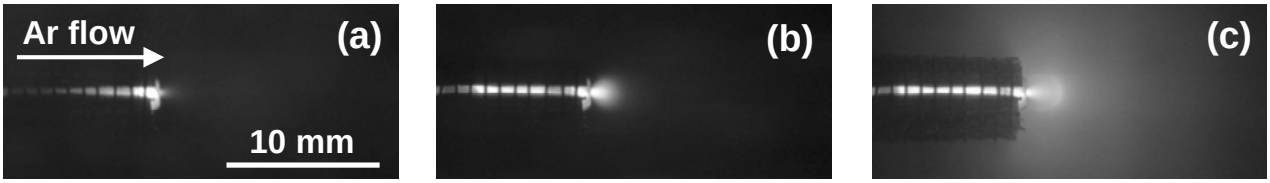

Fig. 4. Photograph images of the emission of microplasma discharges, taken for total microwave power P_t = (a) 3.5, (b) 5.0, and (c) 7.0 W with a microwave frequency f = 4 GHz and a mullite tube (ε_d = 6), measured at an Ar flow rate of 50 sccm, a feed gas pressure of 10 kPa, and a vacuum chamber pressure of 9 Pa.

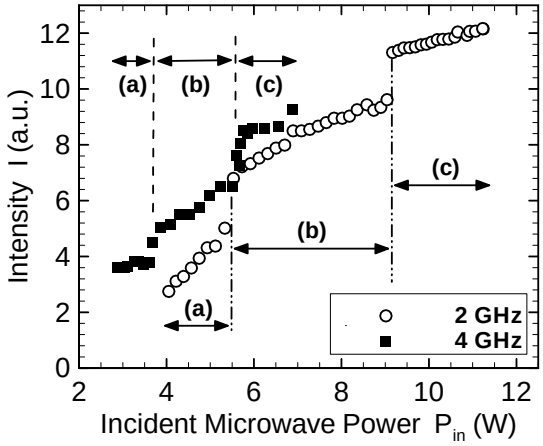

Fig. 5. Emission intensity (Ar I 763.5 nm) as a function of incident microwave power $P_{in} = P_t - P_{rf}$ for different microwave frequencies f = 2 and 4 GHz, otherwise measured under the same conditions as in Fig. 4.

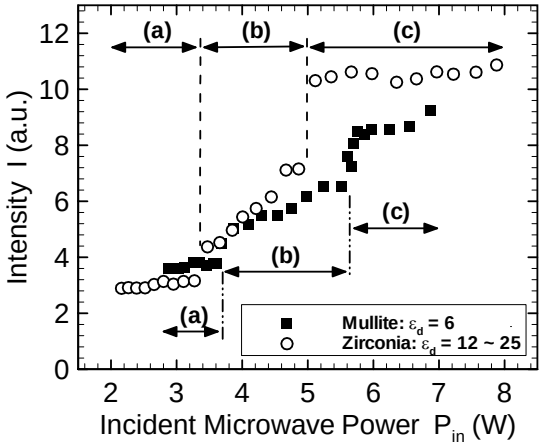

Fig. 6. Emission intensity (Ar I 763.5 nm) as a function of incident microwave power $P_{in} = P_t - P_{rf}$ for different ceramic tubes of ε_d = 6 and 12–25, otherwise measured under the same conditions as in Fig. 4.

Figure 5 shows the emission intensity (Ar I 763.5 nm) as a function of incident microwave power $P_{in} = P_t - P_{rf}$ for different f = 2 and 4 GHz, where P_{rf} is a reflected microwave power, so that P_{in} is assumed to be a net power absorbed in the plasma. Other experimental conditions are the same as in Fig. 4. The emission intensity increases with increasing P_{in}, involving sudden jumps among the regions labeled (a), (b), and (c) in the figure, where these labels correspond to those in Fig. 4. As shown in the figure, higher intensities are observed for the higher microwave frequency at the same incident microwave power; more incident microwave power is required to yield intensity jumps for f = 2 GHz.

Figure 6 shows the emission intensity (Ar I 763.5 nm) as a function of incident microwave power P_{in} for different ceramic tubes of ε_d = 6 and 12–25, where other experimental conditions are the same as in Fig. 4. The emission intensity increases with increasing P_{in}, involving sudden jumps among the regions labeled (a), (b), and (c), like the result in Fig. 5. Higher intensities are observed for ε_d = 12–25 at the same incident microwave power. From the results in Figs. 5 and 6, higher microwave frequencies and dielectric constants are found to be desirable to maintain the plasma discharges in the microplasma source developed. Note that the emission intensities were measured with the spectrometer without light condensing here.

3.2. Electron Density

Figure 7 shows the electron density n_e as a function of incident microwave power P_{in} for different f = 2 and 4 GHz and different ε_d = 6 and 12–25, otherwise measured under the same conditions as in Fig. 4. The electron density increases as P_{in} increases, and higher microwave frequencies and dielectric constants result in higher electron densities at P_{in} > 6 W, although the electron density for f = 2 GHz and ε_d = 6 does not decrease with decreasing P_{in} at lower P_{in} compared to that for f = 4 GHz. This result derived from disturbance due to the probe measurement at f = 2 GHz, whereas there seemed to be less perturbation at f = 4 GHz. Taking the disturbance into account, we could conclude that the electron density tends to become higher at higher microwave frequencies and dielectric constants.

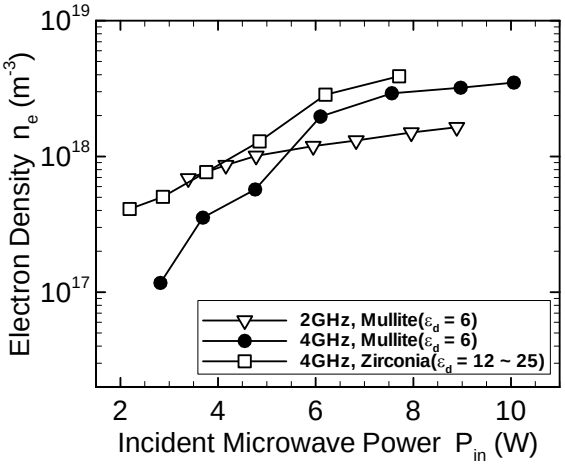

Fig. 7. Electron density n_e as a function of incident microwave power $P_{in} = P_t - P_{rf}$ for different f = 2 and 4 GHz and different ε_d = 6 and 12–25, otherwise measured under the same conditions as in Fig. 4. Here, the Langmuir probe was located at downstream from the orifice as in Fig. 2.

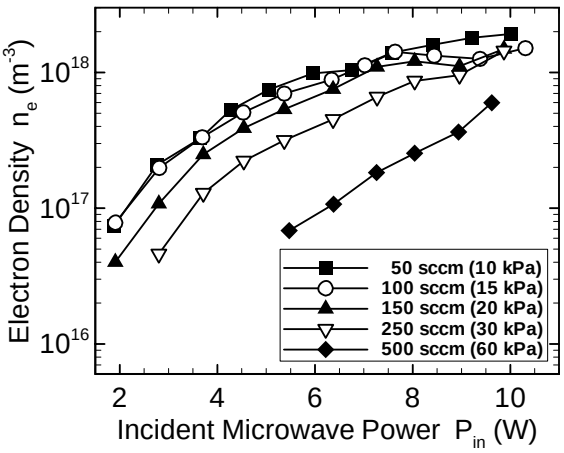

Fig. 8. Electron density n_e as a function of incident microwave power $P_{in} = P_t - P_{rf}$ for different Ar flow rates of 50, 100, 150, 250, and 500 sccm, where corresponding feed gas pressures are 10, 15, 20, 30, and 60 kPa, measured at f = 4 GHz and ε_d = 6.

Figure 8 shows the electron density n_e as a function of incident microwave power P_{in} for different Ar flow rates of 50, 100, 150, 250, and 500 sccm, measured at f = 4 GHz and ε_d = 6. The electron density decreases with increasing Ar flow rates, while the density increases with increasing P_{in} for all flow rates. High flow rates, leading to high feed gas pressures in the plasma chamber, affect the plasma discharges; more microwave power seems to be required to sustain high-density plasmas at high flow rates.

3.3. Rotational Temperature

Since the monochromator employed in this paper does not resolve the rotational structure, we have fitted the experimental data with theoretical calculations by using the transition band of N_2 $C^3\Pi_u$–$B^3\Pi_g$ at 380.49 nm (second positive band), in order to calculate the rotational temperature.

Figure 9 shows the rotational temperature T_{rot} as a function of position of the plasma discharge with a photograph image of the emission taken for incident microwave power P_{in} = 7 W at a microwave frequency f = 4 GHz and a zirconia tube (ε_d = 12–25), measured at an Ar flow rate of 50 sccm, a N_2 flow rate of 0.2 sccm, a feed gas pressure of 10 kPa, and a vacuum chamber pressure of 9 Pa. The rotational temperature increases from

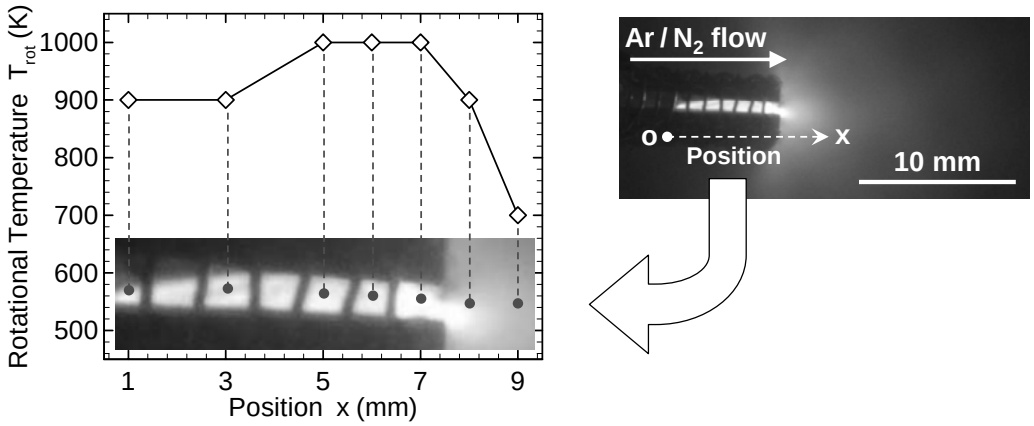

Fig. 9. Rotational temperature T_{rot} (N_2) as a function of position of the plasma discharge (left) and a photograph image of the emission (right), taken for incident microwave power P_{in} = 7 W with a microwave frequency f = 4 GHz and a zirconia tube (ε_d = 12–25), measured at an Ar flow rate of 50 sccm, a N_2 flow rate of 0.2 sccm, a feed gas pressure of 10 kPa, and a vacuum chamber pressure of 9 Pa.

upstream to downstream before the exit of the plasma chamber (x = 7 mm), decreasing at downstream after the orifice. Notice that it is important to increase the temperature at the exit of the plasma chamber where a micronozzle will be equipped, because the thermal energy should be effectively converted into the kinetic energy without any undesirable energy loss in the plasma chamber before the micronozzle. Thus, the temperature distribution obtained indicates that the microplasma source is highly desirable to the miniature thruster presented here.

Figure 10 shows the rotational temperature T_{rot} at the exit of the plasma chamber (x = 7 mm) as a function of incident microwave power P_{in} for different f = 2 and 4 GHz and different ε_d = 6 and 12–25, otherwise measured under the same conditions as in Fig. 9. The rotational temperature increases with increasing P_{in}, where the temperature tends to be higher at higher microwave frequencies and dielectric constants as in the case of the emission intensity and electron density.

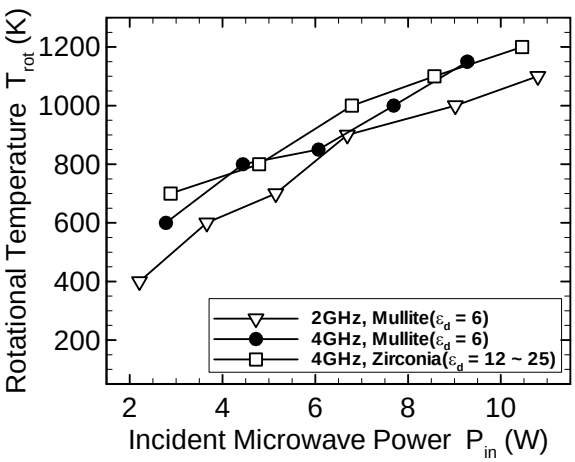

Fig. 10. Rotational temperature T_{rot} (N_2) at a position of 7 mm in Fig. 9 as a function of incident microwave power $P_{in} = P_t - P_{rf}$ for different f = 2 and 4 GHz and different ε_d = 6 and 12–25, otherwise measured under the same conditions as in Fig. 9.

3.4. Specific Impulse

Finally, assuming that the rotational temperature T_{rot} equals the gas temperature T_{gas}, we have estimated the specific impulse by using the results of plasma diagnostics obtained above and the model analysis in [7–10]. Since the plasma source has the orifice 0.4 mm in diameter at the exit to vacuum, a micronozzle with a throat 0.4 mm in diameter is assumed to be equipped with the plasma chamber, in order to calculate the thrust performance. A cross-sectional view and computational grid for the micronozzle are shown in Fig. 11. Moreover, the specific impulse I_{sp}, meaning how much thrust the thruster produces per unit propellant weight per one second, is defined as

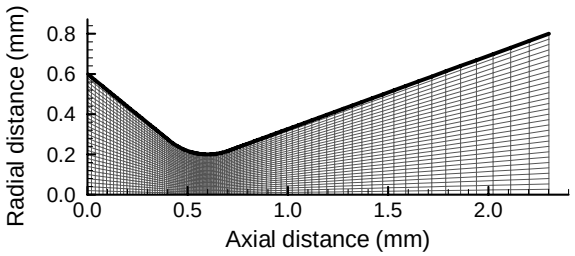

Fig. 11. Cross-sectional view and computational grid for a micronozzle with a 20°-half-cone-angle isothermal wall (T_{wall} = 300 K). The radii of the nozzle inlet, throat, and exit are set at 0.6, 0.2, and 0.8 mm, respectively. The computational domain is divided into 100 cells in the axial direction and 30 cells in the radial direction.

$$I_{sp} = 2\pi \int_0^{r_{ex}} (\rho u^2 + p) r dr / \dot{m} g \ , \tag{1}$$

where r_{ex} is the exit radius of the nozzle, ρ is the mass density, u is the velocity in the axial direction, p is the pressure, $\dot{m}$ is the mass flow rate, and g is the gravitational constant. Thus, the specific impulse is a measure of the fuel efficiency of a thruster; the higher the value is, the more efficient the thruster is.

Figure 12 shows the specific impulse I_{sp} as a function of incident microwave power P_{in} for f = 4 GHz and ε_d = 12–25 with the rotational temperature T_{rot} plotted in Fig. 10, otherwise measured under the same conditions as in Fig. 9. The specific impulse increases with increasing T_{rot} in the range from 60 to 65 s. In the case of a cold gas thruster (T_{gas} = 300 K) under the same conditions, the specific impulse is determined to be 53 s, so that the increasing rate of the specific impulse is 13 to 23 % by generating the plasma.

Figure 13 shows the rotational temperature T_{rot} at the exit of the plasma chamber (x = 7 mm) and the specific impulse I_{sp} as a function of Ar gas flow rate for P_{in} = 7 W, f = 4 GHz, and ε_d = 12–25, at a N_2 flow rate of 0.2 sccm. The specific impulse has the maximum value at a gas flow rate of 250 sccm, decreasing as the gas flow rate increases, because the rotational temperature decreases with increasing gas flow rate owing to the low electron density and the cooling effect of gas flows. Higher specific impulse would be expected by increasing the gas temperature at high gas flow rates.

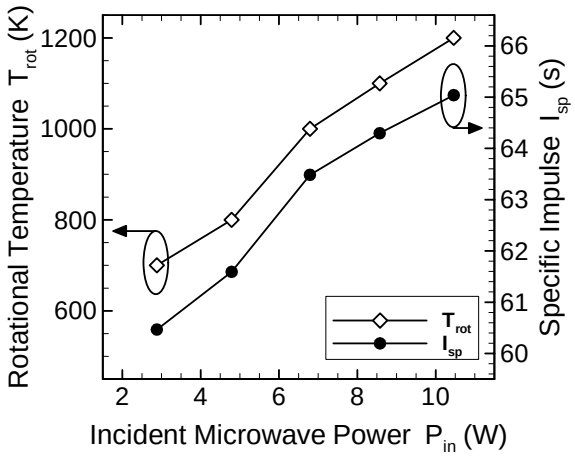

Fig. 12. Rotational temperature T_{rot} at a position of 7 mm in Fig. 9 and specific impulse I_{sp} as a function of incident microwave power P_{in} for f = 4 GHz, and ε_d = 12–25, otherwise measured under the same conditions as in Fig. 9. Here, the specific impulse is estimated from the measured temperature $T_{gas} = T_{rot}$ and the model analysis in [7–10].

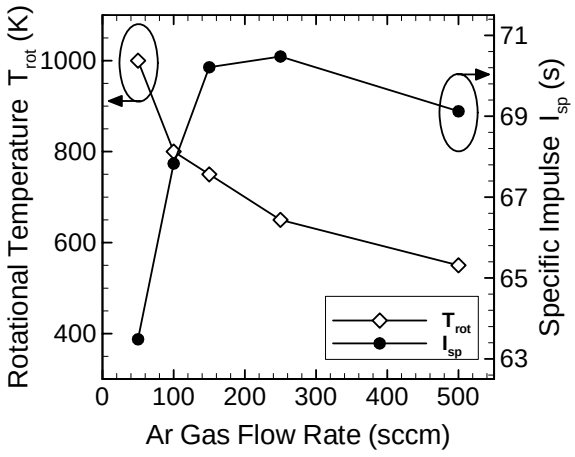

Fig. 13. Rotational temperature T_{rot} at a position of 7 mm in Fig. 9 and specific impulse I_{sp} as a function of Ar gas flow rate for P_{in} = 7 W, f = 4 GHz, and ε_d = 12–25, with a N_2 flow rate of 0.2 sccm.

4. Conclusions

A miniature microwave-excited plasma source for an ultra small thruster has been investigated by optical emission spectroscopy and an electrostatic probe. Experimental results have shown that the emission intensity, electron density, and rotational temperature increase with increasing incident microwave power, microwave frequency, and dielectric constant; whereas the electron density and rotational temperature decreases with increasing Ar gas flow rate. The distribution of the rotational temperature inside the microplasma chamber indicates that the microplasma source presented here is desirable to the microthruster, because the temperature increases at the exit of the plasma chamber where a micronozzle will be equipped. In estimation of the thrust performance, the specific impulse increases with increasing incident microwave power, while it has the maximum value depending on gas flow rates. In the range of microwave powers 2–11 W and of gas flow rates 50–500 sccm, the electron density is 10^{16}–10^{19} m^{-3}, the rotational temperature is 400–1200 K, and the specific impulse is 60–71 s. Fabricating a micronozzle and measuring the thrust performance will be a future work.

Abstract

Experimental observations are conducted for the DC arc plasma jets generated at reduced pressures without or with an applied magnetic field. It is shown that the laminar plasma jets are quite stable, while turbulent plasma jets are unstable and non-axisymmetrical. Arc-root attachment on the anode surface is diffusive for argon arc, while the attachment becomes constrictive when hydrogen is added to the plasma-forming gas and the arc-root rotates quickly around the anode surface under the action of external magnetic field.

Keywords DC plasma jet, flow stability, arc-root attachment, external magnetic field

1. Introduction

Numerous studies have been performed in recent decades concerning the characteristics of DC non-transferred arc plasma jets due to their widespread applications in industries and in labs. Although a wealth of experimental and modeling results have been accumulated in the literature, our understanding on DC non-transferred arc plasma jet characteristics is still incomplete, especially for the plasma jets generated at reduced pressures and for the relationship between the plasma jet characteristics and the arc-root attachment at the anode surface of the DC arc plasma torch used for generating the plasma jet.

In this work, non-transferred DC arc plasma jets are generated at reduced pressures with argon or argon-hydrogen mixture as the plasma-forming gas. The generated plasma jet is studied when it flows as a free jet or as a jet impinging normally upon a substrate. Different gas flow rates are employed in the study in order to obtain laminar and turbulent flow regimes. An external magnetic field is applied if the effect of magnetic field on the arc plasma jet is to be studied. The plasma jets are observed using an ordinary camera to show the jet appearance and using an ICCD camera with much shorter exposure time to obtain the instantaneous plasma jet images in the visible range. Using a specially designed copper mirror, the arc-root behavior on the anode surface of the plasma torch is also observed with the ICCD camera.

2. Experimental details

The non-transferred DC arc plasma torch used for generating the plasma jets at reduced pressures contains a three-piece inter-electrode insert and a co-axial DC magnetic-field coil encircling the torch. Fig. 1 shows the schematic drawing of the torch configuration. The inner diameter of torch anode-nozzle exit is 60 mm, whereas the distance from the cathode tip to the frontal end of anode is 105 mm. Pure argon or argon-hydrogen mixture (with volumetric fraction of hydrogen 0~18% in the Ar-H_2 mixture) has been used as the plasma-forming gas. The total volumetric flow rate of the working gas can be changed in the range of 40~470 STP cm^3/s, and thus both laminar and turbulent plasma flow regimes can be achieved in the experiment. As in Ref. [1], the working gas is introduced axially and tangentially into the plasma torch. The

working chamber pressure can be regulated in the range of (0.05~3.0)×10^4 Pa. Arc current is 80~130 A, whereas the input electric power is 5.5~18 kW, depending on the gas type and pressure and on whether an external magnetic field is applied. The plasma jet is issuing freely into the vacuum chamber or impinging normally upon the substrate (electrically floating) with diameter of 60~120 mm and located 20~300 mm below the torch anode-nozzle exit.

The plasma jets are observed using two different imaging techniques. Namely, photographs of the plasma jet are taken using an ordinary camera to show the jet appearance, and an ICCD camera with much shorter exposure time (may be as short as 5 ns) is used to obtain the instantaneous plasma jet images in the visible range. A copper mirror with good thermal conductance is installed on the water-cooled substrate holder beneath the torch exit and co-axial with the plasma torch. The mirror surface is set to be 45° inclination with respect to the torch axis so that the mirror can reflect the image of the torch exit (with certain depth of field) into the ICCD camera, which is located outside the vacuum chamber, normally to the torch axis and with the same horizontal level as the mirror center. A boron nitride film is coated on the central region of the mirror surface with a size a little larger than the diameter of the central hole-channel of the inter-electrode insert. It is found that in this way the reflection at the mirror surface of the strong light emitted from the central arc column can be greatly weakened and thus the interference caused by the arc column radiation upon the detailed observation of the arc root attachment on the anode surface can be effectively avoided. With this new experimental design, the arc root behaviors in the non-transferred arc Ar and Ar-H_2 plasma torches have been successfully observed.

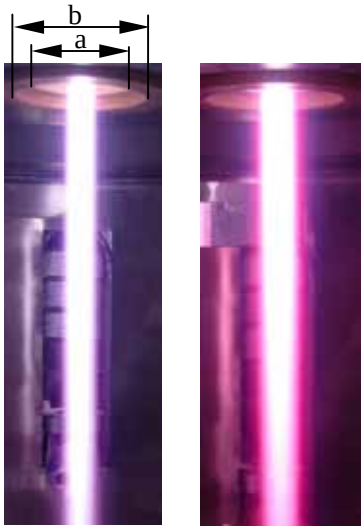
3. Results and discussions

Figures 2(a) and 2(b) show the photographs of Ar and Ar-H_2 plasma jets, respectively, in the laminar flow regime, while Figs. 3(a) and 3(b) show their counterparts for the turbulent regime. The arc current is kept to be 80 A for all the four plasma jets shown in Fig 2 and Fig. 3. The argon flow rate is 290 cm^3/s and the chamber pressure is 3.8×10^3 Pa for Fig. 2(a), whereas they are 320 cm^3/s and 2.2×10^4 Pa for Fig. 3(a). On the other hand, the flow rate is 120 cm^3/s argon plus 7 cm^3/s hydrogen and the chamber pressure is 1.6×10^3 Pa for Fig. 2(b), whereas they are 320 cm^3/s argon plus 17 cm^3/s hydrogen and 2.5×10^4 Pa for Fig. 3(b). It is found that increasing the gas flow rate and increasing the chamber pressure may promote the transition of the plasma jet from the laminar flow regime into the turbulent flow regime, since higher Reynolds number will be involved at higher gas flow rate and at higher gas pressure. Visual observation and the photographs shown in Fig. 2 demonstrate that the laminar Ar and Ar-H_2 plasma jets are stable, axisymmetrical and with longer high-temperature length, but visual observation shows that turbulent plasma jets are not stable and with shorter high-temperature length.



(a) (b)

Fig. 2 Photographs showing the appearance of the pure argon (a) and Ar-H_2 (b) laminar plasma jets. Sizes a and b are 60 and 76 mm, respectively, representing the inner and outer diameters of anode flange plate.

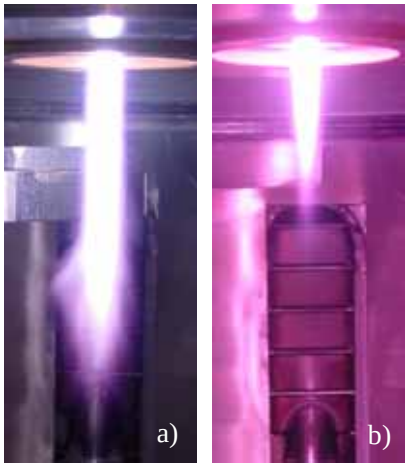


Fig. 3 Photographs showing the appearance of the turbulent argon (a) and Ar+H_2 (b) plasma jets.

Figure 4 gives four luminous-region images of the plasma jets taken by the ICCD camera with two different exposure times, i.e. 5 μs and 10 μs, corresponding jet appearances have been shown in Fig. 2 for the laminar plasma jets and shown in Fig. 3 for the turbulent plasma jets. It is found that the laminar jets are highly stable, and both the two images as shown in Fig. 4(a) and 4(b) do demonstrate that the luminous regions of the laminar Ar and Ar-H_2 plasma jets are well axi-symmetrical and co-axial with the plasma torch even as the exposure time is as short as 10 μs. These observation results for the laminar plasma jets are different from those obtained for the turbulent plasma jets shown in Fig. 4(c) and 4(d), and quite different from those obtained previously [2,3] for the turbulent plasma jets. For a turbulent argon plasma jet issuing into ambient air at atmospheric pressure, Refs. [2,3] reported that the photographs with exposure times of 100 μs and 1 ms showed that the studied turbulent plasma jet was unsteady and thus the forms and sizes of the jet visible-region varied at all time. The turbulent plasma jet images taken at reduced pressures in this study, as shown in Figs. 4(c) and 4(d), reveal almost the same phenomenon as reported in [2,3] for the atmospheric-pressure turbulent plasma jet. Namely, the luminous regions of the turbulent plasma jets shown in Figs. 4(c) and 4(d) are non-axisymmetrical, implying that the turbulent Ar or Ar-H_2 plasma jet generated at the reduced pressure is unstable.

Although the laminar Ar and Ar-H_2 plasma jets all assume axi-symmetrical appearances, as seen in Fig. 4(a) and 4(b), it is difficult to identify correspondent arc-root behaviors only based on their appearances. Fig. 5 gives some additional observation results concerning the arc root attachment with help of the specially designed copper mirror mentioned above and the ICCD camera. In order to show the related dimensions of the plasma torch, Fig. 5(a) gives a rear-view photograph of the torch channel configuration for the cold-state case (without plasma production) using a ruler across the torch exit and using a lamp to illuminate the

observed object. The inter-electrode insert channel cannot be seen in Fig. 5(a) since it is just covered up by the ruler. It is noted that the bright spots seen in Fig. 5(a) are not the arc roots and are formed only due to the reflection of lamp light at the end wall of the torch anode. Fig. 5(b) shows the rear-view image of the argon arc at the chamber pressure of 3.2×10^3 Pa taken by using the ICCD camera with an exposure time of 10 μs. From Fig. 5(b) we only see some low-intensity luminous region on the anode surface, and cannot see any sign of a constricted arc-root formation in the pure argon plasma jet generation. Fig. 5(c) is the correspondent rear-view image of the Ar-9%H_2 plasma jet at the chamber pressure of 2.4×10^4 Pa and with a camera exposure time of 80 μs. It is clearly seen from Fig. 5(c) that constricted arc root attachment appears in the Ar-H_2 plasma generation. It is found that when pure argon is used as the plasma-forming gas, almost completely diffuse attachment of the arc root always appears at the anode surface, no mater whether the plasma jet is in laminar or turbulent flow regime. Such a diffuse arc-root attachment is obviously favorable for reducing the anode erosion and prolonging the service period of the torch anode. The arc root attachment becomes sharply concentrated, as shown in Fig. 5(c), when hydrogen is added into argon for generating the plasma jet even as the content of hydrogen in the mixture is small, and the arc root generally attaches at the anode end-wall with a particular angular-direction. The arc root shows no apparent movement within the observation time of a few minutes if the jet-generating conditions are unchanged. This special feature of Ar-H_2 plasma will lead to relatively serious anode erosion when hydrogen is added into argon to generate the plasma jet. This phenomenon is well known in the DC non-transferred arc plasma generation at atmospheric pressure.

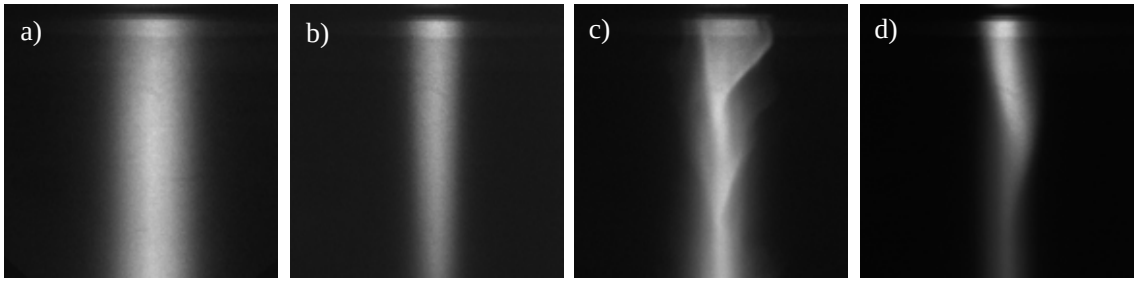

Fig.4 Luminous images of the laminar (a) and turbulent (c) argon plasma jets and the laminar (b) and turbulent (d) Ar-H_2 plasma jets. The exposure time of ICCD camera is 5 μs for (c) and 10 μs for others.

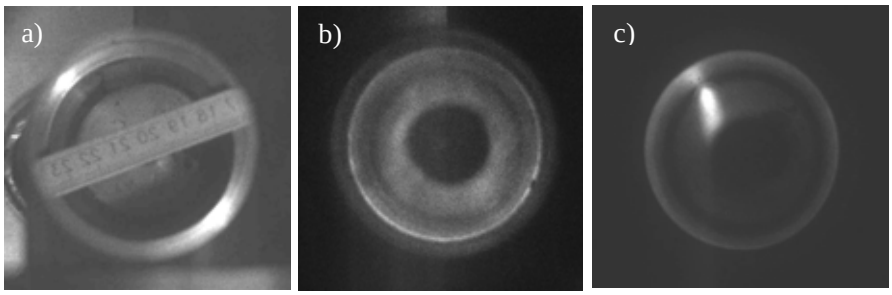

Fig. 5 (a) Rear-view photograph of the torch channel configuration with a ruler across the anode exit section but without plasma; (b) photograph of the Ar plasma at chamber pressure of 3.2×10^3 Pa; and (c) photograph of Ar- 9%H_2 plasma at 2.4×10^4 Pa. The exposure time is 10 μs for (b) and 80 μs for (c).

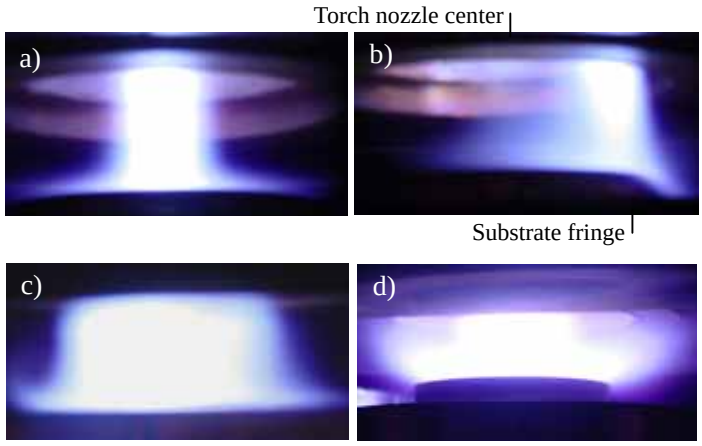

Fig. 6 Appearance of the pure argon plasma jets. (a) - (c) at chamber pressure of 1.7×10^4 Pa and (d) at 6.5×10^2 Pa. External magnetic field is applied for the case (b) and (c).

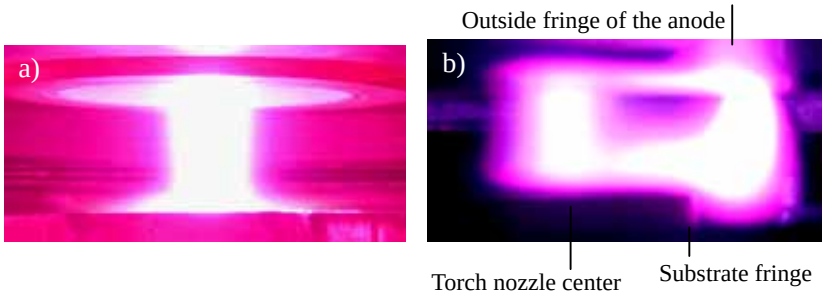

Fig. 7 Appearance of the Ar+H_2 plasma jets. (a) taken at chamber pressure of 1.6×10^3 Pa and 4%H_2 , and (b) at 1.8×10^4 Pa and 15%H_2.

Figure 6 shows the appearance of the pure argon plasma jet generated at 6 kW input power and impinging on the water-cooled substrate. The photographs are taken using the digital camera. Figs. 6(a) - 6(c) are with chamber pressure of 1.7×10^4 Pa, whereas 6(d) is with pressure 6.5×10^2 Pa. Figs. 6(a) and 6(d) are for the case without external magnetic field, whereas Fig. 6(b) and 6(c) are for the case with an applied external magnetic field of about 0.03 T. It is seen that the argon plasma jet is well axi-symmetrical for the case without the external magnetic field, as shown in Fig. 6(a) and 6(d). At the higher pressure, i.e. at 1.7×10^4 Pa, the radial size of high-temperature regions of the argon plasma jet including its impinging zone at the substrate surface are somewhat concentrated, whereas at the lower pressure, i.e. at 6.5×10^2 Pa, the high-temperature regions are more diffusive and can cover up the whole substrate with diameter of 60 mm. The appearance of the argon plasma jet under the action of external magnetic field (Fig. 6(b)) is quite different from that shown in Fig. 6(a) for the case without external magnetic field effect. As seen from Fig. 6(b), the high-temperature region of the plasma jet is no longer axi-symmetrical and is not steady when an external magnetic field is applied to drive the arc root moving along the inner surface of the torch anode-nozzle. The high-temperature region rotates around the torch axis, and thus approximately axi-symmetrical picture can be obtained if the exposure time of the digital camera is long enough, as seen in

Fig. 6(c). With the rotation driven by the external magnetic field, the argon plasma jet can cover up the whole substrate surface with 60 mm diameter. This situation is favorable for getting more uniform heating of the substrate with a relatively large surface area.

When hydrogen is added into argon to generating the plasma jet, the arc voltage increases with the increase of hydrogen content in the Ar-H_2 mixture. Fig. 7 shows two photographs taken by the ordinary camera for the argon-hydrogen plasma jet (a) and arc column (b) without the external magnetic field. When the hydrogen content in the Ar-H_2 mixture is relatively low (about 4%), Fig. 7(a) shows a similar impinging jet characteristics as for the pure argon plasma jet shown in Fig. 6(a). It is found that when the argon-hydrogen mixture is used as the plasma-forming gas, arc column can be blown out from the torch exit for certain parameter combinations. For the case shown in Fig. 7(b), a straight arc column goes down along the torch axis until it reaches the region near the water-cooled substrate surface and then bends up to the anode-nozzle exit with a constricted arc-root attachment at the outer fringe of the anode-nozzle. When the external magnetic field is applied, it is found that the argon-hydrogen arc root rotates quickly along the outer fringe of anode-nozzle, and the arc root attachment location tends to retreat back inside the torch nozzle as the magnetic induction intensity of applied magnetic field increases when the plasma-generating conditions are kept unchanged.

The present observation results suggest that the attachment mode of the arc root in the plasma generator, i.e. as a diffused- or constricted-type arc-root, is mainly determined by the working gas type; and the axial position of arc root and the arc root movement are essentially controlled by the balance between the gas flow action and the magnetic field driving.

4. Conclusions

The present observation results show that the laminar argon or argon-hydrogen plasma jet is very stable, while the turbulent plasma jet is obviously unstable and non-axisymmetrical. Arc attachment on the anode surface is almost completely diffusive when pure argon is used as the plasma-forming gas, while the arc root attachment becomes sharply concentrated when hydrogen is added into argon as the plasma-forming gas even for the case with a rather low content of hydrogen in the Ar-H_2 mixture. When the chamber pressure is reduced, the high-temperature region of argon plasma jet becomes more diffused with a larger cover-area as it impinges on the substrate. When the argon-hydrogen mixture is used as the plasma-forming gas, the arc column is easily blown out from the torch nozzle exit until it reaches the region near the water-cooled substrate surface and then bends up to attach at the outer fringe of the anode-nozzle. When an external magnetic field is applied, the argon-hydrogen arc-root rotates quickly along the anode surface, and the arc-root attachment location tends to retreat back inside the torch nozzle as the magnetic induction intensity of the external magnetic-field is enhanced.

Thermodynamic Properties of Fluorocarbons

M. K. VanOtterloo[1], S. L. Girshick[1], and J. T. Roberts[2]
1 Department of Mechanical Engineering, University of Minnesota, Minneapolis, United States
2 Department of Chemistry, University of Minnesota, Minneapolis, United States

Abstract
A group additivity method was developed to estimate heats of formation for linear and branched radical and closed-shell, gaseous fluorocarbon neutrals containing four or more carbon atoms. These groups are derived from *ab initio* calculations by Bauschlicher and Ricca [1,2]. Heats of formation and other thermochemical properties determined by a group additivity approach will be utilized in the development of a computational model to simulate gas-phase nucleation in an octafluorocyclobutane (*c*-C_4F_8) plasma.
Keywords: Fluorocarbon plasmas; Heats of formation; Group additivity; Radicals

1. Introduction

Fluorocarbon plasmas are commonly used as etchants in integrated circuit fabrication due to selectivity and anisotropic capabilities. Nanoparticles have been observed in these systems [3] but little is known about how the particles form. We have begun developing a computational model to simulate gas-phase nucleation in an octafluorocyclobutane (*c*-C_4F_8) etching plasma, accounting for particle production via chemical reactions, and particle growth by coagulation and surface reactions.

Many important reactions leading to particle formation may be reversible, requiring knowledge of reaction free energies, and hence, knowledge of the standard enthalpies of formation (Δ_fH^o) and entropies of the chemical species involved. Experimental data are available for only a few fluorocarbon species containing more than two carbon atoms. More extensive work has been done by means of *ab initio* computational studies, including a study by Zachariah et al. [4] that reported thermochemical data for around 100 hydrofluorocarbon species. Computational chemistry calculations become more expensive as the size and complexity of the molecule grows, making studies of this sort impractical for our exploration of large fluorocarbon clusters.

In order to provide enough thermodynamic data to proceed with modeling of fluorocarbon cluster formation, we have developed a group additivity method, an empirical method that has been successfully used for hydrocarbons, partially halogenated hydrocarbons [5], and silicon hydrides [6]. In general, group additivity allows for estimation of a molecule's Δ_fH^o by summing the Δ_fH^o values of contributing groups, e.g., group additivity values (GAVs). Yamada and Bozzelli [7,8] and Zhang and Pollard [9] conducted group additivity studies on partially fluorinated systems: hydrofluorocarbons and chlorofluorocarbons, respectively. While these GAVs could be applied to fully fluorinated systems, GAVs for fluorocarbon radicals are lacking in both studies. Yamada and Bozzelli reported no radical groups while Zhang and Pollard reported two radical groups. In the case of plasma chemistry, radicals can be very important to the kinetics and therefore the lack of radical thermochemistry could be a problem. This paper describes the methodology used in determining new GAVs for fluorocarbon molecules, including radicals, and compares results to those previously reported in other studies.

2. Methodology, Results, and Discussion

The accuracy of GAVs depends on the precision of the data used in their estimation and on the size of the database. Bauschlicher and Ricca computationally determined Δ_fH^o for C_xF_y (x=1-3) [1] and cyclic C_4F_n (n=4-8) [2] on the G3MP2 level and found their calculations to be accurate to within ± 2 kcal/mol. We chose to base our group additivity analysis on these values because there is no experimental study, to our knowledge, that could provide us with as large or as accurate a database. The heats of formation from the Bauschlicher and Ricca study are listed in Table 1 along with the generalized molecular structures of the studied species for illustrative purposes. We utilized data for two single-bonded molecules, C_2F_6 and C_3F_8; three single-bonded radicals, C_2F_5, C_3F_7A ($F_3C(CF)CF_3$), and C_3F_7B ($F_2C(CF_2)CF_3$); three double-bonded molecules, C_2F_4, C_3F_4, and C_3F_6; three

double-bonded radicals, C_2F_3, C_3F_2, and C_3F_3; one triple-bonded molecule, C_2F_2; and one cyclic molecule, *c*-C_4F_8. From these data, eighteen groups were defined, including one ring correction, as shown in Table 2.

Table 1. Heats of formation and general geometries from Bauschlicher and Ricca [1,2] used in determination of group additivity values. Data includes five single-bond species, six species containing double bonds, one specie with a triple bond, and *c*-C_4F_8, which requires a four-carbon ring correction.

Single Bonded Species		$\Delta_f H°(298K)$ kcal/mol
C_2F_5		-215.29
C_2F_6		-322.34
C_3F_7 A		-322.41
C_3F_7 B		-315.64
C_3F_8		-422.00

Other Species		$\Delta_f H°(298K)$ kcal/mol
C_2F_2		0.03
c-C_4F_8		-375.60

Double Bonded Species		$\Delta_f H°(298K)$ kcal/mol
C_2F_3		-53.57
C_2F_4		-161.69
C_3F_2		55.19
C_3F_3		-31.94
C_3F_4		-132.34
C_3F_6		-276.04

Table 2. Definition of groups, group additivity values for fluorocarbon compounds, and comparison of GAVs from Yamada and Bozzelli [7].

	Group	$\Delta_f H^o$(298K) kcal/mol	
		Previous work [7]	This work

[a] Assumed value. [b] Ċ: carbon radical. [c] C$_d$: double-bonded carbon. [d] C$_a$: allyl-like carbon ([C]=C=[C]). [e] C$_t$: triple-bonded carbon. [f] R4: four-carbon ring correction.

Fluorocarbons are not a good candidate for the traditional group additivity method introduced by O'Neal and Benson [10], because average errors exceed 10 kcal/mol, as reported by Yamada and Bozzelli [7]. To reduce errors, Yamada and Bozzelli included a correction for interactions between fluorine atoms located on adjacent carbon atoms, determined by studying hydrofluorocarbons. Unfortunately, the Bauschlicher and Ricca study does not produce a large enough database so that both group values and interaction values can be determined. Therefore, we utilized the interaction terms determined by Yamada and Bozzelli, shown in Table 3, for all of our GAV calculations. The groups and fluorine interactions contained in each of the molecules studied by Bauschlicher and Ricca are listed in Table 4.

Given that heat of formation data are available for only thirteen molecules, while eighteen groups are defined in Table 2, five further assumptions are required to determine the set of GAVs. First, we assumed that C-[F]$_3$[Ċ] is equivalent to C-[F]$_3$[C]. The analog to this assumption in the hydrocarbon system, namely that C-[H]$_3$[Ċ] is equivalent to C-[H]$_3$[C], is commonly made, and Marsi et al. [11] determined that on average it affected GAVs

by only 0.5 kcal/mol in an alkyl radical system. Therefore, we supposed that setting GAV for C-[F]$_3$[Ċ] equal to that of C-[F]$_3$[C] would have only a small effect on the fluorocarbon results as well. Similarly, we assigned the GAV of C_d-[F]$_2$[Ċ] to be equal to that of C_d-[F]$_2$[C]. We also assumed that the GAV of C-[F]$_3$[C_d] was equal to that of C-[F]$_3$[C], which was supported by Cohen and Benson [12] in the hydrocarbon system, for which they found that the GAV of C-[H]$_3$[C_d] equaled that of C-[H]$_3$[C]. We also assumed that the GAV of Ċ$_d$-[F][C_d] equaled that of Ċ$_d$-[F][C], based on the same logic. Finally, we assigned the GAV of [C]-C_a-[C] to be equal to Cohen and Benson's [12] value of 34.0 kcal/mol for the same group.

Table 3. Correction values to heats of formation due to interaction between fluorine atoms on adjacent carbon atoms. Values are from Yamada and Bozzelli [7].

Fluorine Correction Terms[a]	$\Delta_f H^o$(298K) kcal/mol
F/3F	7.8
2F/2F	9.8
2F/3F	13.8
3F/3F	15.5
F//2F	8.9
2F//2F	16.1
F///F	-0.50

[a] /, //, /// indicates interaction across a single, double, and triple bond, respectively.

From these assumptions, a step-by-step approach was used in determining the group additivity values from the available database. Though this is not as accurate as performing a least-squares-fit over a large database of molecules, Cohen and Benson [12] found that GAVs determined from accurate data for single molecules were within experimental error. Recall that all fluorocarbon-fluorocarbon interaction values were assumed from Yamada and Bozzelli [7], therefore C-[F]$_3$[C], C_d-[F]$_2$[C], and C_t-[F][C] were determined directly from C_2F_6, C_2F_4, and C_2F_2, respectively. With these values, C-[F]$_2$[C]$_2$ could be determined from C_3F_8. Next, Ċ-[F]$_2$[C], Ċ-[F][C]$_2$, and C-[F]$_2$[C][Ċ] could be derived from C_2F_5, C_3F_7A, and C_3F_7B, respectively, once C-[F]$_3$[Ċ] = C-[F]$_3$[C] was assumed. After C_d-[F]$_2$[Ċ] = C_d-[F]$_2$[C] was assumed, Ċ$_d$-[F][C] was found from C_2F_3. Then, after [C]-C_a-[C] is assigned a value of 34.0 kcal/mol and Ċ$_d$-[F][C_d] = Ċ$_d$-[F][C], C_d-[F]$_2$[C_d], [C]-C_a-[Ċ], and [Ċ]-C_a-[Ċ] were determined from C_3F_4, C_3F_3, and C_3F_2, respectively. Finally, since C-[F]$_3$[C_d] = C-[F]$_3$[C], C_d-[F][C]$_2$ was found from C_3F_6. To determine the ring correction, *c*-C_4F_8 is assumed to be composed of four C-[F]$_2$[C]$_2$ groups and four 2F/2F interactions plus the R4 correction. The resulting group additivity values are listed in Table 2.

Any direct comparison between our group additivity values and those from other studies is only relevant to the extent that the other studies also included fluorine-fluorine interaction corrections. Therefore, GAVs of this work could only be judged against those determined by Yamada and Bozzelli [7]. Comparison of the GAVs of the four groups coincident in both studies, shown in Table 2, resulted in an average difference of 3.1 kcal/mol.

3. Conclusions and Future Work

Group additivity values were developed to determine heats of formation for gaseous fluorocarbon species. GAVs previously defined by Yamada and Bozzelli [7] for four of the groups defined herein are on average within ± 3.1 kcal/mol of the GAVs of this study, lending support that our other GAV estimations are reasonable. These GAVs can be used to estimate the $\Delta_f H^o$ for linear and branched radical and closed-shell, gaseous fluorocarbon neutrals containing four or more carbon atoms.

In the future, this group additivity scheme will be extended to estimate entropies. Also, further ring corrections will be estimated, probably by reference to available experimental work.

Abstract
We report on the deposition of thin film coatings produced at atmospheric pressure by mixing plasma with sprayed chemicals phases. SiO_2 and TiO2 like coating were homogeneously deposited on a variety of materials. Surface analyses show the formation of a very dense layer, comparable to those made with other deposition techniques. Furthermore, deposition temperature can be as low as 50°C for SiO2 and 300°C for TiO2. The whole process can be completed on existing continuous production lines.

Keywords
Atmospheric plasma. Thin film deposition. Silica.

Introduction
Film deposition has a wide range of industrial applications such as protective and abrasion resistant coatings, optical layers, diffusion barriers, hydrophilic / hydrophobic layers, super-hydrophilic and super-hydrophobic surfaces, low-k, high-k, food packaging, etc. Plasma processes are being used for film depositions. They offer important advantages such as: avoidance of wet and hazardous chemical processes, enhancement of chemical reactions, and excellent performance in terms of adhesion and homogeneity. In recent years, plasma technology has evolved considerably and new technological possibilities have emerged. A new post-discharge plasma system has been developed by AcXys Technologies producing low temperature plasma at atmospheric pressure, away from electrodes confinement, and using low cost nitrogen or nitrogen/gases mixtures. This plasma technology is ideally suited to deposit inorganic and organo-inorganic thin films.

1. Atmospheric plasma technology

AcXys Technologies provides equipment and turn-key processes based on a unique atmospheric pressure plasma technology (Figure 1).

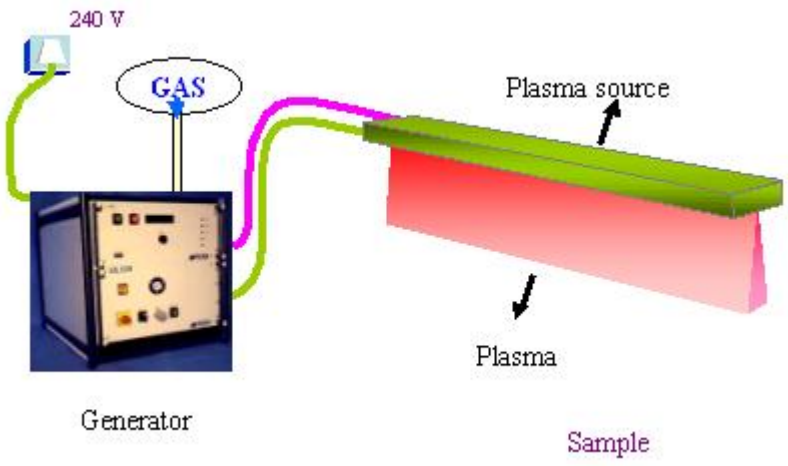

Figure 1: Schematic description of the AcXys Plasma system. The plasma source can vary in lengths.

The AcXys system produces a low temperature reactive atmosphere (Figure 2) capable of treating almost any materials in any size or shape. Examples of materials are: polymers, metals, glass, optics, electronics devices and products, rubbers, textile or webs.

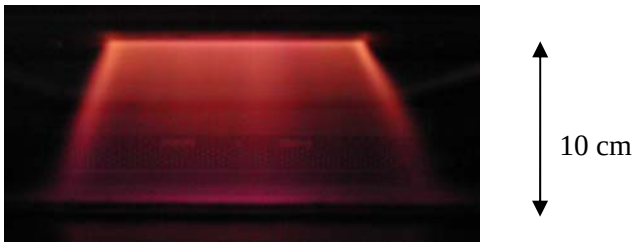

Figure 2 : Nitrogen plasma phase ejected from the plasma source at atmospheric pressure.

This plasma technology is being used in a variety of applications across many industries using nitrogen, nitrogen/gas mixtures or purified air. The technology can be used to clean surfaces, to chemically activate them, to perform oxido-reduction chemistry at surfaces, and to surface engineer materials. Properties like wettability, spreading rates, adhesion and thin film cohesion can be considerably improved. In addition, new concept of adhesion called dry-adhesion have been invented by avoiding the use of wet adhesives.

AcXys Technologies' equipment generate a blade-shaped plasma, which length can be adjusted depending on customer's needs (Figure 3). When used in controlled atmosphere, the plasma phase can be large enough to enable treatment of 3D objects. This makes AcXys the only technology that offers atmospheric plasma treatment for any shape and any size.

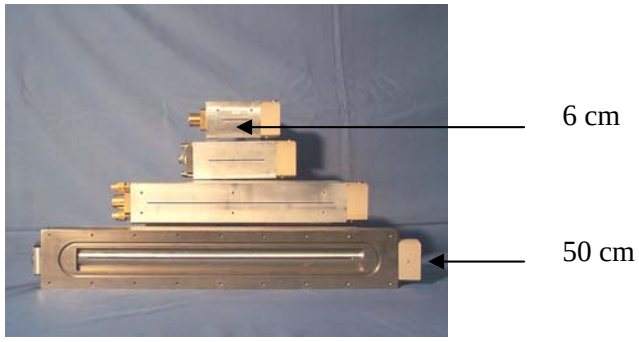

Figure 3 : Plasma sources of varying lengths.

When treatment is required over a precise area or when there is a confinement space from the source, the plasma can be directed through a tube and delivered where and when needed (Figure 4).

Figure 4 : Delivering of a plasma phase for local treatment.

Several kinds of equipment have been designed and proposed for specific needs. For instance, Miniweb equipment is used for web material and films (Figure 5), 3D-Box is used for small objects and ideally replaces low pressure glow discharge plasma systems (Figure 6) and ultra-light is easy to adapt on existing continuous production lines or custom reactors (Figure 7).

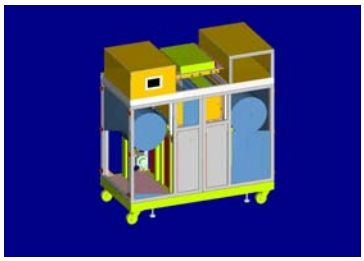

Figure 5 : Web material treatment system incorporating a plasma system.

Figure 6 : Bench-top plasma system for batch treatment of small objects.

Figure 7 : Ultra-light equipment (UL) series for customized applications.

2. Experimental setup

An atmospheric plasma is created in a confined tunnel, then mixed with a sprayed liquid precursor. A substrate holder is conveyed near the mixing zone, so as to realize deposition (Figure 8).

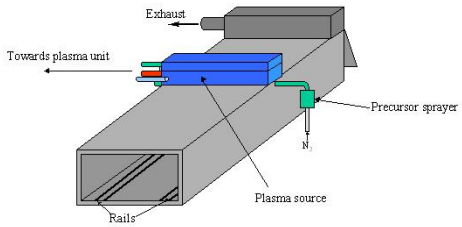

Figure 8 : Schematic of the experimental setup.

Substrate can be conveyed under the plasma with a robot, at a precise speed, thus enabling a precise and homogeneous film deposit (Figure 9).

Figure 9 : Picture of the overall experimental setup.

We used several precursors, such as hexamethyldisiloxane (HMDSO or MM), octamethylcyclotetrasiloxane (OMCTS or D_4) to deposit SiO_2 like films on silicon wafer. We chose silicon because it is easier to analyze and to compare with existing deposition techniques. However, we have been able to deposit other materials on many other substrates like plastics, glass, fabrics, leather.

3. Results

We compared our film deposits to those made with traditional deposition methods with the following means: Scanning Electron Microscopy (SEM), FTIR, and Variable Angle Spectrocopic Ellipspometry (VASE).
SEM views (Figure 10) show a very dense layer, without cavities.

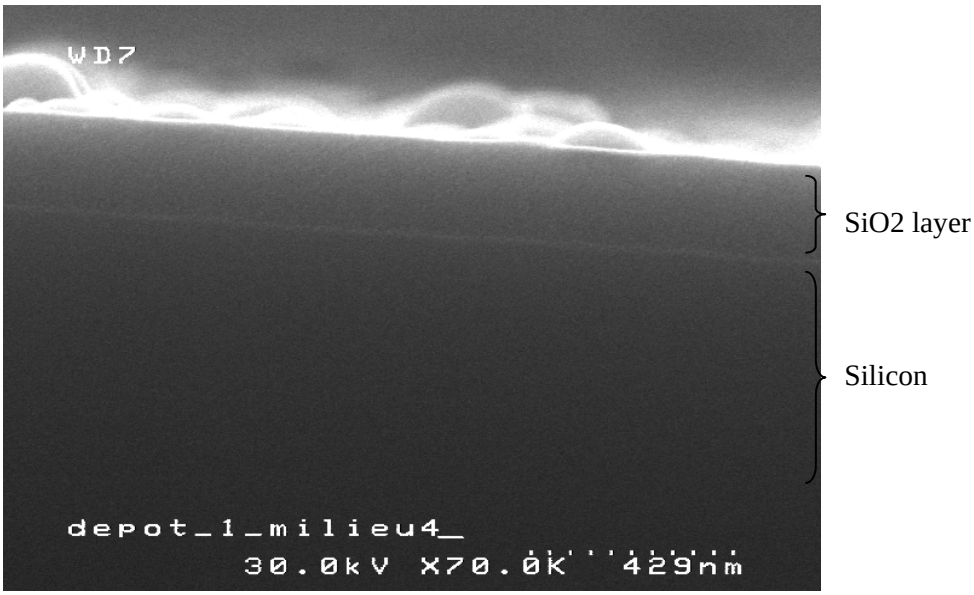

Figure 10 : SEM view of a SiO_2 film deposit

We compared FTIR spectra of four layers made with our technology with those of layers made with classical PECVD methods (Figure 11). They are very similar.

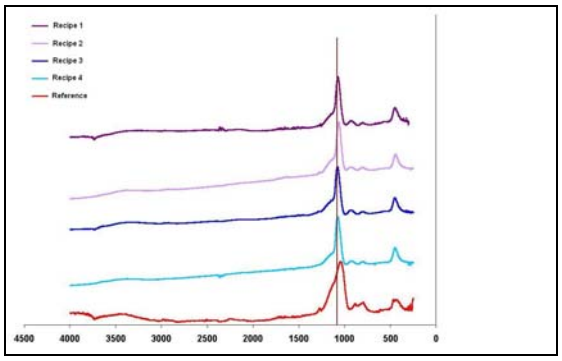

Figure 11 : Four FTIR spectra compared to those of a classical PECVD deposit (bottom)

VASE measurements show refractive index as a function of wavelength (Figure 12). Several materials made with different techniques have been compared in term of refractive index, and thus in term of density (Table 1). It appears that very dense layers can be deposited with atmospheric plasma. Indeed, the density is higher for our films than for sol-gel layers and nearly the same as PVD layers. Density has been evaluated at 1,7 g/cm^3.

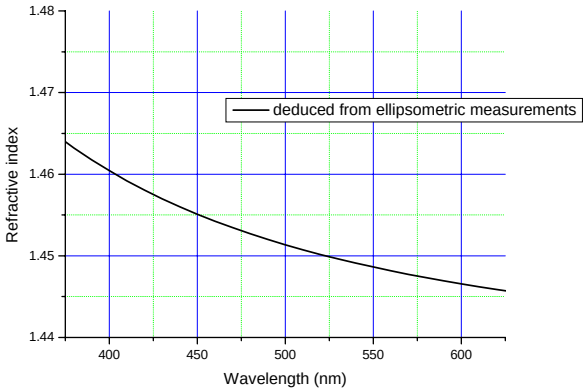

Figure 12 : Ellipsometry measurements of the silica-like film.

Technology	Ion Beam Sputtering	Evap. 250°C	AcXys plasma	Sol-Gel
n @ 600 nm	1.5	1.475	**1.446**	< 1.35

Table 1 : Comparaison of refractive indices (n) of the silica films deposited by different techniques.

Homogeneous deposits have been produced on 4” wafers (Figure 13). This is a very promising result, showing industrial viability of the process.

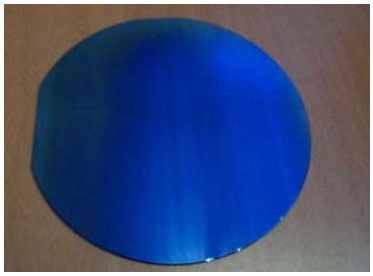

Figure 13 : Homogeneous silica film deposit on a 4" silicon wafer.

4. Towards lower temperatures

SiO_2 film deposition is produced from organosilicon precursors without preheating the substrate. This latter is naturally heated by the plasma and can reach 200°C, depending on the distance between the substrate and the plasma source, the plasma treatment time, and the nature of the substrate. The heat can be avoided by using several short time cycles so as to let the substrate cool.

A new way to decrease plasma temperature has been experimented with success. It is based on duty cycle control of the plasma power. Plasma is regularly switched on and off at 100 Hz with a duty cycle that can be set from 0 to 1. Thus, it is possible to monitor plasma temperature from ambient to approximately 200°C. With this method, deposition of a 150 nm SiO_2 layer has been completed at 50°C.

5. Deposition of TiO2 at low temperature

Similar experiments have been performed with TiO2 precursors. A TiO2 crystal thin film has been deposited at less than 300°C.

Acknowledgments

An important part of this work was realized by Rémy Maurau during his graduation internship at AcXys Technologies, with technical support from Patrick Lassagne and Laurent Lassagne. We would like to thank Dominique de Barros, Carmen Jiménez and François Weiss (Laboratoire des Matériaux et du Génie Physique) for their work on TiO2. FTIR measurements have been realized with the help of Michel Langlet. SEM measurements have been realized by Jérôme Thiault.

Abstract
In this work, the influence of different impurities (N_2, O_2, Ar and H_2) on the thermal behaviour of an atmospheric microwave plasma is studied. Substituting 500 ppm of N_2 by 500 ppm of H_2 makes the gas temperature vary by about 500 K. Infra-red thermal analyses of the fused silica tube confirm the sensitive influence of the additive gas on the thermal behaviour of the plasma.

Keywords. Atmospheric pressure glow discharge, Helium, TALIF, OES, Temperature measurements

1. Introduction

The development of applications of atmospheric pressure plasmas requires a better understanding of phenomena that control the discharges. Recent theoretical and experimental characterizations of atmospheric discharges in helium pointed out the importance of impurities in the description of the plasma [1-2]. For example, small amounts of additive gases (~1%) are known to play a role in the stability of Atmospheric Pressure Glow Discharges (APGD) [3].In the present work, the influence of different impurities is studied. The main criterion retained here to appreciate the influence of the impurities is the gas temperature which is determined either by simulating the rotational spectra of OH radicals [4] or from the Doppler broadened line shape the H_α and D_α lines measured by means of Two Photon Absorption Laser Induced Fluorescence (TALIF) [5]. Indeed, in the microwave cavity used as plasma source, huge thermal gradients are observed. In the flow conditions retained in these experiments, the Reynolds number is in the range from 2 to 15, whereas the Grashof number (Gr=$\frac{g\beta\rho_{ref}^2\Delta T_{ref}R^3}{\mu_{ref}^2}$ where g is the gravity, β the compressibility factor of helium, ρ the gas density, μ its viscosity and R, the radius of the tube) reaches 5340 at 3000 K. In this case, where the Gr/Re ratio is sufficiently high, instabilities are observed [6] since mixed flow conditions prevail. Recently, Castaños Martinez et al. [7] have shown the importance of thermal gradients on plasma contraction at sufficiently high pressure.

2. Experiment

The experimental device is presented in Figure 1. The gas mixture is introduced into a 28 mm inner diameter tube made of fused silica. The flow rate of Helium is 2000 sccm (standard cubic centimetre per minute). The microwave power is kept at a constant value of 300 W. All gases (He, N_2, H_2, O_2 and Ar) have the same level of purity (99.995%) and the flow rates are controlled by mass flow meters (typically between 1 sccm (~ten times higher than the amount of impurities initially contained in "pure" helium) and 100 sccm). The discharge is produced using a cavity connected to a microwave generator (2.45 GHz). Optical Emission Spectroscopy (OES) is carried out in the discharge using a HR640 Jobin Yvon spectrometer equipped with a 1200 gr/mm grating and a CCD detector. The spectral resolution is thus $\Delta\lambda \sim 0.33$ nm
For TALIF experiments in He-H_2 mixtures only, photo-excitation is provided by a YAG-pumped dye laser (Quantel TDL50). The Nd-Yag emission at 1064 nm is frequency doubled into a KDP crystal before pumping the dye cells. For our purpose, the dye laser operates with Rhodamine 640 to produce a 615 nm laser beam which is next frequency tripled (~205 nm). The two-photon absorption is then used to probe the Ly_β transition

at 102.57 nm. The detection set-up for TALIF measurement is made of the set: Photomultiplier, interference filter, amplifier and Boxcar presented in Fig. 1. Finally, deuterium is substituted to hydrogen to calibrate the full width at half maximum (FWHM) of the hydrogen adsorption peak [5].

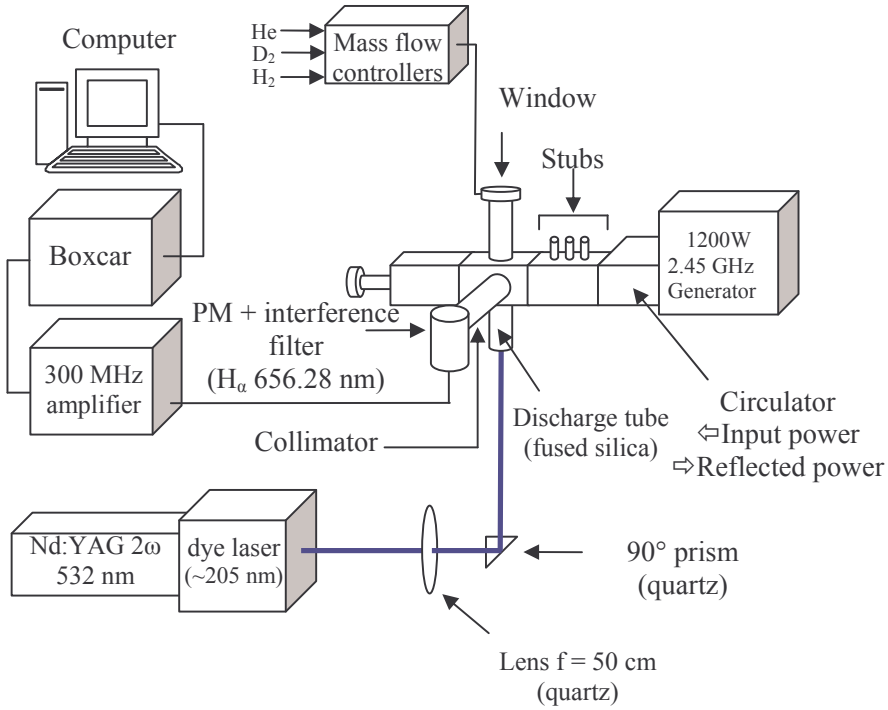

Figure 1: Experimental set-up.

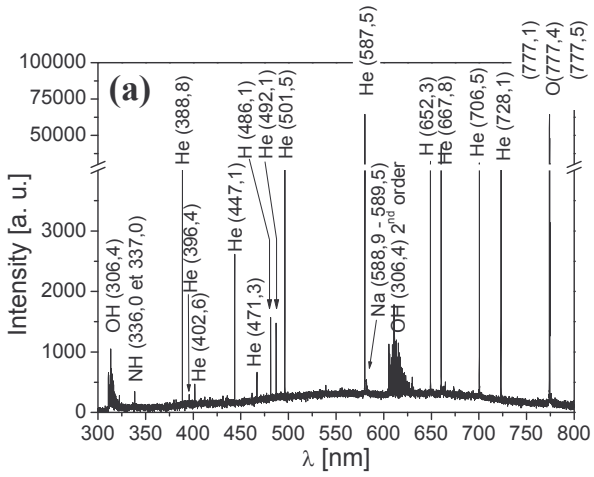
3. Experimental results

Visible optical emission spectra of helium plasmas of different additive gases are depicted in figure 2. They are very similar to those presented in other kinds of discharges [8-9]. Dimmer emission is not detected at 300 W since the temperature of the gas is too high to keep these species at sufficiently high densities [7].
At 0.1% of additive gases, the emission spectra are very similar to those that would be obtained in discharges of the pure additive gases.



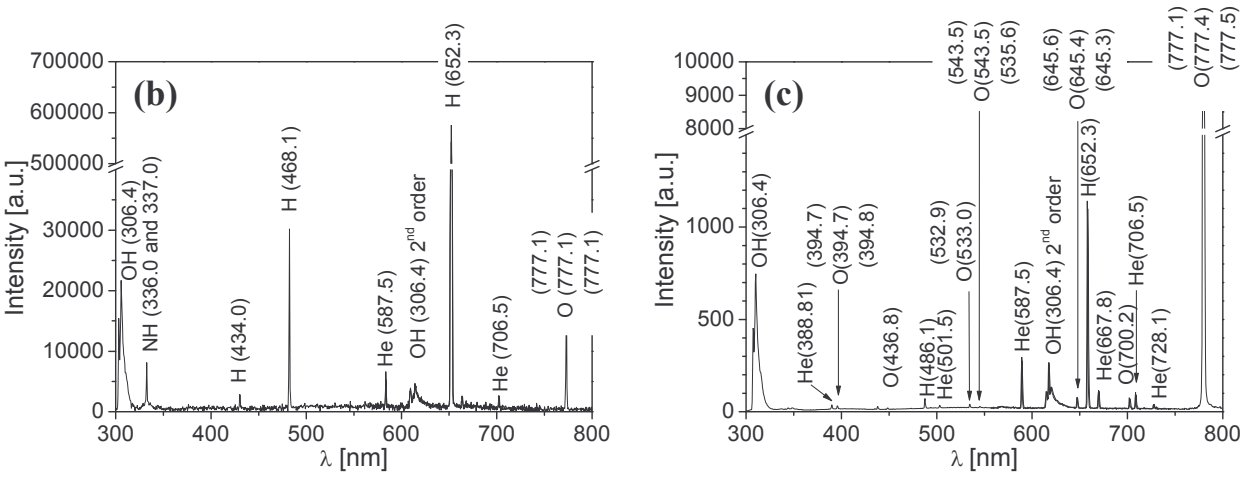


Figure 2: Optical emission spectra in the visible region of atmospheric helium plasmas (300 W) with (a) : 0 sccm of additive gases, (b) 0.1% H_2, (c) 0.1% O_2.

The presence of OH emission enables us to predict the temperature of the gas with a satisfying accuracy as already studied in detail by [10] in a very similar experimental arrangement to the present device.

3.1. Gas phase temperature

In a first step, a comparison is draw between the temperatures determined by OH rotational spectrum simulation and TALIF measurements (Figure 3). The mean temperature increases significantly from 0 to several hundreds of ppm of hydrogen (from 2700 K to about 3000 K). A discrepancy is noticed between OES and TALIF measurements between 0 and 2% of H_2 whereas at higher concentrations, both types of results merge.

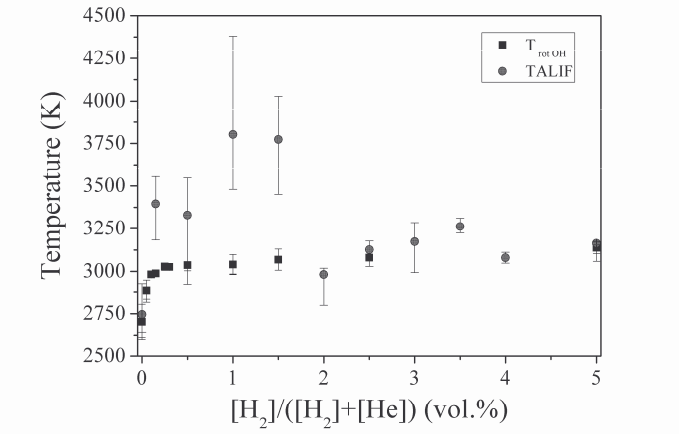

Figure 3: Comparison between temperatures determined by TALIF and synthetic spectra of OH from optical emission spectroscopy.

OH rotational temperature is determined from a spectrum of optical emission spectroscopy acquired from the whole volume of the plasma, whereas the TALIF measurement is spatially resolved. Furthermore, the reproducibility of TALIF results is much lower than that of OES as shown by error bars.

In a second step, the influence of different gases introduced as impurities in helium is studied. Results are reported in Figure 4. Clearly, it can be seen that nitrogen or argon cools the plasma whereas hydrogen or oxygen heats it. From 500 ppm N_2 to 500 ppm H_2, a difference of nearly 500 K is measured.

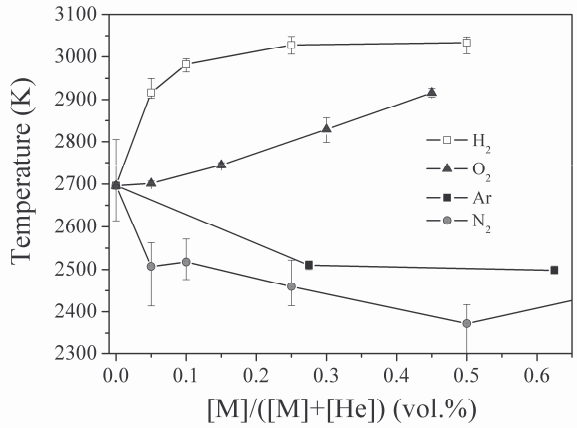

Figure 4: Influence of H_2, O_2, Ar and N_2 introduced as impurities in helium on the plasma mean temperature determined by OH rotational temperature.

This huge difference shows the importance of the additive gas on the thermal behaviour of the plasma, even at low concentrations.

3.2. Wall temperature

To evidence the role played by additive gases on the thermal behaviour of the plasma, even at low concentrations, infra-red thermal analyses of the tube enclosing the helium gas flow were performed. For these measurements, a square window is opened in the waveguide. Experimental results are depicted in Figure 5 in which the limits of the window are indicated by vertical arrows.

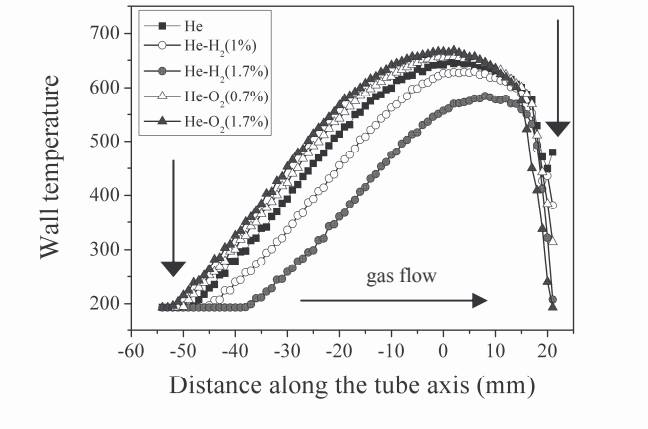

Figure 5: Wall temperature profiles measured by infra-red thermal camera for five different gas mixtures. The maximum temperature is close to the plasma location.

Clearly, the wall temperature of the fused silica tube increases when oxygen is introduced in helium whereas the opposite effect is noticed when hydrogen is introduced. With nearly one percent of each gas, the wall

temperature varies by 100 K. This effect should be enhanced with nitrogen. Experiments are in progress to confirm the effect of that gas on the wall temperature of the fused silica tube.
It is however striking to observe an opposite evolution to that already noticed for the gas temperature. We do not know yet the reason for such a behaviour even though it is likely related with the gas flow. Indeed, the gas temperature determined by OH spectrum simulation was measured along the tube axis. The resulting profile is provided in figure 6.

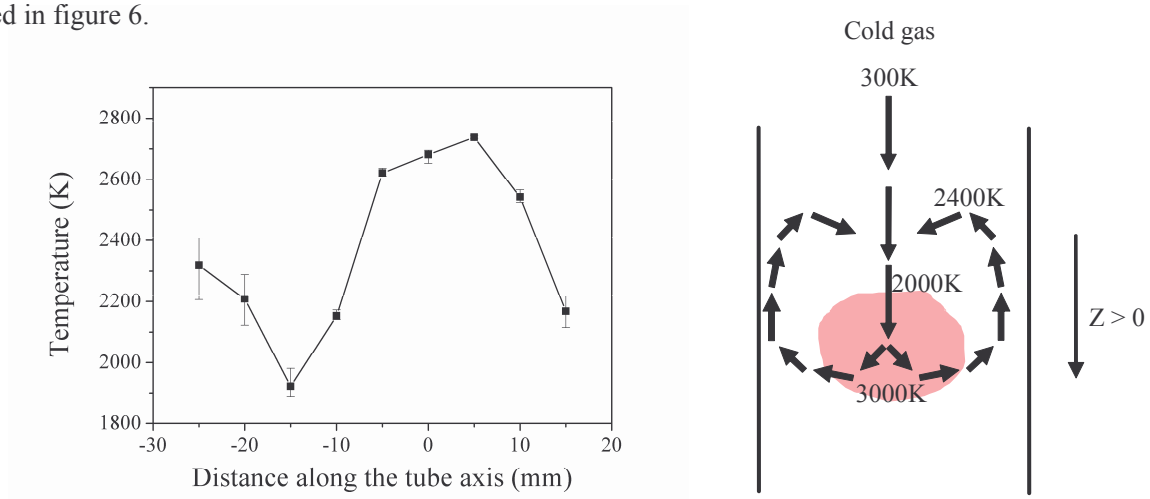

Figure 6: Gas temperature profiles along the axis of the discharge tube measured by simulation of OH emission spectrum. A He-3%H_2 mixture was used (300 W). Possible recirculation flows creating the drop of temperature observed just above the plasma.

It clearly appears that the gas mixture hydrodynamics is complex and recirculation flows probably occur. The minimum in temperature observed in figure 6 can only be due to a recirculation of the cold gas above the much warmer plasma.

4. Conclusion

The influence of small amounts of N_2, H_2, O_2 and Ar on the thermal behaviour of helium microwave discharges at atmospheric pressure was investigated. Even at low concentrations, additive gases strongly affect the thermal behaviour of the helium plasma.

Abstract
An RF O_2/HMDSO plasma assisted chemical vapour deposition (PACVD) process, used for SiO_2 deposition, is analyzed by optical emission spectroscopy (OES) and Fourier transform infrared absorption spectroscopy (FTIRAS). OES investigation leads us to point out two different regimes according to whether the organic precursor is highly or slightly diluted in oxygen. Meanwhile, on the basis of FTIRAS measurements, the dissociation of the monomer is studied as a function of the dilution ratio of the monomer and the input RF power. Therefore, it is shown that the dilution rate to power ratio is the relevant parameter for the dissociation of the HMDSO molecule in the plasma. From these experimental results, a dissociation schema for the organosilicon precursor is proposed and results of a numerical modelling of the discharge are presented, which allow us to estimate the dissociation rate of HMDSO by electron impact.
From the comparison of FTIR analyses of the films with plasma characterization, direct correlations are drawn between the plasma composition and that of the deposited films.

1 - Introduction

RF capacitively coupled plasmas utilizing organosilicon precursors are widely used for SiO_x deposition for many applications such as improvement of wetability and adhesion, protective barrier coatings or anti-reflection films. Because the coating properties depend on the plasma and process parameters, the process plasmas have been widely investigated over the last decade, especially for what concern the use of organosilicon precursors such as hexamethyldisiloxane (HMDSO = $(CH_3)_3SiOSi(CH_3)_3$) [1-4]. These studies may be of useful interest in the development of numerical modelling aiming at the best description and understanding of the deposition process. However, the development of such a complete description suffers from the lack of basic data concerning the HMDSO molecule and the HMDSO–O_2 gas mixture. In particular, it is of prime importance to get knowledge in both the precursor fragmentation schema and the main chemical kinetic pathways (in the gas phase) involving the dissociation by-products. On the other hand, correlations have to be drawn between the plasma analysis and the film characterization in order to determine the growth mechanisms and the species that act as the coating precursors.
The goal of this paper is first to present and discuss experimental results dealing with the O_2/HMDSO RF plasma investigations in close connection with the film composition in order to improve the knowledge and the understanding of the deposition process. The obtained results will then serve as a basis to the establishment of a numerical modelling of the plasma kinetics, which is presented in the second part of this paper.

2 - Experimental arrangement

The complete experimental arrangement is describe in detail in ref [5]. Roughly speaking, experiments are carried out in a parallel-plate capacitively coupled radio frequency (13.56 MHz) plasma CVD reactor. The HMDSO gas line is temperature stabilized at 40°C to avoid condensation of the organic precursor inside the gas line. The total gas flow rate is adjusted with respect to the [HMDSO]/[O_2] ratio in order to keep the total pressure at a constant value of 80 Pa (0.6 Torr).
The gas phase is investigated by means of both optical emission spectroscopy (OES) and Fourier transform infrared absorption spectroscopy (FTIRAS). OES measurements are carried out over the spectral range 300-

900 nm with a spectral resolution of 0.039 nm. In the case of FTIR measurements, each spectrum is acquired over 40 scans with a resolution of 2 cm^{-1} to improve the signal to noise ratio. Owing to the CaF_2 windows that equip the plasma chamber, it was not possible to perform measurements below 1000 cm^{-1}.

3 – Plasma characterization

3.1 OES investigation

The variation of emission line intensity of the optical transitions of H (H_α 656 nm), O ($^5P–^5S_o$ 777 nm) and CO ($B^1\Sigma$-$A^1\Pi$ (0,2) 520 nm) are shown in figure 1. As reported in previous works [5, 6], the electron density and temperature do not change significantly with the monomer content and it is reasonable to consider the emission line intensity as representative of the atom (or radical) density.

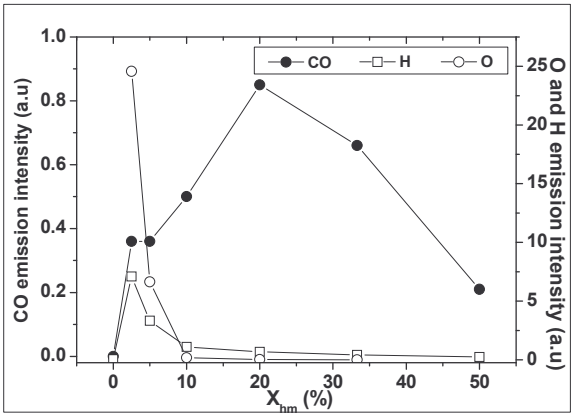

Figure 1 : O-777 nm (○), H-656 nm (□) and CO-520 nm (●) emission line intensity vs HMDSO content in O_2. P_{rf} = 100W

The variations of the line intensities with the monomer content in oxygen gas ($X_{hm} = \frac{[HMDSO]}{[HMDSO]+[O_2]}$) point out two different regimes.

- For X_{hm} < 20 %, the behaviour of the line intensity exhibits two different modes :
  - At first, when X_{hm} < 10%, the density of O-atoms decreases sharply while the one of carbon monoxide increases as X_{hm} increases. In fact, O-atoms are mainly issued from the dissociation of O_2 molecules by electron impact in the discharge and are lost through oxidation of carbon-containing species (especially CH_3) coming from the dissociation of the organic precursor to form CO. This loss process of atomic oxygen agrees the results reported by other authors in the case of RF [1] or microwave [7] plasmas. Thus, we can consider that O-atoms are consumed by oxidation reaction leading to the formation of CO radicals
  - As a consequence, for X_{hm} > 10%, O-atom density is close to zero and the production of CO comes from another process which consists mainly in carbon oxidation by molecular oxygen ($C + O_2 \rightarrow CO + O$). However, the reaction $HCO + O_2 \rightarrow CO + HO_2$ may also contribute to the formation of CO, especially when the concentration in CH_3 increases since the HCO radical is issued from the oxidation of the methyl radical ($CH_3 + O_2 \rightarrow HCO + H_2O$).
- For X_{hm} > 20 % the dilution of HMDSO in O_2 is low and only CO and H-atoms are the main observed species, the density of which decreases with increasing X_{hm}. Two effects can explain this behaviour. At first the consumption of atomic species to form large molecules, such as formic acid (CO_2H_2) or formaldehyde (COH_2). The second effect relates to the dissociation of the monomer by electron impact, the efficiency of which may decrease with increasing the quantity of the monomer. Both these effects are pointed out by the FTIR analysis of the gas phase, as discussed below.

3.1 FTIRAS analysis of the gas phase

As already reported by several authors [3-5, 8-10] the dilution rate of the organic precursor in oxygen plays a significant role in the fragmentation of the monomer. In fact, as depicted in figure 2, the IR absorption bands that are characteristic of the HMDSO molecule (CH_3 asym. stretch. 2966 cm^{-1} ; SiOSi asym. stretch. 1072

cm^{-1} and $SiCH_3$ sym. stretch. 1263 cm^{-1}) exhibit an increase as the amount of HMDSO in O_2 is increased. Nevertheless, the variation of the absorbance with X_{hm} is not linear -as one could expect- and is different according to whether the monomer is highly ($X_{hm} < 50\%$) or slightly ($X_{hm} > 50\%$) diluted in oxygen gas.
From these measurements, it is possible to define a dissociation ratio τ for each of the characteristic bond of HMDSO : $\tau = (A_o - A)/A_o$ where A_o and A stand for the area of the absorption band with the plasma off and on respectively. The τ-values deduced from figure 2 are reported in figure 3 that clearly show the influence of the dilution rate on the dissociation of the precursor.

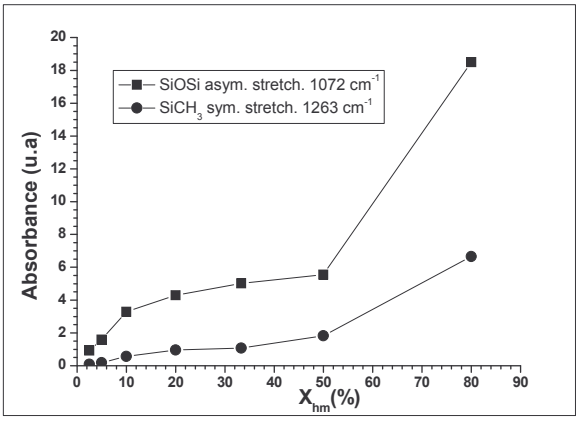

Figure 2 : Variation of the absorbance peak area of the characteristic bonds of the monomer vs the amount of HMDSO in O_2. $P_{rf} = 50W$

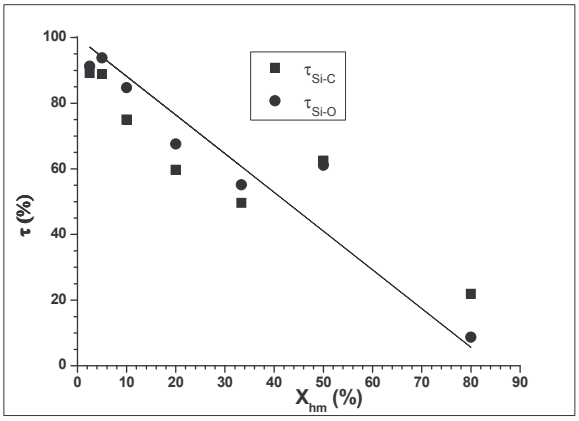

Figure 3 : Variation of the dissociation ratio of the characteristic bonds of the monomer vs the amount of HMDSO in O_2. $P_{rf} = 50W$

On the other hand, the breaking of the precursor bonds depends also on another major plasma parameter, namely the input RF power. Indeed, as soon as the RF power is switched on and increased, the characteristic absorption bands of the HMDSO molecule strongly decrease to reach a nearly constant level close to zero for an input power higher than 100 W (figure 4). That decrease in the absorption bands is significant of an increase in the dissociation of the organic precursor.
Therefore, it seems reasonable to assume that the dissociation of the monomer mainly occurs through electron collisions. Indeed, the electron density depends on the RF power (P_{rf}) and increases with increasing the input power [11]. Thus the above results may be summarized by looking at the behaviour of the dissociation rate as a function of the dilution rate to power ratio. As shown in figure 5, the variation of the dissociation rate seems to decrease linearly as X_{hm}/P_{rf} increases, which allows us to predict the τ-value from the knowledge of the two process parameters.

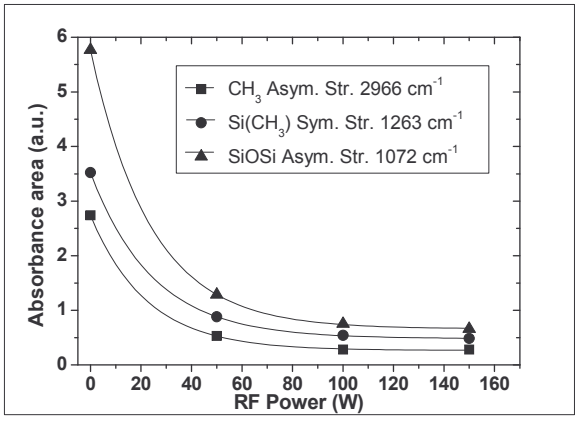

Figure 4 : Variation of the absorbance peak area of the characteristic bonds of the HMDSO molecule vs input power. Pure HMDSO plasma

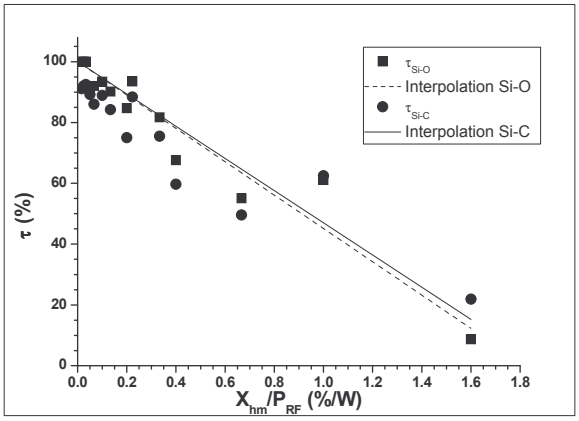

Figure 5 : Variation of the dissociation rate of the characteristic bonds of the monomer vs the dilution rate to power ratio.

4 – Correlation between the film and the plasma compositions

In order to establish some possible correlation between the film composition and the species present in the gas phase, we performed the analysis of the coatings using FTIR spectroscopy. Taking care to the deconvolution of the absorption bands of the films, we paid a particular attention to the following absorbing bonds in the films: Si-O-Si, 1072 cm^{-1} ; Si-OH, 921 cm^{-1} and Si-CH_3, 1260 cm^{-1}. From the comparative variation of these species in both the film and the plasma as a function of the amount of HMDSO in the gas mixture, it clearly appears that their behaviour in the gas phase and in the solid are strongly different ; such a comparison is given for the SiOSi bond in figure 7

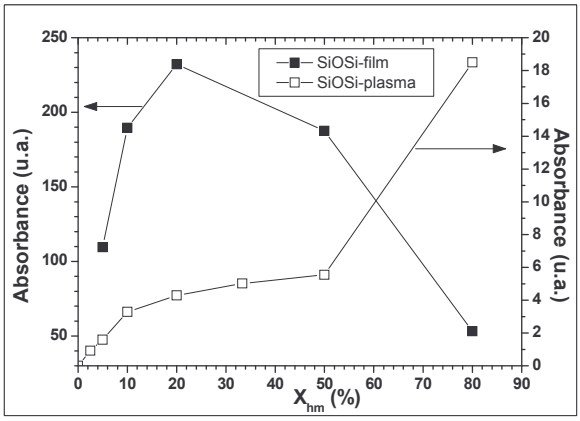

Figure 7 : Comparative absorbance of the SiOSi (1072 cm^{-1} bond measured in the gas phase and in the films vs HMDSO content in O_2.

However, the study of the relative variation of these species in both phases points out that a direct correlation exists between the composition of the gas phase and that of the deposited film (figure 8). The analytical interpolation of the experimental data points takes the form : $y = \frac{a}{(X_{hm} - b)^c}$; the value of the fitting coefficients are reported in the table below.

Table 1 : Fitting coefficients used in the interpolation of figure 7.

	a	b	c
SiOSi/$SiCH_3$ (plasma)	2.65	0	0.384
SiOSi/$SiCH_3$ (film)	1.85	5	0.384
SiOH/SiOSi (plasma)	3.76	2.5	0.658
SiOH/SiOSi (film)	2.83	4.17	0.658

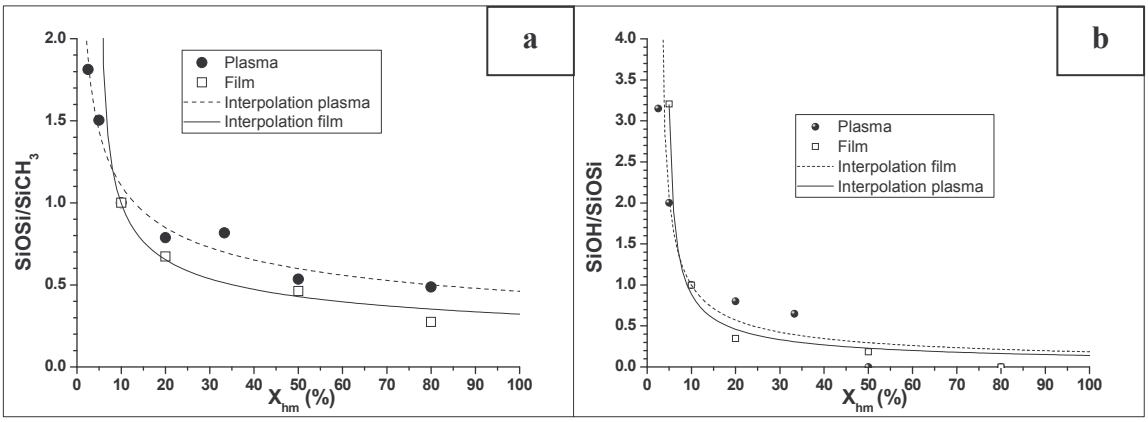

Figure 8 : Variation of the absorption band area relative to that of SiOSi. a) $SiCH_3$; b) SiOH

This interpolation allows us to describe the variation of the relative quantity of the different bonds in the films. Meanwhile, such an interpolation leads us to establish threshold values of the amount of the monomer (for X_{hm} = b) for which the films composition will be dominated by SiOH bonds with regard to SiOSi ones for X_{hm} slightly greater than 4.17% and by SiOSi bonds with regard to $SiCH_3$ ones for X_{hm} slightly greater than 5%

An important point to note concerns the silanol group whose relative concentration in the film is directly related to that in the plasma and is strongly reduced as the HMDSO amount is increased. In fact, the growth of SiO_2 films is achieved from two SiOH radical, as proposed by Selamoglu et al. [12]. Thus this direct correlation has great interest in offering the possibility of controlling the amount of silanol in the film through an in situ analysis of the plasma.

5 – Kinetic modelling

In order to complete the experimental investigation, we developed a simple numerical model aiming to describe the behaviour of the plasma gas. Owing to the lack of basic data concerning the HMDSO molecule and the HMDSO/O_2 gas mixture, we suppose that the monomer is broken by electron collisions according to:

$$(CH_3)_3\text{-Si-O-Si-}(CH_3)_3 + e \xrightarrow{K_{HMDSO}} 6CH_3 + SiO + Si$$

This implies that Si-O and Si-C bonds are supposed to be preferentially broken by electron impact whereas C-H is broken in a further step by oxidation through :

$$CH_3 + O \xrightarrow{K_{CH3}} CO + H_2 + H$$

where $K_{CH3} = 5.6.10^{-11}$ cm^3/s [13].

From the dissociation products of the previous reactions, the plasma chemistry develops to create more complex molecules such as CH_4, COH_2 or CO_2H_2. Thus the numerical model takes into account 62 chemical reactions describing the kinetics of 32 chemical species. The reaction rates are issued from the literature (a complete list of the reactions and reaction rates is given in [14]). The one-dimensional model consists in solving the balance equations for each species by considering the system has reached a steady state. According to the experimental reactor configuration, the neutral species are considered to run out across the electrode gap (4 cm). The electron number density involved in the dissociation equations of HMDSO and O_2 by electron impact, is issued from a fluid model developed previously to describe the behaviour of the charged particles [11] and is typically in the range $10^9 – 10^{10}$ cm^{-3}. The electron impact dissociation rate of the HMDSO molecule consists of an input parameter of the model and is adjusted by comparison with experimental results.

Some of the results obtained as a function of X_{hm} are presented in figure 6 for different K_{HMDSO} values.

Though some disagreements are observed between the experiments and simulations, the behaviour of the species issued from the numerical results for $K_{HMDSO} = 1.10^{-8}$ cm^3/s, seems consistent with that given by the experimental measurements, especially at high dilution rate of the organic precursor in oxygen.

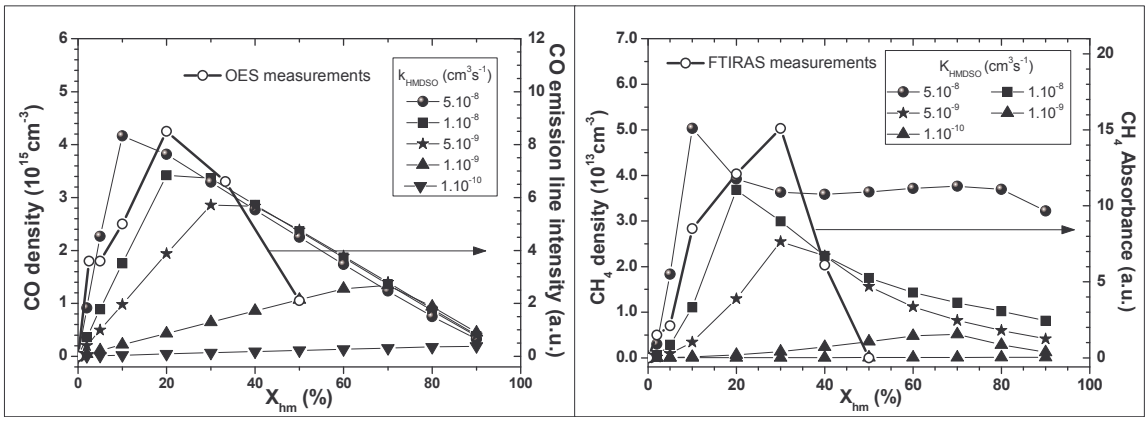

Figure 6 : Density of CH_4 (left) and CO (right) radicals issued from the kinetic modelling of the discharge for different K_{HMDSO}-values, and comparison with the corresponding experimental results.

However, some differences can be pointed out. For example the experimental maximum for CH_4 is around 30% whereas it is close to 20 % for the numerical results.
However, the comparison between experimental and numerical results points out the influence of the dissociation rate constant and justifies our assumption about the monomer dissociation by electron impact.

6 – Conclusion

Experimental investigation and numerical modelling of a RF capacitive O_2/HMDSO plasma used for SiO_2 deposition have been carried out. Experimental results have led us to highlight the dominating role of electron in the dissociation of the monomer while the simulation allowed us to estimate the electron impact dissociation rate of the monomer. In spite of some discrepancies between experimental results and numerical calculation, the simple model, which must be considered as a first step in the complete modelling of the O_2/HMDSO discharge, is able to roughly predict the behaviour of the main species in the discharge, especially at high dilution rate of the organosilicon precursor. From the comparison of the film analyses with the plasma results, it has been established that a strong correlation exists between the composition of the two phases (gas and solid) that may be useful for predicting the nature of the film, which may exhibit a mineral trend at high dilution rate or a more polymeric nature at low dilution of the monomer.

Application of Atmospheric Microwave Pure Steam Plasma to Treatment of Plastic Wastes

H.Sekiguchi, S.Nakanishi, M.Murakami and H.Arimatsu

Department of Chemical Engineering, Tokyo Institute of Technology, Tokyo, Japan

Abstract

Atmospheric steam plasma generated by microwave discharge was applied to the treatment of plastics. Three kinds of the plastics and their mixture were treated by the plasma. The results indicated that the gasification into H_2, CO, CO_2, CH_4 and C_2H_4 was successful, however, soot was also produced. The amounts of steam reacted per carbon content in the feed plastics were almost independent of the feed plastics and their mixtures. The results suggested that the steam plasma was a promising method to gasify plastic wastes.

Keywords

Steam plasma, microwave discharge, plastic wastes, and gasification

1. Introduction

The mass of plastic wastes has increased year by year and many studies have been carried out to treat them efficiently. Due to the development of plastic recycling systems, the percentage of plastic wastes treated for recycle has been raised greatly in this decade. However, it is not ideal level because plastic wastes are still increasing. Much effort is continuously put into the studies on plastic recycling systems to overcome this severe problem. In this study, atmospheric microwave pure steam plasma, which is one of advanced techniques in the plasma technology, is applied to treat various plastics. Atmospheric microwave discharge provides non-equilibrium plasma containing radicals, ions and electrons. These active particles efficiently decompose plastic wastes. Furthermore, it is advantage that water used as a plasma medium is cheap and safe for environment. Plasma is roughly classified to three kinds by their power frequency; direct current discharge, high frequency discharge, and microwave discharge. The microwave discharge does not require electrodes, which makes advantages that the system of the plasma torch is simple and the material component of electrodes do not contaminate the plasma. Recently, the atmospheric pure steam plasma using microwave discharge has been applied to the reforming of hydrocarbon, where the steam plasma is effective for generating hydrogen with CO [1, 2]. Microwave steam plasma supplies reactive radicals such as H, OH, and O in non-equilibrium state, resulting in high performance for the treatments of various materials. We have also carried out the preliminary study on the gasification of polyethylene using microwave plasma where the plasma gas was a mixture of argon and steam [3]. Plastics mostly consist of carbon and hydrogen, so that the treatment of plastics with the steam plasma likely produces synthesis gas containing CO and H_2 similarly to the reforming of hydrocarbon. Moreover in treating PVC by the steam plasma, Cl can be fixed with H into HCl, which will be easily absorbed with a scrubber. Hence, the proposed method is to produce synthesis gas and to treat halogen components simultaneously. The previous study has concluded that the microwave steam plasma has a potential to convert plastic into CO, CH_4 and H_2 effectively [3].

This study is placed as the second step for the treatment of plastic wastes with the steam plasma. Here we use three kinds of plastics; polyethylene (PE), polyethylene terephthalate (PET), polyvinylchloride (PVC) and mixtures of them since these plastics are utilized so much in the various fields. Powdered epoxy resin containing bromine (Br) is also treated with the steam plasma here. Usually printed circuit boards in electric instruments are made of this resin reinforced with glass fibers. To prevent burning, Br is added as a flame retardant into the resin. Due to the incombustibility, the wastes of the resin dust are generally disposed to landfill. Hence, we have preliminarily examined the possibility on the treatment of this fireproof plastic using the steam plasma.

2. Experimental

Figure 1 shows the experimental system which is almost the same as in the previous study [1,2] except for the power generator. The experiment was conducted with 2.45GHz microwave power supply giving a maximum power of 1.5kW. Steam was heated and introduced to the discharge zone in a quartz tube where microwave was irradiated through a wave-guide. Argon (Ar) was only employed for the ignition. These gases were supplied into the quartz tube through the brass block connected at the top of the tube. This brass block was designed to make a tangential flow in the quartz tube which was effective for the plasma stabilization. The size of the quartz tube was 700mm in length, 12mm and 10mm in outer and inner diameter, respectively. The tube had a branch from which the plastics were introduced into the steam plasma as illustrated in Fig.1. The plastics were attached to the tip of the quartz stick and the treatment was done to push the stick into the steam plasma. Commercial PE, PET, PVC and their mixtures were used as models of the plastic wastes. Product gas was gathered in a gas-sampling bag after cooling in the exhaust gas line to condense steam. Then the gas was quantitatively analyzed with gas chromatograph (GC). Ion chromatograph was also used for the analysis of halogen ion dissolved in water condensed in the exhaust gas line. The experimental conditions are summarized in Table 1.

Another experiment was carried out using a printed circuit board grinded. The board consisted of tetra bromine bisphenol A (TBBPA) type epoxy resin reinforced with glass fibers. The powdered samples having an average size of 10μm and 630μm were prepared by grinding the board. The powder was fed into the plasma from the top of the reaction tube shown in Fig.2 which was different from that used in the above experiment.

3. Results and Discussion

The photo of the steam plasma is shown in Fig.3. The plasma was generated only near the wave-guide from which intensive emission of light was observed. The emission spectra could evaluate the temperatures of gas and electron in the plasma, hence, the measurements of the emission spectra were carried out using another steam plasma equipment with similar plasma conditions. The gas temperature and electron temperature were respectively estimated 2-3000K and 6-7000K from UV OH band [4] and the atomic emission spectra of hydrogen. Therefore, the steam plasma showed non-equilibrium similarly to microwave N_2 plasma [5].

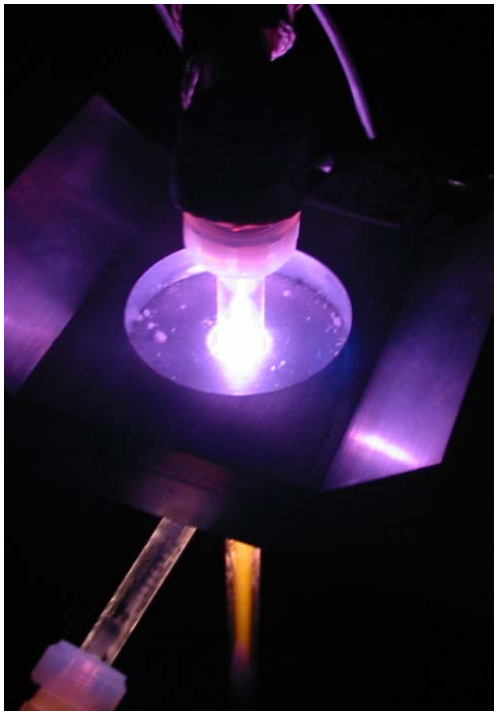

Fig.3 Steam Plasma

3.1 Treatment of PE, PET and PVC

The experimental results showed that the microwave steam plasma treated the plastics perfectly and the plastics were converted into gas and soot. The analysis with GC indicated that the product gas contained H_2, CO, CO_2, CH_4, and C_2H_4 in all the treatments of the plastics. Assuming only soot was produced except for the above gases, the amount of soot was estimated from the material balances of the feed and products. Figures 4 (a-c) show the results of the treatments of PE, PET and PVC respectively where the abscissa denotes carbon content in the feed plastics. The amounts of the gases increased with increasing the feed plastics and H_2 was most produced in all the treatments. The treatment of PVC indicated that soot was formed with highest selectivity. This might be because PVC was easily dechlorinated to form polyene structure in low temperature.

Figure 5 shows the carbon yield defined by the following equation:

$$Carbon\,Yield = \frac{\sum Carbon\ Amount\ Contained\ in\ Puroduct\ Gas}{Total\ Carbon\ Amont\ of\ \ Initial\ Feed\ Plastic} \quad (1)$$

The carbon yield for PE treatment was roughly independent of the feed amount. However, for the cases of PET and PVC, the yields decreased as the feed increased. As shown in Figs.4, soot was most produced in PVC treatment, hence, the carbon yield for PVC case appeared least among the three plastic cases.

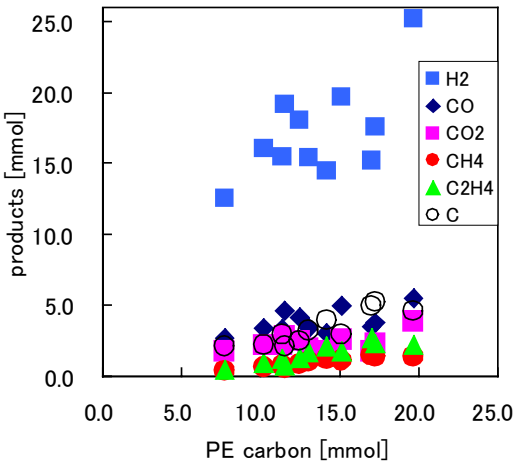

Fig.4(a) Amounts of products produced in the treatments of PE

Figure 6 shows the amount of steam reacted. The amount increased with increasing the feed plastic. As expected from Fig.5, H_2O was least reacted in PVC treatment.

To compare the results of the three plastics, the ratio of the reacted steam to carbon content in the feed plastic, that is, the amount of steam reacted per 1 mol carbon in feed, was indicated in Fig.7. Even when the data for three cases exhibited a scatter, a correlation between the ratio and the carbon content could be seen independently of the feed materials. This was because the reaction of carbon with steam to form H_2, CO and CO_2, which was endothermic with relatively large reaction energy, seemed to be a main mechanism of the gasification of the plastics. The ratio decreased with increasing the feed because more energy was required when more plastics were fed. This was clearly supported by Fig.6 where the amount of steam reacted increased with the feed plastic.

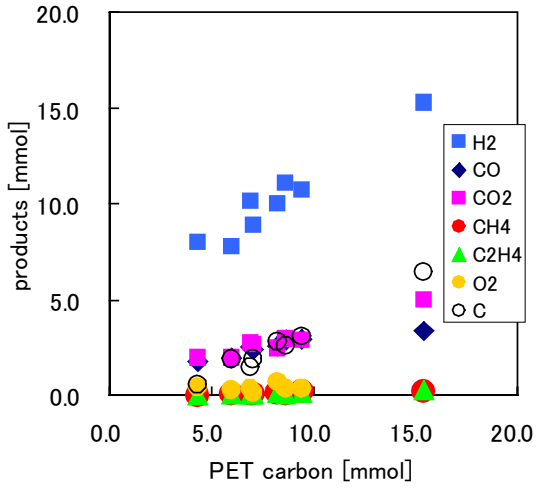

Fig.4(b) Amounts of products produced in the treatments of PET

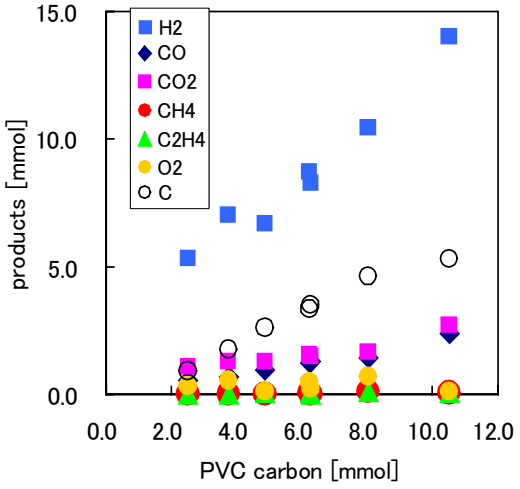

Fig.4(c) Amounts of products produced in the treatments of PVC

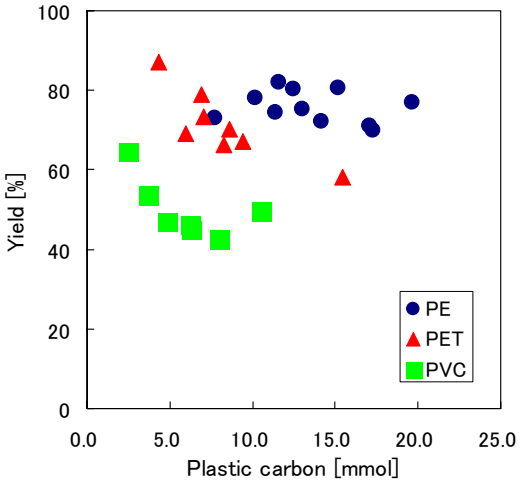

Fig.5 Carbon yield

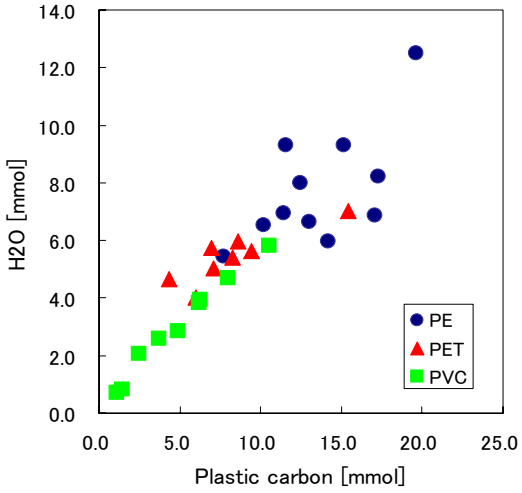

Fig.6 Amount of H_2O reacted

3.2 Treatment of a mixture of PE, PET and PVC

The results of the mixture treatment are shown in Fig.8 where PE and PVC were fed together. In the experiment, total carbon content in the feed plastic was adjusted to the same when samples of the mixture were prepared. The abscissa denotes the fraction of the plastics. The data for the mixed plastics were almost on the interpolations between the results for the pure plastic treatments, suggesting that the mixture did not affect the treatment. This could be also observed in Fig.10 where the amount of steam reacted was independent of the ratio of the plastics.

Similar behaviors were observed in the mixture treatments of PE-PVC and PET-PVC.

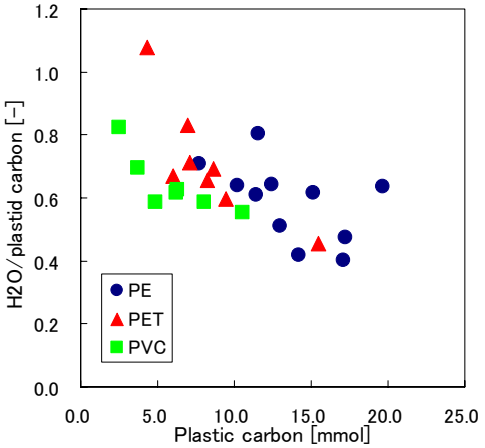

Fig.7 Reacted H_2O per 1mol carbon in feed plastic

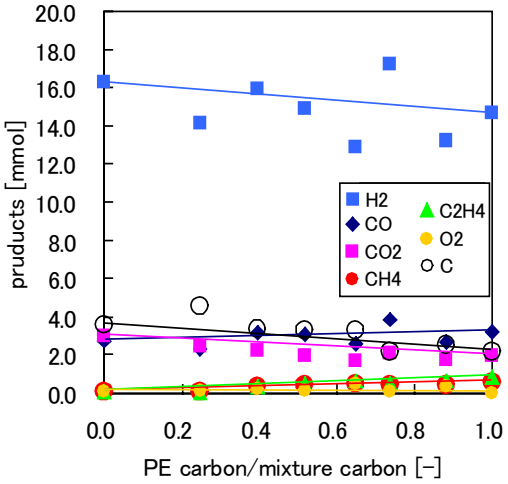

Fig.9 Amounts of products produced in the treatments of PE-PET mixture

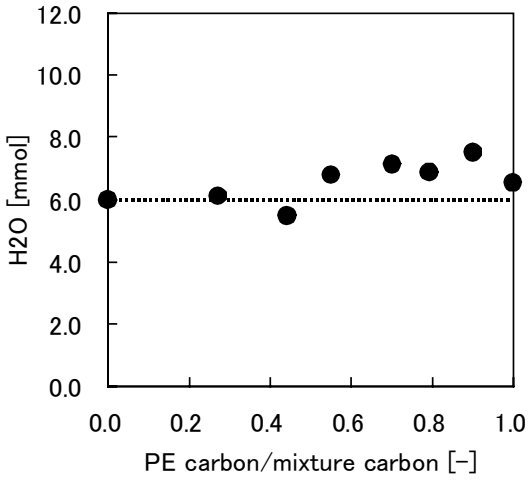

Fig.10 Amounts of H2O reacted in the treatments of PE-PET mixture

3.3 Energy efficiency

The recycling process for plastic wastes should be evaluated from the energy aspect. Therefore, the energy efficiency was defined by the following equation to evaluate the plasma treatment process:

$$\eta = \frac{\sum Combustion\ Heat\ of\ Puroduct\ Gas}{Total\ Combustion\ Heat\ of\ Initial\ Feed} \quad (2)$$

Fig.11 shows the efficiency of the treatments where all the data are plotted including the treatments of the pure and mixture plastics. The efficiency revealed almost higher than unity, indicating that the process could at least recover the initial energy in the feed plastics.

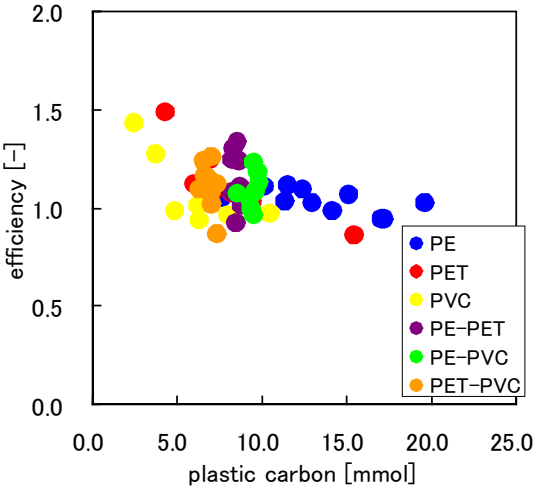

Fig.11 Energy efficiency

3.4 Treatment of powdered epoxy resin

Figure 12 shows the result of the epoxy resin treatment. Because the steam plasma was diminished when the powder was introduced, Ar was added at a flow rate of 12 l/min as a supporting gas. From the figure, the gasification into H_2, CO and CO_2 took place and larger sample showed better treatment. This might be because small particles were not well introduced into the plasma due to strong tangential flow regime in the reaction tube. The present results were regarded as preliminary data, therefore, further investigation using pure steam plasma should be carried out with substantial modification on the powder feed method.

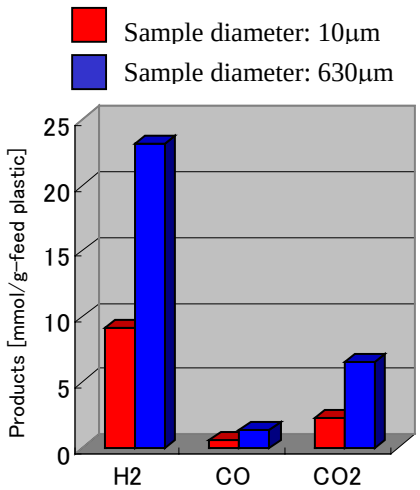

Fig.12 Results of epoxy resin treatment

3.5 Halogen detection in condensed water

The analyses of halogen ions existing in water condensed in the exhaust gas line were carried out using the ion chromatograph for the treatments of PVC and epoxy resin. Chloric ion was detected for the former case,

while, bromic ion was observed for the latter case. However, quantitative analyses could not be done for both the treatments.

4. Conclusion

The microwave pure steam plasma was used for the gasification of the plastics of PE, PET, PVC and their mixtures. The results indicated that all the samples were converted into H_2, CO, CO_2, CH_4 and C_2H_4. Soot was also produced. The amount of steam reacted per carbon content in the feed was almost independent of the feed plastics and their mixtures. Preliminary experiment for epoxy resin containing Br also indicated the possibility of the gasification of the resin. The results suggested that the steam plasma was a promising method to covert plastic wastes into valuable gases.

Abstract

A RF thermal plasma process combined to a molten silicon bath polarization by a variable DC source was used to purify metallurgical grade silicon. The silicon sample was first molten by thermal argon plasma and then polarized via a direct voltage. Optical Emission Spectroscopy was used to follow the evaporation's kinetic of silicon and impurities during treatment. In addition to these on-line analyses, the sample chemical composition was given by Laser Induced Breakdown Spectroscopy. This work led to understand the role of sample biasing in the process of impurities elimination.
Keywords: thermal plasma, purification, silicon, polarization

1 Introduction

With an aim of meeting the needs for the fastly increasing photovoltaic market and reducing the manufacturing cost of solar cells, a certain number of processes were developed to produce photovoltaic grade silicon starting from metallurgical grade material [1,2,3]. The process developed in our laboratory leads to massive silicon purification by thermal plasma together with sample biasing. Molten silicon bath was polarized via a DC source to improve impurities elimination by influencing electrochemical mechanisms at plasma/silicon interface.

2 Experimental Setup

2.1 General Apparatus

The experimental apparatus is shown in figure 1. The part of the process concerning plasma purification consists of a stainless steel water-cooled reactor, a RF plasma torch (P = 20kW) equipped with an injector linked to the electrical ground and a copper water-cooled substrate holder in the axis of the plasma. The solid silicon sample is deposited on a graphite electrode used as substrate. This unit is sitting on the water-cooled copper substrate holder covered by a refractory material in order to prevent any contact between the plasma and electric ground. The last part of the apparatus is used for polarization of the sample. It consists in a DC generator connected to the graphite electrode by an alumina sheathed tungsten wire. In order to prevent HF current from the plasma generator to reach and disturb the DC generator, a HF filter is added to the electric circuit between the sample and the DC source.
Molten by the plasma, the silicon sample becomes conductor. At this time the sample is polarized to influence electrochemical mechanisms and, as a result, improve the plasma purification process.

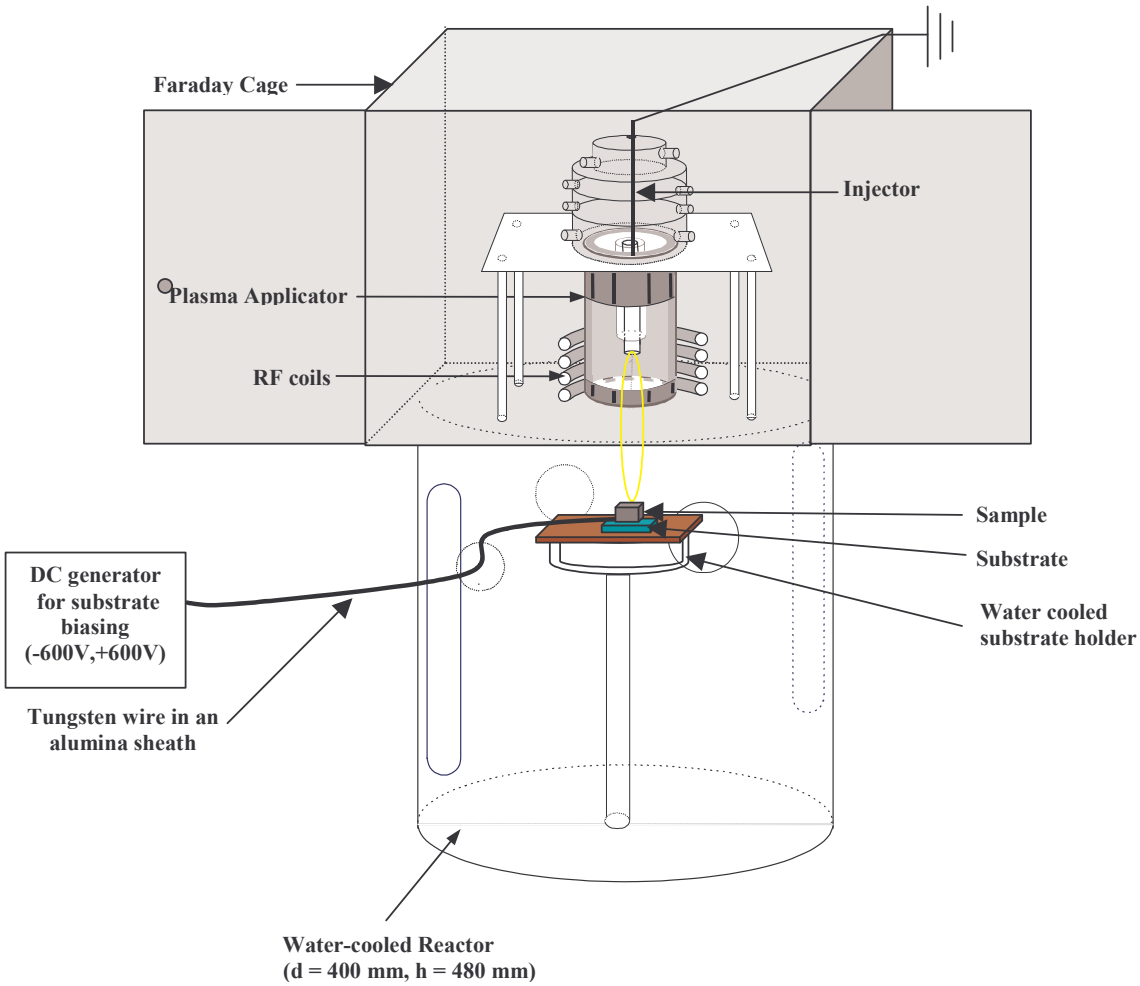

Figure 1: Experimental Apparatus

2.2 Polarization circuit

Before polarization we tried to determine the direction of the current in the circuit composed by the sample, the plasma and the injector. We deposited LiCl on our sample before plasma treatment without any bias. During treatment, we were able to see the direction of the current by following the direction of Li cations emitting in pink color. They were going upstream in the plasma as shown in figure 2.
Measurements with an amperemeter confirmed that there was already a closed electric circuit. Indeed we were able to measure a direct current of about 15 mA between the sample and the injector during the plasma treatment without any polarization from the DC source.

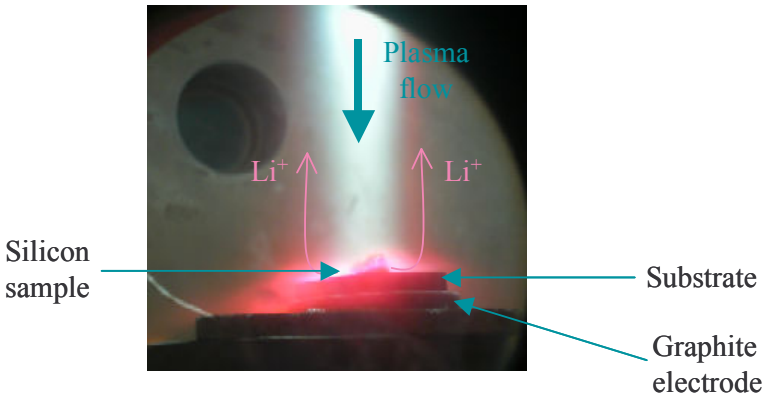

Figure 2: Photograph of a plasma treatment in the presence of LiCl

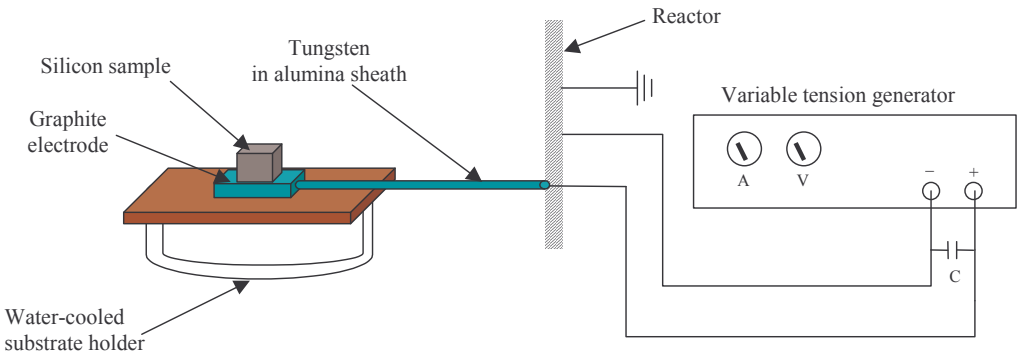

Figure 3: Scheme of polarization circuit

The potential was applied on the sample by the DC generator via a tungsten wire (figure 3). Indeed we have to simultaneously solve thermal and electrical problems to bring the current to the sample. Tungsten has both the characteristics because it's conductive and its melting point is above silicon's one (1410°C). Alumina sheath prevents any contact between plasma and polarization circuit.
The plasma generator (ν = 4,5 MHz) was responsible for a parasite RF signal disturbing DC generator's one. As a result, under these conditions, the electrochemical parameters of the polarization of the sample couldn't be controlled.
Measurements of RF and direct signals led to the elaboration of a specific RF filter permitting to prevent parasite signal from reaching the DC generator and consequently keep polarization process under control.
This filter was introduced in the polarization circuit between the sample and the DC generator.
It also revealed that this plasma had a floating potential of about +90 V.

3 On-line spectroscopic measurements of plasma emissions during treatment

3.1 Experimental conditions

During treatment, the plasma generator provides a 20 kW power. The plasmagene argon flow was set to 40L.min^{-1} and sheathing argon flow to 25 L.min^{-1}. The potential applied onto the sample was set to a define value between -25 V and +90 V. Treatment with on-line follow-up goes on 30 minutes.
The aim of these on-line spectroscopic analyses was to follow the purification's kinetics. This was done in order to know the evaporation processes taking place during the thermal plasma treatment.
On-line analyses were carried out by the means of an optical fiber pointing at the sample surface and connected to a CCD detector and a spectrometer. Spectra were recorded between 350 nm and 950 nm.
The first step consisted in recording the whole spectrum in the presence of argon plasma but without the sample to obtain argon reference.
Then, silicon sample was brought near to the plasma and melted. When the whole sample was molten a spectrum was recorded every 10 minutes for half an hour.

3.2 Results

Without sample, only argon lines were recorded. This spectrum was the mean of knowing which kind of species were evaporated from the sample by subtraction from the spectrum recorded during the sample purification.
In the presence of the molten sample, we recorded phenomena developing at the plasma-silicon interface. We observed evaporated silicon lines but also impurities lines like iron, aluminum or calcium. These elements are highly concentrated in metallurgical grade silicon and were eliminated by the evaporation phenomenon due to the thermal effect of the argon plasma and chemical effect of an added reactive gas like oxygen for boron elimination [4. Consequently, this technique permitted to follow the elimination's kinetic of impurities from the silicon sample as a function of time and experimental conditions like chemical composition of the plasma and sample biasing value.

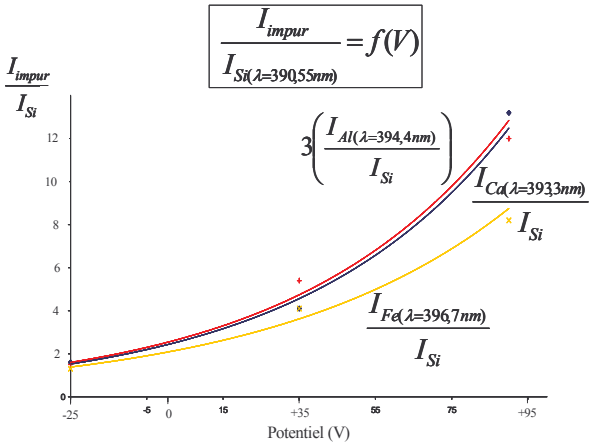

Figure 4: Ratio of impurities and silicon lines intensity versus sample potential

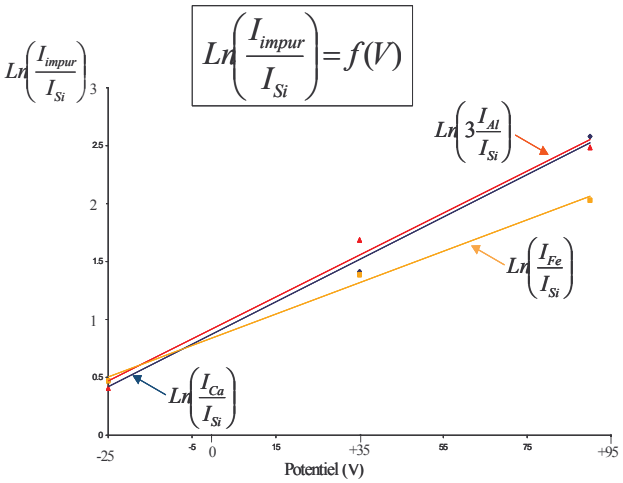

Figure 5: Ratio of impurities and silicon lines intensity versus sample potential

Analysis of figures 4 and 5 shows that the potential applied on the sample has a determining role in impurities evaporation phenomenon. Indeed, we can see that evaporation rate of cationic impurities increases with sample potential.
To confirm that these selective evaporations of impurities lead to the purification of the silicon sample, we compared the concentration of these elements in initial sample and in a plasma treated one by LIBS.

4 Laser Induced Breakdown Spectroscopy analyses

4.1 Principle of the technique

This method consists in focusing a laser pulse near the surface of the sample in order to create an intensive electric field on the focal point. A high quantity of energy is concentrated in a small volume so that the sample is locally vaporized producing a high thermal plasma (10,000 to 20,000 K). The molecules of the sample are completely dissociated during the plasma formation process and the plasma is mainly constituted of ionic and atomic species which characteristic de-excitation emission lines can be used for detection in less than 1 ms for one laser shot. Indeed photons resulting from plasma emission are collected by a spectrometer via an optical fiber. Spectroscopic analysis of atomic and ionic emissions of plasma relaxation gives complete information on chemical composition of the sample. These qualitative (atomic and maybe molecular composition) and quantitative spectrochemical analyses allow performing in-situ, fast and potential remote diagnosis.

4.2 Experimental procedure

For each sample we carried out 10 laser shots series. The 10 spectra obtained were superimposed to confirm the reproducibility of the analysis on the one hand and to know the general appearance of the spectrum by working out the average of all the spectra on the other hand. Therefore spectra obtained with the first and the second shots were systematically removed. This way, we avoided considering surface pollution of samples.
Then spectra were analyzed to know the exact elementary composition of each sample.
From parallelepiped of metallurgical grade silicon samples, thermal plasma leads to a specific geometry of the silicon due to the density differences between solid and liquid state during the fast crystallization at the end of the treatment.
The last area of crystallized silicon (area 1) formed on the sample surface seems to concentrate impurities as it can be seen on figure 6. We analyzed this portion of the sample, together with another area (area 2) at the other end of the sample.

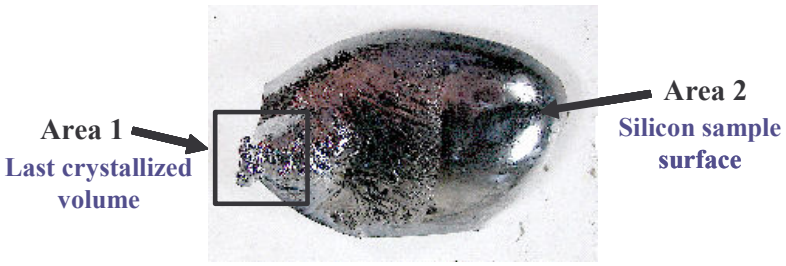

Figure 6: Photograph of a treated silicon sample

4.3 Results

LIBS spectra of metallurgical grade silicon and plasma treated silicon (area 1 and 2) are shown in figure 7.

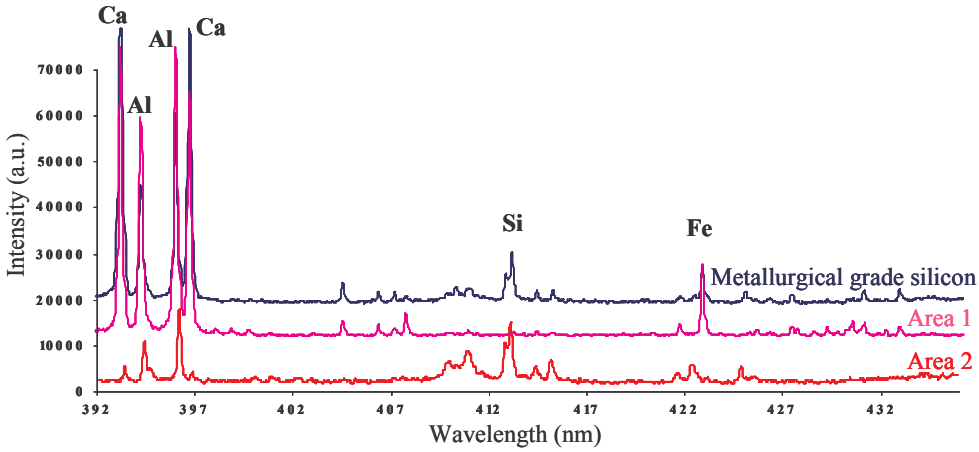

Figure 7: Comparison of LIBS spectra in the range of wavelength 392-432 nm

In order to be able to compare these spectra, we normalized relative intensities of emission lines in both areas of the plasma treated sample compared with intensity of the same lines in the metallurgical grade sample:

$$ratio = \frac{I_{\text{emission line of treated material}}}{I_{\text{emission line of metallurgical grade material}}}$$

Results are listed in the table below:

Impurities in metallurgical grade silicon (ratio = 1)	Plasma treated sample (Area 1)	Plasma treated sample (Area 2)
Fe	2,45	0,33
Al	1,26	0,53
Ca	1,50	0,29
C	0,75	0,52

Table 1: Comparison of impurities emission lines in metallurgical grade and treated samples

These results show that impurities are concentrated in area 1. During the melting process, impurities go up to the surface of the sample where they are partially evaporated. When the sample is crystallizing, impurities concentrate in the last liquid area of the purified sample. In the same way the concentration of impurities in area 2 shows that the sample was purified by the plasma treatment.

5 Conclusion

The use of *in situ* (Optical Emission Spectroscopy) and *ex situ* (LIBS) analyses demonstrated that plasma treatment leads to the purification of silicon samples.
With the same techniques, we were able to demonstrate that the potential applied onto the sample played a determinant role on the phenomenon of evaporation of impurities.
Indeed, emission spectra obtained during the treatment showed that evaporation of cationic impurities increased significantly with the applied potential.
These results let us to conclude that elimination of cationic impurities increases with the potential.
The reference potential value is the plasma potential one (+90 V). For potential values above this reference, transfers kinetic of cationic impurities from the liquid bath to the plasma would be improved. Investigations are currently performed for values bellow this reference. They should prove that the evaporation of anionic impurities is improved together with hydrogenation of the sample (carried out with Ar/H_2 plasma) for a potential value lower than the reference value.

Abstract
A novel ICP-MS based method of protein quantitation is discussed. Multiplexing capabilities of this technique are demonstrated for cell surface membrane receptors that are specific for a particular cell and are widely used in leukemia diagnosis. Experiments for the simultaneous identification of several surface and intracellular antigens in a human megakaryocytic leukemia-derived cell line were conducted. This new technique provides an innovative arena for ICP-MS in the analysis of biological samples.

1. Introduction

New technology that enables accurate protein quantitation is required in the booming area of proteomics and drug discovery as well as in areas of clinical and diagnostic testing. It is also important in biological research aimed at analyzing protein synthesis, function and disease at the molecular level. Currently, there are several existing techniques that are widely used for estimating protein concentration including: Bradford and Lowry assays, UV spectroscopy, organic mass spectrometry, HPLC, flow cytometry, ligand binding assays, ELISA (Enzyme Linked Immunosorbent Assay), and RIA (RadioImmunoAssay). Nevertheless, this extensive assortment of well-established analytical tools and research techniques remains insufficient for today's challenges. The failures of these methods relate to limitations in sensitivity, selectivity, dynamic range, and the ability to determine the concentration of several proteins simultaneously in an accurate and absolute manner (multiplexing). The realization that elemental analysis offers significant advantages to the field of protein quantitation has directed the development of several new methods of protein quantitation via Inductively Coupled Plasma Mass Spectrometry (ICP-MS) linked immunoassays [1-5]. This new technique provides an innovative arena for ICP-MS in the analysis of biological samples.

The ICP-MS technique maintains its well deserved place in the analysis of some biological samples and has been widely used for the quantitation of toxic elements, studying transport of metals, and monitoring the absorption and metabolism of metals and metallo-drugs, metallo-amino acids, metallo-proteins. In all of these cases, the bio-molecules being analyzed are already associated with a metal component. In contrast, the ICP-MS linked immunoassays provide a means to determine the concentrations of proteins that do not necessarily naturally contain a metal. To achieve this, ICP-MS immunoassays rely on the use of affinity products that include an elemental (mostly metal) containing tag. The most straightforward approach includes antibodies that have been raised specifically against the antigens (eg. proteins) of interest and tagged with metal.

ELISA with fluorescent tags and RIAs methods are under continuing development, with recent advances in microsphere immunoassays and flow cytometry reporting the ability to quantitate up to 15 targets almost simultaneously [6,7] with somewhat limited dynamic range. Although, it is feasible to have an optical emission detector capable of distinguishing more than 15 wavelengths (for example ICP-OE, Optical Emission) and an excitation system with significantly broad range, it is still physically impossible to create a set of non-interfering fluorophores for massively multiplexed assays. In the multiplex configuration, non-overlapping signal fluorescent dyes are required. This results in mismatched overlap of the excitation and absorption wavelengths, with a corresponding loss in sensitivity for some of the fluorophores. More significantly, the emission spectra are not well baseline-resolved. That is, some overlap of the fluorescent signals is obtained and this becomes important when the target antigen concentration differs substantially (a large signal in one channel overlaps strongly into the weaker signal channel).

2. Experiment and discussion.

The most important advantage of ICP-MS is its stability and matrix resistance. A large number of heavy metals and their isotopes will provide distinct signals that can be detected simultaneously. Thus many (>50) elemental tags could be created; the obtained intensity ratio vs. tag mass fingerprint could serve as a signature of the disease-state. Secondly, the abundance sensitivity of ICP-MS, a measure of the overlap of signals of neighboring isotopes, is large ($>10^6$ for the quadrupole analyzer), and this ensures independence of the detection channels over a wide dynamic range. The third key property is that MS is very sensitive.

Classes of reagents suitable for the ICP-MS application as well as specific tags for elemental analysis have not yet been developed. Commercially available immuno-reagents that contain elemental tags for unrelated purposes can be used. Fortunately, there is a variety of metal containing immuno-reagents such as gold-tagged antibodies that are routinely used in electron microscopy. It has been found that small gold clusters (1.4nm diameter) [8] and colloidal gold particles can be successfully analyzed by ICP-MS [1-5,9,10]. In addition, four lanthanide (Eu, Tb, Dy and Sm) tagged antibodies [11] produced for fluorescence-based ELISA methods (by PerkinElmer) were also found to be good candidates for ICP-MS based immunoassays [4]. Both the 1.4nm nanogold and lanthanide tags were determined to have several valuable characteristics for elemental analysis including, i) uniform size (number of atoms), ii) more than one tag atom per conjugate; iii) covalent attachment to antibodies, iv) biological inactivity with low steric hindrance, v) a reproducible ratio of tag to antibody, and vi) low natural background.

The protein targets already examined employing ICP-MS included Smad proteins (which play a role in cardiac muscle development) and various regulatory proteins found in human serum which are involved in the immune response, including: Immunoglobin (IgG), Interleukin-1beta(IL-1β), Interleukin-6 (IL-6), Interleukin-8 (IL-8), Interleukin-13 (IL-13), Interferon-gamma (IFN-γ) and Tumor Necrosis Factor-alpha (TNF-α) [1,3-5].

For example, Sandwich and competitive ELISA coupled to the ICP-MS detector yielded reproducible and linear responses to antigen concentration. They also enable 96 immunoassays to be run per plate. Primary antibody plates were found to be more sensitive than secondary antibody plates allowing lower levels of protein to be detected. This is probably due to the restricted well capacity of secondary antibody plates resulting from the steric hindrance of over-lying antibodies. A comparative study of three analytes in 81 patient samples (estriol, AFP and hCG), has been performed [3] where it was found that the ICP-MS detection reproduced results currently achieved on the same plates with fluorometers.

It should be evident that antigens having independent antibodies that are distinguishably tagged by elemental labels, can be determined simultaneously, or multiplexed using the ICP-MS. Five commercially available tags (Au, Sm, Eu, Dy, and Tb) enable a 5-plex assay assuming that the antibodies are not cross-reactive.

The cell surface membrane carries a host of receptors (antigens) that are specific for a particular cell. This is widely used in leukemia diagnosis since knowing the cell type, stage of maturation and receptor abundance determines the correct and personalized therapeutic intervention. Experiments for the simultaneous identification of several surface and intracellular antigens in a human megakaryocytic leukemia-derived cell line were conducted. Expression of intracellular oncogenic kinase Bcr/Abl, myeloid cell surface antigen CD33, human stem cell factor receptor c-Kit and integrin receptor VLA-4 were investigated using live and permeabilized leukemic cells. Current studies were performed with live and fixed cells using primary antibodies, which were detected by secondary antibodies linked to metals (Au, Eu, Tb, Sm). Depending on the abundance of antigens it was possible to use as little as 10,000 cells per 150 μl sample for several receptor identifications.

Comparative flow cytometric analysis was done on a four-color fluorescence capability FACScalibur™ flow cytometer (BD Biosciences, San Jose, CA) equipped with 488 nm argon-ion and

635 nm diode air-cooled lasers. Data acquisition and analysis was run through the BD CellQuest™ software. The following secondary fluorescent labeled antibodies were used: anti-mouse-phycoerythrine (PE) and anti-rabbit-fluoresceine-isothiocyanate (FITC); streptavidin-peridinin chlorophyll-a protein (StrAv-PerCP) and streptavidin-allophycocyanin (StrAv-APC) conjugates. Human monocyte cell lines MBA-1 and MBA-4, derived from Mo7e by stable transfection of p210 BCR/Abl expression plasmid were propagated in synthetic media supplemented with 10% fetal bovine serum.

Antibodies used to identify cell surface as well as intracellular antigens were obtained from commercial sources. Anti-CD33, mouse monoclonal, 2 mg/ml (Immunotech Inc. France); biotinylated anti-human SCFR/c-Kit antibody (CD117) (R&D Systems) and biotinylated anti-human Integrin alpha4 (CD49d or VLA-4) mouse monoclonal antibody (R&D Systems). Anti-BCR antibody raised in rabbit (Cell Signaling Tech) detects total levels of endogenous BCR and the p210 kDa Bcr/Abl fusion protein.

Cells in logarithmic growth phase were collected by centrifugation (1200 rpm, 10 min), washed once in PBS/10%FBS and counted in a hemocytometer. Cells were distributed into round bottom 5 ml flow cytometry tubes (BD Biosciences, USA) in triplicates for staining. Incubation of cells with primary antibodies was carried out on ice for 30 min. Permeabilization (BD Bioscience, Permeabilization solution #2); was done for 30 min at room temperature, after which the cells were washed and non-specific antigen sites were blocked with PBS/10%FBS; cells were then stained for intracellular antigens. After secondary antibody incubation (30 min, ice) cells for ICP-MS analysis were washed twice, centrifuged and pellets were dissolved in concentrated HCl (75 µl per tube) for 10 min at room temperature. As an internal standard for ICP-MS measurements, 75 µl of 1ppb Ir solution was added to each tube. Cells prepared for flow cytometry analysis were resuspended in PBS/10%FBS at $1x10^6$ cells/ml.

Three cell antigens, CD33, VLA-4 and c-Kit, were analyzed on the surface of live MBA-1 cells by ICP-MS. As secondary affinity reagents, NANOGOLD™ anti-mouse-Au (1:25) was chosen as the identifying agent for CD33 antigen; StAv-Tb (1:50) – for biotinylated anti-c-Kit, and StAv-Sm (1:50) – for biotinylated anti-VLA-4. MBA-1 cells were distributed into triplicate tubes at $1.5x10^5$, $3x10^5$, and $1x10^6$ cells per tube. There is a good correlation between the number of cells

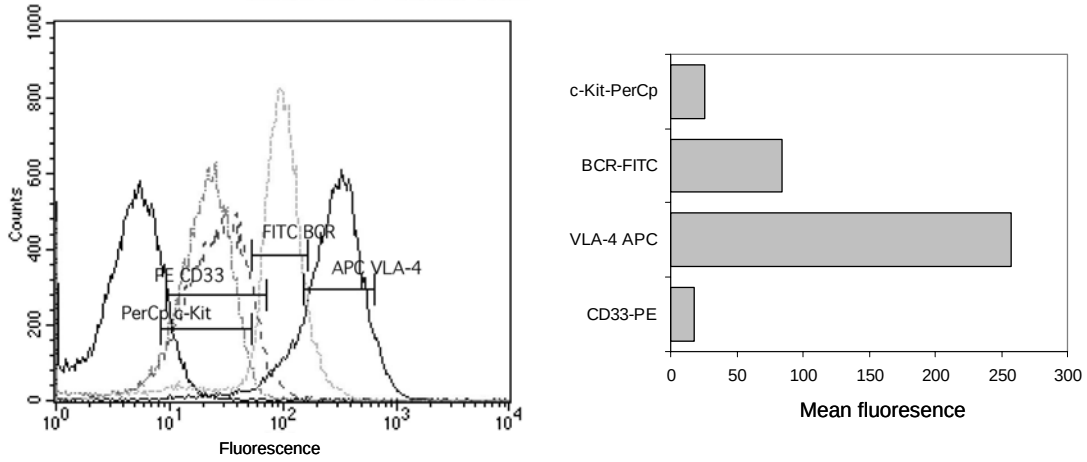

Figure 1.Simultaneous four-antigen staining of MBA-4 cells analysed by flow cytometry. Histogram representation of results with demarcations for geomean values (CellQuest software). Unmarked peak – autofluorescence of negative control cells; PerCp c-Kit – primary anti-c-Kit-biotinylated antibody and strepavidin-PerCp; PE CD33 – primary anti-CD33 and anti-mouse-PE secondary antibodies; FITC BCR – primary anti-BCR and anti-rabbit-FITC secondary antibodies; APC VLA-4 – primary anti-VLA-4-biotinylated antibody and streptavidin-APC. Bar graph representation of geomean fluorescence values.

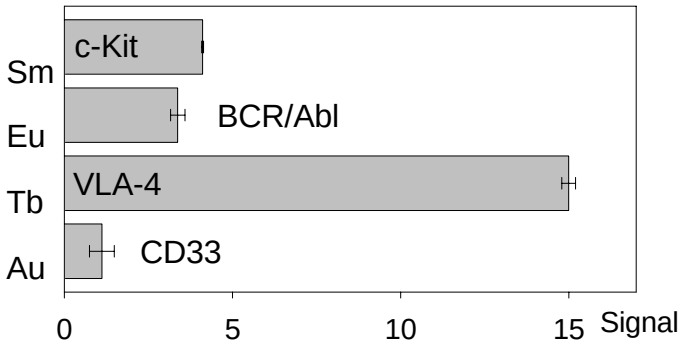

Figure 2. Simultaneous four-antigen staining of MBA-4 cells analyzed by ICP-MS. (background subtracted, corrected for the Ir internal standard, and differences in the size of the metal tags). Cells were stained with primary anti-c-Kit-biotinylated antibody and strepavidin-Sm; primary anti-CD33 and anti-mouse-Au secondary antibodies; primary anti-BCR and anti-rabbit-Eu secondary antibodies; primary anti-VLA-4-biotinylated antibody, and streptavidin-Tb.

used and signal obtained.

Live cells were also stained with anti-CD33 and anti-c-Kit, permeabilized, stained with a mix of anti-BCR, anti-mouse-Au, StrAv-Sm; finally stained with anti-VLA-4, followed with StrAv-Tb for ICP-MS (Figure 2). FACS was done simultaneously with the same cells and primary antibodies, followed by secondary antibodies labeled with fluorochromes. To obtain an accurate histogram of the sample stained with all four antibodies and fluorescent dyes, it was necessary to set compensation parameters using samples individually labeled with each fluorochrome-conjugated antibody. The resultant histogram is shown in Figure 1. To compare results of FACS with that of the ICP-MS data, mean fluorescent intensity values (GeoMean; CellQuest software) were obtained and are presented as a bar graph (Figure 1). Comparing Figure 1 and Figure 2 it is evident that both methods of antigen detection give similar results. Both methods indicate that the most abundant cell surface antigen is the integrin receptor VLA-4, with lesser amounts of intracellular kinase BCR/Abl, and cell surface antigens CD33 and c-Kit antigens.

Two-dimensional simulation of the interaction between plasma dynamics and bulk flow in direct current microdischarges

P.S. Kothnur[1] and L.L. Raja[1]
[1]*Department of Aerospace Engineering and Engineering mechanics, University of Texas at Austin, Austin, TX, USA*

Abstract

Direct current microdischarges permit the generation of plasmas over length scales of a few hundred microns. Here, a two-dimensional modeling study of the interaction between plasma dynamics and bulk flow in direct-current microdischarges is presented to support our proposed concept of a microdischarge-based small satellite electrothermal propulsion device. Results indicate that there is significant gas-heating with microchannel bulk flows, and that the gas temperature distribution depends strongly on the nature of the wall boundary condition. The possibility of intense gas-heating at micron length scales raises the prospect of new applications that exploit this concept.

Keywords High-pressure discharges, direct-current microdischarges, glow discharges, plasma-flow interactions, two-dimensional modeling

1. Introduction

Direct-current microdischarges (MDs) are discharges that allow the generation of plasmas at length scales of a few hundred microns. Microdischarges are operated at relatively high pressures (~10 Torr-1 atm) to overcome plasma quenching effects and achieve reasonable low breakdown and sustain voltages. Recently, these discharges have generated much interest due to possible applications such as sources of UV and visible radiation [1] and maskless etching of thin films [2]. Some attempts at diagnosing the microdischarge plasmas directly have been made [3]-[5]. These studies indicate that electron number densities are expected to range from 10^{17}-10^{20} m^{-3} depending on the geometric configuration, operating conditions and choice of gas. Further, these studies indicate the presence of high levels of excited states of ions with excitation energies of several tens of electron volts, suggesting that electron temperatures in microdischarges are much higher than in low-pressure glow discharges. Recently we have performed modeling studies in planar direct-current microdischarges using a one-dimensional model [6] and helium discharges in a microhollow electrode geometry using two-dimensional modeling [7]. Prominent features include presence of a sheath region comparable to the bulk plasma region, and high electron (several tens of eV) and gas (~1000 K) temperatures. Experimental observations of microhollow cathode discharges in the high-current high-pressure operating regime have also shown significant bulk gas heating, with gas temperatures of ~1000K being measured [8]. For some applications such as photonics [9], high gas temperatures are detrimental to performance, but in other applications such as microchemical reactors [10], high gas temperatures can be beneficial. Our motivation in studying this class of discharges arises from our proposed concept of electrothermal class of small spacecraft (1-10 kg) propulsion devices that utilize microdischarge based gas heating to provide highly controllable thrust levels. The focus of the present study is to explore the interactions between bulk flow and the plasma in a microchannel geometry using a two-dimensional self-consistent representation of the plasma and the flow. The objective of the study is to provide a fundamental understanding of underlying physical phenomena to aid the understanding and design of such devices.

2. Description of Model

The model is based on a two-dimensional multifluid description of the plasma, described in detail elsewhere [7], and the SIMPLE (semi-implicit pressure linked equations) approach [11] for the flow. A brief description of the model is presented below.

Assumptions (1) A continuum fluid approach is used to model the MD phenomena. This approach is reasonable for the relatively high pressure operation of the discharge. At a pressure of 300 Torr, the mean free path for electron-neutral collisions in helium is about 1 μm while gradient length scales are of order discharge dimension, or ~100 μm. (2) Fast secondary electrons emitted from the cathode are not treated explicitly. (3) A common gas

temperature is used for all the heavy species even though significant thermal nonequilibrium exists in microdischarges. Ion-neutral energy transfer length scales for a 300 Torr plasma is ~0.25 μm, which is much smaller than discharge dimensions. Ion energy is therefore locally redistributed among all heavy species, justifying the use of a common heavy species temperature. (4) Resonant excited species are neglected, and radiative energy transfer processes are ignored. This is a reasonable assumption for the high-pressure operation being considered. (5) Compressibility effects are ignored at the low flow velocities that are of concern here.

Governing Equations Multiple charged and neutral species are considered, as well as the effect of chemical reactions and surface interactions. The electric field is governed by the Poisson's equation, and the species number densities are governed by the species conservation equations incorporating generation and transport. The drift-diffusion formulation is used to compute the species number and energy fluxes, with the additional term to account for convection due to bulk fluid flow. The electron energy equation is used to determine electron temperature distribution and the gas energy equation is solved to capture the gas heating effects. Sources of thermal energy in the gas heating equation include elastic electron-neutral collisions and ion joule heating by the electric field. All equations are cast in full time-implicit form and solved using Newton-iterations. Six helium plasma species are considered—electrons, helium ions (He^+, He_2^+), helium metastable species (He^*, He_2^*) and background helium atoms are considered. High-pressure helium plasma chemistry taken from the literature (see Ref. [7] for values of rate constants and references) is used to compute source terms for the plasma species in the species continuity equation. Secondary electron coefficients of $\gamma^+ = 0.105$ for ions and $\gamma^* = 0.115$ for metastable species is chosen. These values have also been used in our previous work [7]. A circuit model comprising of a ballast resistor (~100 kΩ) is used to stabilize the solution.

A separate flow module based on the SIMPLE (semi-implicit pressure linked equations) methodology [11] is used to solve global conservation equations for the flow through the discharge. Solution of the flow proceeds via SIMPLE iterations for the continuity, momentum and energy equations. The gas density is updated after each iteration using the local gas temperature and the ideal gas law. Typically, about 20 iterations are needed to achieve convergence in the flow module. Since the flow time scales are typically much larger than plasma time scales, the flow solver module needs to be invoked only a few times during the plasma simulation to achieve converged results.

3. Results

Results are presented below for a microchannel configuration corresponding to a net flow rate of 192 sccm, and with an inlet Reynolds number based on the channel width and centerline velocity of about 25. A parabolic velocity profile with a centerline velocity of 20 m/s is imposed at the inlet. The net electrical power input to the system is about 0.1 W. Figure 1 shows the geometry of the microchannel discharge being considered. The configuration consists of anode and cathode surfaces of thickness 100 μm separated by a dielectric surface of thickness 100 μm. The channel width is 400 μm. A Cartesian grid with grid stretching near the walls provides adequate resolution of the relatively thick sheath regions.

Figures 2 and 3 show contours of different plasma and flow variables in the microchannel geometry. The contour lines for this figure and all other figures in this paper are at equally spaced intervals between the levels specified in the figures. The potential contours (shown in Fig. 2(a)) shows that electric fields in this discharge are localized, most of the electric potential gradients occurring in the cathode sheath region which is about 40 μm. Electron number density contours are shown in Figure 2(b). Peak electron and ion (not shown) number densities are about 10^{20} m^{-3}, and occurs along the centerline near the cathode surface. This value is consistent with available quantitative experimental data for microhollow cathode discharges in other noble gases [8] and molecular gases [12]. The electron number density distribution is relatively unaffected by the presence of the flow, as is the case with ions. Electron temperatures, shown in Figure 2(c), are of the order of 1 eV in the bulk of the discharge, and reach peak values of several tens of eV in the cathode sheath regions. Indirect evidence of high electron temperatures in microdischarges is provided by experimental studies of emission from high-lying

excited states of ionic species in noble gas microdischarges [13]. The electron temperature distribution is also relatively unaffected by the presence of bulk fluid flow.

Monomer and dimer metastable species number densities are shown in Figure 2(d) and 2(e). Both the metastable species are present in significant concentrations, with number densities of order 10^{20} m^{-3}. The predicted metastable species densities are of the same order as those measured experimentally in another type of microdischarge [8]. The monomer metastable species are also relatively unaffected by the presence of flow, and are primarily present in the region near the cathode surfaces. The presence of high-energy electrons in this region (as shown Fig. 2(c)) and the increased importance of quenching of metastable downstream of the electrodes are responsible for the observed localized nature of the monomer metastable species. In contrast to the monomer metastable species, the effect of flow on dimer species number densities is much more noticeable. Figure 2(e) shows the distribution of dimer metastable species number densities. The figure shows that significant dimer species concentrations can be found at locations several channel widths downstream of the discharge electrodes.

Figure 2(f) shows the bulk flow axial velocity contours in the discharge. The inflow velocity profile is modified due to density gradients caused by gas heating. The maximum velocity occurs along the centerline and reaches values as high as 60 m/sec for the case corresponding to adiabatic wall boundary conditions.

Figure 3 shows the gas temperature plots corresponding to a flow rate of 100 sccm. The figure shows results corresponding to different fixed wall temperatures of 500K (Fig. 3(a)) and 800K (Fig. 3(b)), and a third scenario corresponding to an adiabatic wall (Fig. 3(c)). Gas heating is significant, and gas temperatures near the cathode surface can reach values that are several hundreds of K higher than the ambient. The figure also shows that the gas temperature distribution is very sensitive to the wall boundary condition. Gas temperatures in the vicinity of the cathode are of order several 100's of K above the ambient, but it is quenched at the walls effectively owing to the low Reynolds numbers. In the limiting case of an adiabatic wall (no heat losses at the wall), the gas temperature is predicted to reach values as high as 1200K (Fig. 3(c)) downstream of the discharge. However, for realistic scenarios involving finite wall losses, the downstream gas temperature will be less than the value predicted by the adiabatic wall assumption. For example, Fig. 3(b) shows that when the wall temperature is fixed at 500 K, the gas temperature falls by about 200 K one channel width downstream of the cathode edge. A comparison of the source terms in the gas energy equation (not shown) indicates that ion joule heating is the primary source of energy in the gas energy equation as compared to electron-neutral elastic collisions.

4. Conclusions

Helium microdischarge phenomena in microchannel geometry in the presence of substantial bulk fluid flow are investigated using a two-dimensional self-consistent continuum model. Except for the dimer metastable species, all plasma parameters are relatively unaffected by the presence of bulk fluid flow. Charged species densities of the order of 10^{20} m^{-3} and metastable species densities of the order 10^{20} m^{-3} are observed, both values being consistent with experimental data available for other micron scale discharge geometries. Electron temperatures that are several tens of eV and gas temperatures of several hundreds of Kelvin higher than ambient are observed. The possibility of achieving intense gas heating in these micron-sized geometries raises the prospect of potential new applications such as our proposed microdischarge plasma thruster for small satellite propulsion. The gas temperature distribution is very sensitive to the nature of the wall boundary conditions, due to the low Reynolds numbers and quenching of gas energy at the wall. The results emphasize the localized nature of gas heating in hollow-electrode microdischarge geometries, as well as the need for the development of refractory materials to withstand such high temperatures, and insulating materials to limit wall losses.

Microdischarge-assisted ignition characteristics of large-volume dielectric-barrier atmospheric pressure glow discharges

J. Shin and L. L. Raja

Department of Aerospace Engineering and Engineering Mechanics, University of Texas at Austin, Austin, Texas,USA

Abstract : Ignition characteristics of atmospheric pressure dielectric-barrier discharge (DBD) in the presence of dc microdischarges are studied in pure helium and pure nitrogen gas. The ignition voltages for various conditions are monitored with or without microdischarges being turned on. The substantial reduction of the ignition voltage for DBD is observed for both working gases when microdischarges are turned on. Somewhat localized glow forms within a discharge gap when high pressure DBD turns on in the presence of microdischarges. Intensified CCD image shows the structure and formation of localized glow discharge and I-V characteristics verifies a localized discharge mode is more like glow mode rather than a streamer mode.
Keywords : microdischarge, breakdown voltage, dielectric-barrier, atmospheric pressure

1. Introduction

Dielectric-barrier atmospheric pressure glow (APG) discharges are an excellent source of uniform, non-equilibrium glow plasmas at high pressures. These discharges can be used in large-volume, open-chamber processes such as sterilization [1], ozone generation [2], and aerodynamic flow control [3]. Due to the high *pd* (pressure-distance) value at high pressure, relatively high breakdown voltage (order of kilovolts) are required to successfully operate dielectric-barrier APG discharges. Helium gas has the lowest breakdown voltage of all APG working gases and several studies with helium gas have been reported [4-7]. In large-scale industrial processes, molecular gases such as nitrogen are desirable and in other applications such as aerodynamic flow control even attaching gases such as air are encountered. The breakdown voltage for dielectric-barrier APG can be exceedingly high in these cases resulting in difficulty in establishing a uniform glow mode [8]. This work explores an approach to reduce the breakdown and working voltage of dielectric-barrier APG discharge. We report the use of high-pressure microdischarges to seed the formation of large-volume dielectric-barrier APG discharges at lower voltages. Microdischarges such as the microhollow cathode discharge can be generated stably at low voltages in a number of working gases including attaching gases such as air [9, 10]. Microdischarges are a source of copious amounts of charged and radical species that can provide seed electrons for ignition of other discharges. Indeed, such microdischarges have been used to assist in the ignition of high-pressure arc lamps before [9], and have the potential for use in dielectric-barrier APG discharges, as is reported in this study.

2. Experiment setup and results

In this study, we employ a hybrid discharge configuration as shown in the schematic (Figure 1). A classical parallel-plate DBD configuration is modified to include an array of several microdischarges on one of the electrode surfaces. The upper electrode (aluminum) is powered while the microdischarge array is placed on the other side. The cathode layer of the microdischarges which also serves as the ground electrode for DBD faces the upper electrode. A mica layer (100 μm) is placed on the lower ground electrode which serves as the dielectric barrier, while the upper electrode has an alumina barrier (635 μm). The microdischarges have 342 μm

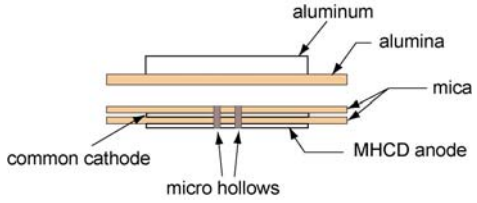

Figure 1. Discharge schematic for hybrid mode dielectric-barrier APG discharges.

hole with 150 kΩ individual ballast. Nickel or aluminum are used for microdischarge electrode and separated by 200 μm mica dielectric. Both helium and nitrogen working gases are studied. 5 mm and 6 mm gas gap are used for helium gas and 3 mm is used for nitrogen gas. The pressure is varied over a range of 300 Torr to 700 Torr. The main discharge (large-volume dielectric-barrier APG) is driven by an ac power supply with an oscillatory voltage of the order of 1-10's kHz. The microdischarge array is driven separately by a dc power supply.

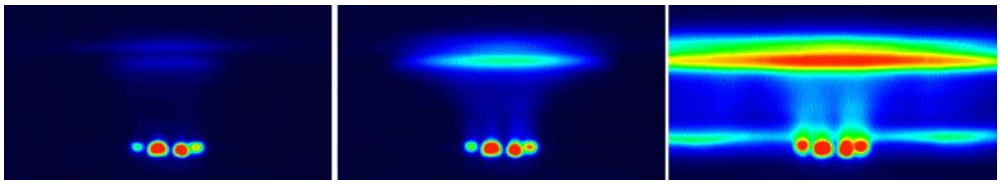

Figure 2. Images of DBD with 4 microdischarges being turned on at 15 kHz, 300Torr helium with 6 mm gas gap. DBD voltages are a) left : 427 V, b) center : 500 V, c) right : 700 V.

With a helium gas, a highly stable glow discharge can be obtained at high pressures. Figure 2 shows the time-averaged intensified CCD (ICCD) images of DBD in the presence of microdischarge array at 15 kHz, 300 Torr with 6 mm gas gap. For these conditions, the average ignition voltage is measured as 825 V with the microdischarges turned off. The microdischarges are switched on with a total power of 3.2 W for the four discharges array. With the microdischarges on, incipient localized glow is observed to form in the dielectric barrier gap at a DBD voltage as low as 427 V. The intensity of glow in the DBD gap increases as the external DBD voltage increases (center image). The discharge plume from microdischarges connects with localized glow. The I-V waveform in the Figure 3 tells that the localized glow discharge near the upper electrode is more like a classical DBD in that it has a single current pulse with tens of microsecond pulse width [4]. The asymmetric current pulse is caused by geometric asymmetry of discharge setup and this is consistent with time-resolved ICCD image where the localized glow discharge forms when the potential of powered electrode becomes negative. Further increase in voltage makes the glow discharge expands over the entire gap (right image in Figure 2) and generates positive current pulse even though it is still asymmetric in the magnitude. The glow in

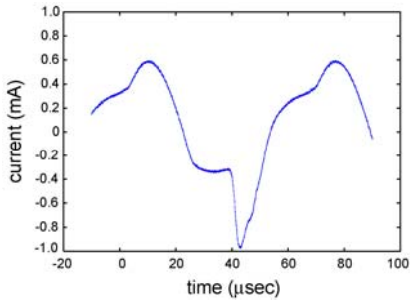

Figure 3. I-V waveform of hybrid mode DBD at 15 kHz, 300 Torr in helium with 6 mm gas gap. 4 mA microdischarges current and 500 V DBD voltage.

the bulk region is weaker than that of regular DBD and the positive glow is much weaker than negative glow. Changing the power input of the microdischarges can result in a change in the intensity of glow and the on-set voltage at which the dielectric-barrier APG is formed. The intensity of the glow becomes slightly stronger with an increase in the microdischarge current. This is different from the observation of Eden *et al.* [9], who report that the ignition voltage is insensitive to microdischarge current. The average ignition voltages of helium dielectric-barrier APG at different pressures are plotted in Figure 4. The discharge conditions are 5 mm gas gap at 15 kHz. A dotted line represents the breakdown voltage of DBD only, without microdischarge being turned on and is close to the theoretical estimate of the dc Paschen breakdown voltage for the gas in helium assuming a 0.01 secondary electron emission coefficient (γ_{se}) [11]. When the microdischarge is kept on, the ignition voltage of the glow (localized glow) is reduced by about 50 % (solid line) over the pressure range. At this point, the current pulse is weak and so is the emission intensity. Further increase in external voltage makes localized

dielectric-barrier APG abruptly expands over the entire electrode (overall glow) as indicated by the dot-dash line in the Figure 4. The voltage at which the glow extends over the entire dielectric-barrier volume is about 80-88 % of breakdown voltage without microdischarges on.

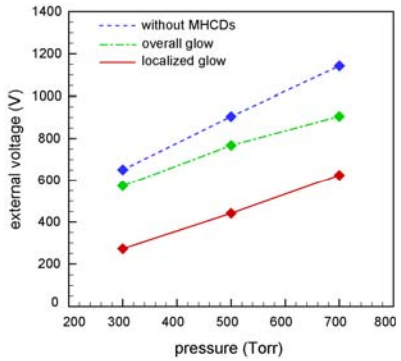

Figure 4. Ignition voltages of helium DBD with the presence of microdischarges at 15 kHz, 5 mm gas gap.

The same experiment is performed with nitrogen which requires much higher ignition voltage than helium. A DBD in nitrogen gas at high pressure has normally a mixed mode character where the streamers form within a uniform glow discharge and make current waveform appear noisy. Other studies have indicated that the streamer component can be reduced by using a Polyethylene Terephthalate (PET) dielectric with meshed electrode [8]. In contrast to helium case, the localized dielectric-barrier APG with the microdischarges on is much more confined to the centerline of microdischarge hole and appears to have peak intensity in the middle of discharge gap (Figure 5). The detail discharge structure inside localized glow in the figure looks similar to that of DBD and the current waveform shows the discharge is glow mode rather than streamer. A horizontal line in the discharge

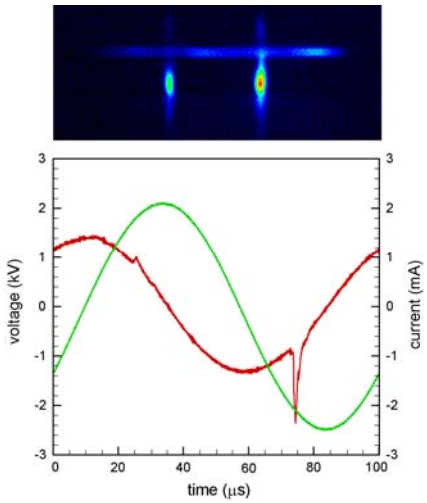

Figure 5. I-V waveform and corresponding discharge image when localized glow occurs in nitrogen gas at 300 Torr, 10 kHz with 4 microdischarges of 6mA on.

image is just a reflection from plexiglass frame. The ignition voltages for nitrogen gas at different pressures are plotted in Figure 6. The dot-dash line shows the breakdown voltage without microdischarges being turned on. The values are also close to the theoretical dc Paschen breakdown values with $\gamma_{se} = 0.1$. The solid line represents the ignition voltages when the localized glow (as in Figure 5) turns on within a discharge gap with the presence of microdischarges. A reduction in voltage for localized glow discharge is about 45% which is similar to helium experiment. For nitrogen case, the on-set of uniform glow discharge in the gap was hard to identify since the discharge mode continuously changes its intensity and current waveform along with gradually increasing streamer formation as the external voltage increases. The structure of overall glow is similar to that of helium

case in that the intense negative glow occurs at every half cycle and relatively weak glow is in the middle of a discharge gap with weak streamers formed within a glow.

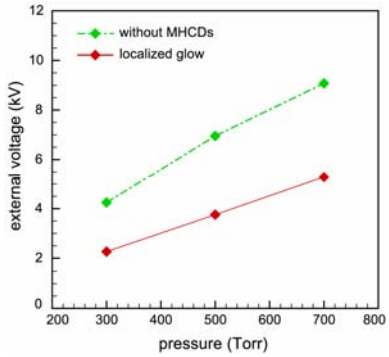

Figure 6. Ignition voltages of nitrogen DBD with the presence of microdischarges at 10 kHz, 3 mm gas gap.

Approximate electron number density (n_e) can be estimated by assuming a current is electron mobility (μ_e) limited. Electron number density $n_e = J / (e\mu_e E)$ where J is a current density, e is an electron charge ($=1.6\times10^{19}$) and E is an electric field. The values of μ_e with a valid range of a reduced electric field (E/p) are listed in the literature [11]. For the case in Figure 5, a reduced electric field (E/p) is 25.2 (V/cm·Torr) and it gives a value of $\mu_e p$ for nitrogen gas as 0.42×10^6 cm^{2}Torr/V·s. Stark *et al*. used a temperature dependent electron mobility approximation [10]. The gas temperature of air microdischarge is about 2000 K [12] but the extended plume can be expected to have a room temperature. Assuming gas temperature as 300 K in the localized glow region, $(\mu_e p)_T = (\mu_e p)_{To}$. The diameter of localized glow is approximately twice of microdischarge hole diameter. Assuming four localized glows have the same area, effective area $A = 4\times0.25\pi(2\times342\times10^{-4})^2 = 1.5\times10^{-2}$ cm^2. With a peak current of 2.4 mA, current density $J = I / A = 0.16$ A/cm^2 and hence $n_e \approx 9.4\times10^{16}$ m^{-3}. This verifies a localized glow is regarded as a dielectric-barrier glow discharge ($n_e \sim 10^{17}$ m^{-3}) rather than microdischarge ($n_e \sim 10^{20}$ m^{-3}).

3. Summary

In this study, we observe a significant reduction in the ignition voltage for glow discharge mode of dielectric-barrier high pressure discharge when the microdischarge is used. The reduction for localized glow discharge with microdischarges on in the dielectric-barrier gap is as low as 50% of ignition voltage of DBD without microdischarges. For uniform glow discharge in the dielectric-barrier gap, the reduction is about 80%. The current waveform for localized glow shows an asymmetric pulse with a low magnitude. The ICCD images show the localized glow discharge is formed only at the negative cycle of DBD power which is consistent with the asymmetry in the current waveform. The structure of the localized glow looks similar to that of a dielectric-barrier glow discharge except for its low intensity and asymmetric shape. The approximate calculation of electron number density as well as the current density waveform verifies that the localized glow is more like a dielectric-barrier glow discharge rather than a microdischarge. In our previous study, we showed that the breakdown and sustenance of dielectric-barrier APG discharge does not depend on the number density between current pulses. Instead, the ignition voltage is very dependent on pressure and gap distance with a given working gas. But this study shows that the breakdown of DBD at high pressure can be initiated at much lower voltage when there is an external source of high number density seed particles, such as the microhollow cathode discharges.
